The reactor protection system which is discussed includes the sensing elements, logic functions, and actuator controls as shown in Fig. 1. It should be noted, however, that two other critical steps exist between the incidence of an unsafe condition and a shutdown. The unsafe condition must be sensed by the primary element, and the control rods must actually insert part of their negative reactivity before a scram has really taken place.

Basic System Characteristics

The important characteristics of a reactor protection system can be defined as speed of response, operational reliability, freedom from nuisance operations, and provisions for trouble monitoring, testing, repair, and maintenance. The relative importance of each of these characteristics is not the same, but all are important and a serious weakness in any one is a significant weakness in the protection as a whole.

Speed of Response

The speed of response for the whole scram system (including sensing of the unsafe condition and enough reduction in reactivity to put the reactor on a negative period) must be adequate to control safely some limiting potential accident. The limiting accident is usually the start-up accident,[1] which is determined by the nuclear characteristics of the reactor and the maximum reactivity insertion rate attainable from the control system.

The delay due to the protection system, as described herein, is only a portion, and often a small portion, of the total delay. The delay involved in getting the control rods to move far enough to produce significant negative reactivity is a major portion of the total delay, and the delay involved in sensing an unsafe condition by the primary sensing element may be a serious delay in some cases.

Operational Reliability

If the protection system has adequate speed of response, its prime characteristic is operational reliability. This can be defined as the ability to cause a reactor shutdown when it is required. Failure probabilities as low as one in a million are necessary for some situations.

Nuisance Operations

A nuisance operation can be defined as a protection-system operation which causes a shutdown of all or part of the plant when there is no danger. The most common example of nuisance operation is a nuisance scram.

Many of the reactor protection systems in use today cause a relatively large number of nuisance operations when compared to what is generally considered acceptable for a modern power plant.

Trouble Monitoring, Testing, and Maintenance Provisions

The ability to annunciate the failure of any of the components of the reactor protection system will greatly affect the operational reliability and the nuisance failure rate of the system. This is because the probability that the protection system will fail to operate when required is a function of the time that it takes to detect and repair a component failure. Somewhat the same thing applies to the nuisance failure rate but it is greatly affected by the particular protection system design.[2]

Testing can be considered a method of extending the trouble-monitoring capability by means of periodic checks. Ideally, the trouble monitor would check all components continuously and no routine testing would be required, but this is generally not practical. The testing pro-

visions should give complete coverage of those areas that have been omitted by the trouble monitor, so that no practical, unsafe failure could be left undetected.

To keep the detection and repair time for a failed component to a minimum, provisions for quick and easy repair are very important. The ability to maintain and repair components with the reactor plant in operation is particularly important in a power plant where the reactor may be expected to operate for long periods without a shutdown.

Dual-Channel System

The Dresden-type dual-channel reactor protection system meets the reliability requirements by making use of coincidence techniques rather than by using extremely reliable components. The failure of any one component or power supply is assumed to be a normal design condition. The system is designed so that, in nearly all cases, such failures will not cause an operational failure or a nuisance operation, but will trip one protection channel with the other channel still intact.

Fig. 1 shows a 1-line diagram of a typical Dresden-type system as it might be applied to a boiling-water reactor. The sensed conditions will be different for different types of reactors, but the basic design should be applicable to a variety of reactor types.

The system consists essentially of two grounded 120-volt a-c circuits which are supplied from two induction-motor-driven synchronous generators with flywheels to provide a few seconds of stored energy.

Each numbered contact shown in Fig. 1 symbolizes a scram relay. A coil of each relay is supplied with power from an "independent" primary sensor, so each of these contacts may be thought of as symbolizing a primary sensor. The pairs of holding coils shown each symbolize one or more pairs of actual holding coils or solenoid valves. These coils or valves are mechanically interconnected in such a way that both must be de-energized before a protection system operation takes place.

Two-of-Four-Sensor Grouping

The high-reactor pressure sensor shown in Fig. 1 is typical of the two-of-four-sensor grouping which forms the basis for this dual-channel system. A typical scram relay circuit for one of these sensors is shown in Fig. 2

If the reactor pressure should reach the trip level, the pressure switches 1, 2, 3, and 4 will open their contacts. This will de-energize their respective scram relays and open the four high-reactor-pressure contacts shown in Fig. 1. These contacts will de-energize everything which is shown below them, including the holding coils controlling the ventilating ducts and the scram valves.

If any one of the switches or relays should fail to open its contacts, the other relay in its protection channel will open the circuit and the scram will still be accomplished.

If one switch or relay in each channel should fail to operate, the other two relays will still cause the required scram. This allows one switch in channel *A* and one in channel *B* to be connected to the same manifold without the possibility of a single plugged manifold's preventing a required scram. The fact that two manifolds may be used safely instead of three or four can result in significant savings in piping costs in a high-pressure system.

If any one of the high-reactor-pressure sensors should accidentally open its contacts, or have its circuits open-circuited or short-circuited, its associated scram relay would be de-energized. This would interrupt the current to one of each pair of ventilation-duct and emergency-cooling holding coils and one of each pair of scram solenoids, but the other holding coils and scram solenoids would remain energized and prevent a nuisance scram. The annunciator and trouble indicator light associated with this sensor would be energized so as to identify positively the circuit that caused the protection channel to trip. If the failed component were in an accessible location, it could be replaced or repaired without disturbing the plant output.

If the power output of one of the motor-generator sets were interrupted or short-circuited, the power to the ion chambers, amplifiers, relays, holding coils, and solenoids which are associated with that protection channel would be de-energized. Since no components in the other protection channel are supplied from this source, the other channel would still be operative and the reactor would continue to operate.

Two-of-Three-Sensor Grouping

The two-of-three grouping of sensors may be used with a dual-channel system when the saving of one sensor justifies the added complexity, cost, and/or the higher nuisance failure rate. The operational failure probability for the two-of-three grouping is nearly the same as for the two-of-four grouping.

The short-period sensor shown in Fig. 1 is typical of the two-of-three grouping. Fig. 3 shows a typical scram relay circuit for this sensor.

If reactor period reaches the trip level, the short-period sensors 1, 2, and 3 will de-energize their respective relays. The twelve short-period contacts shown in Fig. 1 will open and de-energize the holding coils controlling the ventilating ducts and the scram valves.

If any one of these sensors should fail, the other two will still open both circuits and cause the required scram. However, these three sensors must be completely independent because a failure which could affect any two might prevent a required scram or cause a nuisance scram. For instance, if the high-reactor-pressure sensor described were to use this two-of-three grouping, three independent manifolds and three independent power supplies would be required.

The power for the ion chambers and amplifiers in one of the three short-period sensors is taken from the instrument a-c supply, which is separate from the two motor-generator supplies. This is so that the interruption of one of the motor-generator supplies will not involve more than one of the three short-period sensors, and cause a nuisance scram. This short-period sensor will experience more nuisance operations than the other two because of voltage disturbances on the instrument supply However, this is not very important if the period sensors are normally bypassed when the reactor is in the power range, as they will be at Dresden.

Design Techniques and Components

A reactor protection system can be built using a wide variety of components and techniques. The following discussion explains why certain of these are selected for use in the Dresden-type system.

Fail-Safe Design

A fail-safe design can be defined as one in which the most common modes of failure are such that they maintain or increase the operational reliability of the system. Since some devices have two opposite, common modes of failure, a truly fail-safe design may be approached, but is rarely achieved.

Fail-safe design may be considered as a method of providing an effective trouble monitor for the electric components of the protection system. When the system is used in a power plant, long lengths of wire are needed to connect many of the sensing elements to the logic component. Since these wires are necessarily somewhat exposed to damage, it is very important to monitor these circuits continually.

Fail-safe design is not necessarily required for use with the dual-channel protection system, but until an equally effective trouble monitor at a comparable cost has been developed, it appears to be the best available technique for obtaining high operational reliability.

Dual-Channel Design

The number of nuisance operations is reduced by the use of a second, identical fail-safe channel which also must be de-energized in order to produce a scram.

The operational reliability appears to

have been reduced by a factor of two because of the addition of the second channel. This apparent reduction is not considered important for two reasons: First, it is difficult to calculate the system reliability or the required reliability within a factor of ten, so any system which would become unsatisfactory by a reduction of reliability by a factor of two is already too near the margin. Second, because accidental tripping of one channel due to a component failure is not in itself serious, the use of bypasses and "jumpers" will undoubtedly be reduced and the operational reliability of each channel will be increased. This somewhat intangible increase will probably result in a dual-channel reliability considerably greater than the reliability of an equivalent single-channel system.

DUAL ELEMENTS IN EACH CHANNEL

To reduce the probability of an operational failure due to an "unsafe" failure of a component, two elements are used in each channel in such a way that both must fail before the channel will be unable to scram from any one scram condition. These two elements are physically located so that the possibility of damage by a single accident is small. They are also installed in such a manner that a single failure, such as plugging of a single pressure line or control-rod shadowing of a single ion chamber, cannot affect more than one of the two sensing elements in one channel.

SCRAM RELAYS

The scram relay is a basic part of this system design. Relays have been justly criticized for their performance in some applications, but the manner in which a properly selected relay is likely to fail is quite well established.

The application of relays to a reactor protection system presents few significant problems and the selection of a relay which will perform satisfactorily should be quite simple.

Proper dust protection should easily reduce to a negligible value the probability of sticking. The probability of a contact welding is very small when a properly sized relay is supplying a resistive or inductive load. The expected number of operations is so small that fatigue problems are negligible.

The maximum currents involved are approximately 5 amperes a-c. This is well within the rating of the General Electric Company type *HFA* relays which were selected for use at Dresden.

Because of the thermal aging of the coils, the operation of the scram relays with continuously energized coils is a problem. However, it is believed that the type *HFA* relays will still have negligible coil failures. Since the failure of a coil will trip only one protection channel, a few coil failures can be tolerated without appreciably reducing the plant reliability.

The time delay introduced by the scram relays used at Dresden is approximately 10 milliseconds. While any delay is significant, this is less than 5% of the scram time for Dresden and was compensated by an increase in control-rod scram speed.

The maintenance required for relays is also an important consideration. It is expected that the scram relays at Dresden will be inspected once yearly, but will require little or no cleaning or burnishing of contacts. This can hardly be considered a serious maintenance problem.

POWER SUPPLIES

Each of the two main power supplies to the protection system consists of an induction motor with a flywheel which drives a 120-volt single-phase synchronous generator. The motors are supplied from the station auxiliary a-c system at two points which are as electrically remote from each other as possible. This is to reduce the probability of a single electrical disturbance affecting both power supplies when some a-c power is still available. If all a-c power is lost, the reactor will probably have to be shut down anyway because of the loss of important pumping, control, or instrumentation power.

A flywheel is included in each motor generator set to provide enough stored energy so that a short, auxiliary-power interruption will not scram the reactor. A practical amount of stored energy allows the protection system to continue to operate for 3 to 5 seconds after all power is interrupted.

Excitation for the synchronous generator is provided by a direct-connected exciter to provide maximum reliability.

The use of 120 volts a-c provides a good compromise between size of wire in relay and solenoid coils and current-interrupting and film-drop problems in switch and relay contacts. This is also a convenient voltage for supplying the ion-chamber and flux-amplifier power supplies. One side of each of the protection circuits is grounded so as to remove the possibility of two accidental grounds causing a sensor to be bypassed.

By means of a manual transfer switch, instrument a-c power can be used in place of the synchronous-generator output while one motor-generator set is being serviced or repaired. This temporary mode of operation will result in a somewhat higher nuisance failure rate. However, this condition can probably be tolerated for considerable periods so long as the other motor generator set is working properly. (The third short-period sensor will be transferred from the instrument a-c supply to the running motor generator set for this abnormal mode of operation.)

TROUBLE MONITORING, TESTING, AND MAINTENANCE PROVISIONS

Trouble monitoring for most of the electric system is provided by additional normally closed contacts on the scram relays as shown in Figs. 2 and 3. Since the protection circuits have one side grounded, either a short or open circuit will result in a dropout of the scram relay. This will cause tripping of one protection channel and will operate the trouble indicator light and an annunciator. The annunciator provides the operator with an audible and visual identification of the scram function involved, and the trouble indicator light positively identifies the circuit involved so that a maintenance mechanic can be sure he is working on the correct circuit.

Since the most common source of trouble will probably involve open or short circuits, this trouble monitor is expected to indicate and annunciate most protection system troubles.

Since the primary elements are transducers, they cannot be completely tested electrically. With a dual-channel system, however, routine operational checking of primary elements is possible without interrupting plant operation. For example, if the high-reactor-pressure censors are to be tested, one of the switches can be isolated from the reactor by closing the associated root valve, and an external pressure can be applied to the pressure switch until its protection channel is tripped. The trip setting and the operability of the switch and its associated circuits will both be checked by this test. After the test has been completed, the protection channel can be reset and the remaining switches tested one by one in a like manner.

All sensors which are in accessible locations and can be provided with an artificial primary signal can be operationally tested in a similar manner.

Testing of the scram mechanism will have to be accomplished by performing an actual scram. However, if it should be necessary, individual control rods or groups of rods can be scrammed by individually de-energizing their control valves with the remainder of the reactor in operation.

Since there are two independent, protection channels, either channel can be de-energized for maintenance without disturbing the other channel or the output of the plant.

The location of components and circuits at Dresden is such that there is little likelihood of a mechanic's accidentally disturbing the operating channel while testing or maintaining the other channel.

Conclusions

The Dresden-type dual-channel protection system appears to be able to meet the operational reliability required for reactor protection while still maintaining the nuisance failure rate low enough to be acceptable in a modern power plant. A design has been completed using proved, commercially available components in conventional circuits which lead to a high degree of predictability of performance. The proof of the design, however, still awaits the actual operating experience which will be obtained when Dresden Nuclear Power Station starts producing power.

Transients in Logarithmic Count-Rate and Period Meters

BRUCE B. BARROW
NONMEMBER AIEE

ROBERT MAITLAND
NONMEMBER AIEE

IT HAS BEEN found desirable and practical, in designing automatic control devices for starting nuclear reactors, to measure flux transients at extremely low flux levels, using the output from neutron-counting circuits. In general, a logarithmic count-rate circuit is used, and the logarithmic indication of flux thus obtained is differentiated electrically to yield an indication of the period of the reactor flux.

The special problem that arises when a period meter is built around a logarithmic count-rate meter is random fluctuation of the meter output, or *noise*. This noise is inseparably associated with the quantity being measured, for it arises in the randomness with which neutrons are detected in a fission counter or equivalent device. To reduce this noise requires, in general, measurement over a larger number of neutron detections, which means measurement over a longer time, i.e., slower transient response, assuming that counter sensitivity cannot be increased. It is possible, however, to achieve a good compromise between quick response and low noise, and the procedure for achieving such a compromise has been discussed in earlier papers.[1,2]

This paper cannot easily be studied apart from its predecessors. To write it otherwise would have required excessively long repetitions. This paper begins, therefore, where the others ended. Several classes of differentiating networks are analyzed in connection with the general problem of differentiating a signal while filtering out undesired wide-band noise. An indication of the relative quality of performance of these various networks is given, and confirmed quantitatively for the log-diode period meter. Experimental measurements of transient performance are reported, and these confirm the predictions from theory. The experiments involved both a simple log-diode circuit and an entire period meter. Transient inputs were obtained from an exponential-current generator and, later, from a reactor simulator operated with various reactivity inputs.

Differentiating-Network Design

GENERAL PROPERTIES

At least two types of logarithmic count-rate circuits have been used in period meters. The first of these, the log-diode circuit, consists essentially of a logarithmic diode, usually a vacuum diode operated in the logarithmic region of its current-voltage characteristic, in parallel with a capacitor. An electric charge is dumped onto this capacitor each time a neutron is detected, and the current leak through the diode causes a voltage that is more or less proportional to the logarithm of the counting rate. The important properties of this circuit are known.[2]

The second type of logarithmic count-rate circuit consists of the parallel combination of a number of diode pump circuits with staggered time constants. Cooke-Yarborough and Pulsford have published an admirable study,[3] both theoretical and experimental, of this circuit, but the results do not include expressions for, for example, transient response or bandwidth of the randomly fluctuating output signal. An analysis in depth for these properties seems to be quite difficult, though it would be of considerable value to the designer of period meters.

It is clear, however, that the behavior of the two circuits is similar, qualitatively, in two important and related respects: both circuits have faster transient response at higher count rates, and both circuits exhibit more rapid fluctuations in measured count rate when operating at higher count rates.

In the log-diode circuit the amplitude of the fluctuations in the voltage output remains constant as counting rate varies. At the same time the bandwidth of the frequency spectrum of these fluctuations remains proportional to the counting rate. In the multiple-pump circuit the amplitude of the fluctuations in voltage output decreases somewhat with increasing counting rate. At the same time the fluctuations become more rapid, since the short-time-constant pumps dominate at high counting rates.

A differentiating network used with either type of logarithmic count-rate circuit to measure period must per-

Manuscript submitted December 1, 1958; made available for printing February 9, 1960.

BRUCE B. BARROW is with the SHAPE Air Defense Technical Center, The Hague, Holland, on leave from the Hermes Electronics Company, Cambridge, Mass. ROBERT MAITLAND is with the General Electric Company, Cincinnati, Ohio.

Mr. Barrow's contribution to this paper was supported in part by the General Electric Company, through a consulting agreement, and in part by the Hermes Electronics Company (formerly Hycon Eastern). An earlier version of this paper was presented in Paris on September 17, 1958, at the Colloque International sur l'Electronique Nucléaire, which was sponsored by the Société des Radioélectriciens.

form a dual function: it must differentiate the low-frequency portion of the voltage output of the count-rate circuit, and it must suppress the high-frequency fluctuations or noise. Various differentiating networks and their relative effectiveness in this dual role are discussed in what follows.

First, the frequency-response functions of differentiating networks offering varying degrees of suppression of high frequencies are presented. To compare these on a fair basis, parameters are so adjusted that all have an equally fast transient response. Then the frequency-response functions of the various networks are compared. Here narrow bandwidth is the desired quality, for, among networks with equally good transient response, the one that most effectively filters out noise must be preferred.

Conclusions drawn from the frequency-response comparison, valid whether log-diode circuit or multiple-pump circuit is used in the period meter, are checked analytically for a log-diode period meter. Finally, the practical realization of these networks is discussed.

THE PERFECT DIFFERENTIATOR

The complex-frequency function of a perfect differentiator is

$$H_{id}(s)=s \tag{1}$$

where s represents complex frequency $(j\omega+\sigma)$. If $j\omega$ is substituted for s in equation 1, the result expresses the fact that a perfect differentiator has a phase response of +90 degrees for all frequencies and an amplitude response that is proportional to frequency. Such a device is not physically realizable, for no circuit can maintain output proportional to frequency over an unbounded range of frequencies. On the other hand, for the reasons noted above, it is desirable that the differentiating network used in a period meter differentiate only low frequencies, and attenuate high frequencies. Such networks are physically realizable.

PRACTICAL DIFFERENTIATING NETWORKS

Consider the following functions representing realizable differentiating networks listed in increasing order of complexity:

$$H_1(s)=a_1s/(s+a_1) \tag{2}$$

$$H_2(s)=a_2^2s/(s+a_2)^2 \tag{3}$$

$$H_3(s)=(a_3^2+b_3^2)s/\{(s+a_3)^2+b_3^2\} \tag{4}$$

$$H_4(s)=(a_4^2+b_4^2)cs/(s+c)\{(s+a_4)^2+b_4^2\} \tag{5}$$

The a's, b's, and c are positive real constants. Each function, at low frequencies, is that of a differentiator. This may be seen by letting s approach zero. Except for the first, each offers attenuation at high frequencies, as may be seen by letting s increase without limit.

The function of equation 2 is that of the simplest realizable differentiating network, which may be built from one resistor and one capacitor; see Fig. 4(A). Physical realization of the other functions is discussed below. The differential equation corresponding to equation 3 is of second order, critically damped. Those corresponding to equations 4 and 5 are of second and third order, respectively, underdamped.

CHOICE OF PARAMETERS

To compare the different types of analog differentiators defined by equations 2 through 5, some arbitrary criteria had to be set up. First, it was decided to set the solution time at 15 seconds. (The solution time is defined as the time required for the output of the network to reach within 10% of steady-state value after sudden application of a unit ramp at the input. The unit-ramp function is zero for negative time and equal to t for positive time.) This is sufficient to fix a_1 and a_2. The unit-ramp response corresponding to equation 2 is

$$f_1(t)=1-exp(-a_1t) \tag{6}$$

and the constraint of 15-second solution time requires that

$$a_1=0.153/\text{sec (per second)} \tag{7}$$

The unit-ramp response corresponding to equation 3 is

$$f_2(t)=1-(1+a_2t)exp(-a_2t) \tag{8}$$

and the constraint of 15-second solution time sets

$$a_2=0.259/\text{sec} \tag{9}$$

Equation 4 contains two constants to be fixed. It is possible therefore to choose the ratio a_3/b_3 and then set the solution time equal to 15 seconds.

Solutions for various networks of this type showed that an optimum was reached when b_3 was set equal to a_3. The unit-ramp response corresponding to this condition is

$$f_3(t)=1+2^{1/2}exp(-a_3t)\sin(a_3t-3\pi/4) \tag{10}$$

This response shows an overshoot of only 4%. Although underdamped, the network is only slightly oscillatory. Setting the solution time at 15 seconds requires that

$$a_3=0.125/\text{sec} \tag{11}$$

The three constants of equation 5 were varied, relative to each other, to give a series of solutions, the best of which obtained when

$$a_4=b_4=c/2 \tag{12}$$

For this special case the unit-ramp response is

$$f_4(t)=1-exp(-2a_4t)-2exp(-a_4t)\sin(a_4t) \tag{13}$$

Setting the solution time at 15 seconds fixes

$$a_4=0.168/\text{sec} \tag{14}$$

The four ramp-response functions are shown, together, in Fig. 1. This figure gives a clear comparison of the transient response properties of the four types of networks. If for any application a solution time other than 15 seconds is desired, it is only necessary to multiply the above constants (the a's) by $15/x$, where x is the desired solution time, in seconds.

AMPLITUDE RESPONSE OF VARIOUS DIFFERENTIATING NETWORKS

The amplitude-response functions of the four types of networks are shown in Fig. 2. For each case the straight-line asymptotes are also given. The curves are obtained by setting $j2\pi f$ in place of s in each of equations 2, 3, 4, and 5, and by taking the absolute value of the result.

All four cases are seen to approach the response of the perfect differentiator, $2\pi f$, at low frequencies. The function of Case 1, $H_1(j2\pi f)$, derived from equation 2, offers no attenuation to high frequencies. The "breakpoint" frequency, at which the high-frequency and low-frequency asymptotes cross, is 0.024 c/s (counts per second).

The function of Case 2, derived from equation 3, attenuates high frequencies in inverse proportion to the frequency. This curve is symmetric about its maximum (0.0168 or −17.8 db), at a resonant frequency of 0.041 c/s.

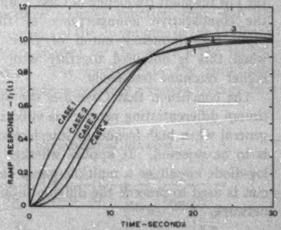

Fig. 1. **Transient-response functions of various differentiating networks with ramp input suddenly applied; parameters chosen for 15-second solution time**

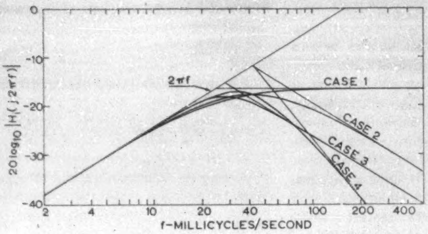

Fig. 2 (above). Frequency-response functions of various differentiating networks, together with straight-line asymptotes

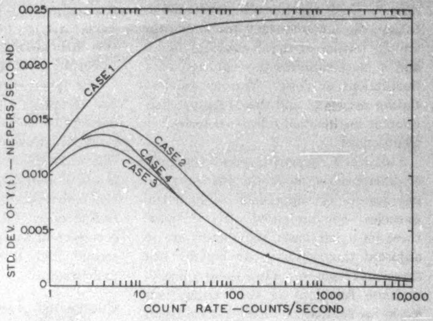

Fig. 3 (right). Standard deviation of indicated growth factor versus count rate, for log-diode period meters using various differentiating networks

Comparison with the function of Case 3, derived from equation 4, is interesting. The latter function is also symmetric about its maximum (0.0156) and this maximum is only slightly less than that of Case 2. It occurs, however, at 0.028 c/s, a much lower frequency. It is clear that the filter of Case 3 provides better discrimination than does the Case-2 filter against interfering signals at higher frequencies. The function of Case 4, derived from equation 5, on the other hand, resonates at a slightly higher frequency (0.034 c/s), and has a higher peak value. A filter of this type will, therefore, not be better than a Case-3 filter, even though the high-frequency portion of the response curve falls off faster, i.e., as $1/f^3$. Fig. 1 shows slightly less overshoot for the Case-4 filter, but the difference seems too small to justify the increase in circuit complexity.

When making comparisons from Fig. 2, it must be remembered that the logarithmic scales tend to give a distorted picture. The response of the various filters to wide-band noise would be more easily seen if the frequency-response curves were plotted with linear axes. Such a plot would show the advantage of the low resonant frequency of Case 3, and the comparative unimportance of the rapid high-frequency cutoff of Case 4 when this is obtained together with a higher resonant frequency.

The conclusion that Case 3 is the optimum differentiating network is valid in general when high-frequency interference is to be rejected. It applies whether a log-diode circuit or a multiple-pump circuit is used to precede the differentiating network.

PERFORMANCE WITH LOG-DIODE CIRCUIT

The performance of the various differentiating networks when operated with a log-diode circuit can be judged by examining the output fluctuations in indicated period at various steady-state counting rates. To describe these fluctuations, due entirely to the random nature of the neutron-detection process, it has proved convenient to work in terms of the growth factor, a variable that is proportional to the reciprocal of the period. The magnitude of the fluctuations may be determined in each case by solving the integral

$$var\{\gamma\}=\int_0^\infty \frac{nQ^2}{\pi}\cdot\frac{1/C^2}{\omega^2+(nQ/AC)^2}\cdot\frac{|H_i(j\omega)|^2}{A^2}\,d\omega, \qquad (15)$$

where $var\{\gamma\}$ denotes the variance (mean-square fluctuation about the mean) of the measured growth factor, γ. The factor nQ^2/π is the power density spectrum of the input to the log-diode circuit, a series of short current pulses, each of charge Q, occurring randomly at an average rate of n pulses per second. The second of the three factors in the integrand is the squared magnitude of the frequency-response function of the log-diode circuit, or, rather, of its linear approximation, which varies with n. The last of the three factors involves $H_i(j\omega)$, the frequency-response function of a differentiating network, and A, the log-diode constant, which is needed for calibration. If A is expressed in volts/-neper, then γ, the growth factor, will be expressed in nepers/second, and will be equal to the period reciprocal. The whole integrand gives the power density spectrum of the output from the period meter (the measured growth factor), and integrating over-all frequency gives the variance. The derivation of equation 15 and its physical significance have been discussed in more detail in an earlier paper.[1]

The integral of equation 15 has been solved for each of the types of differentiating network considered above. $H_i(j\omega)$ is obtained by setting $j\omega$ for s in each of equations 2 through 5. For Case 1, the simple differentiating circuit of equation 2,

$$var_1\{\gamma\}=a_1^2QN/2AC(N+a_1) \qquad (16)$$

where for convenience the count-rate variable

$$N\equiv nQ/AC \qquad (17)$$

is introduced. For Case 2, a second-order differentiating network, critically damped, from equation 3,

$$var_2\{\gamma\}=a_2^2QN/4AC(N+a_2)^2 \qquad (18)$$

For a second-order differentiating network, underdamped, from equation 4,

$$var\{\gamma\}=(a_3^2+b_3^2)^2QN/4a_3AC\{(N+a_3)^2+b_3^2\} \qquad (19)$$

and this reduces, in Case 3, to

$$var_3\{\gamma\}=a_3^2QN/AC(N^2+2a_3N+2a_3^2) \qquad (20)$$

For a third-order differentiating network underdamped, from equation 5,

$$var\{\gamma\}=\frac{(a_4^2+b_4^2)^2c^2(N+2a_4+c)QN}{4a_4AC(N+c)\{(N+a_4)^2+b_4^2\}\{(c+a_4)^2+b_4^2\}} \qquad (21)$$

This expression reduces, in Case 4, to

$$var_4\{\gamma\}=2a_4^2QN(N+4a_4)/5AC(N+2a_4)\times(N^2+2a_4N+2a_4^2) \qquad (22)$$

Fig. 3 shows plots of the standard deviation (square root of variance) of $\gamma(t)$, the measured growth factor, as a function of count rate, for each of the above cases. Here AC/Q has been taken equal to 20, a practical value for a well-designed period meter.[2] Fig. 3 confirms, for the log-diode period meter, the deductions made from Fig. 2. The differentiating network of Case 3 is seen to be the best, both because the peak of the random interference is lower and occurs

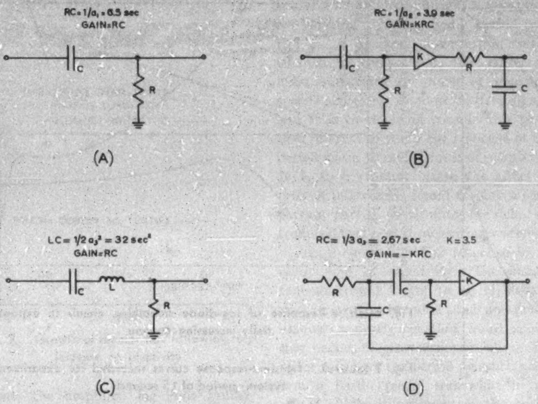

Fig. 4. Possible circuit configurations for various differentiating networks

at a lower counting rate, and because the interference at all counting rates is at least as low as for the other cases.

Realizability of Differentiating Networks

The above analysis is of use only if the mathematical functions of equations 2 through 5 can be realized in practical networks. Fig. 4 shows the essential elements of various differentiating networks having response functions discussed above. The differentiator gains listed are the outputs, in volts, for input ramps of 1 volt/sec. The numerical values shown for R-C (reactance capacitance) and L-C (inductance capacitance) products apply for a 15-sec solution time.

The simple differentiating circuit of Fig. 4(A) has the transfer function of equation 2. It is the simplest and most common differentiating network, and is of use wherever the filtering of high-frequency interference is not important.

The network of Fig. 4(B) realizes the function of equation 3. It can be built with no difficulty. The network of Fig. 4(C) would realize the function of equation 4, but the L-C product required to achieve the low resonant frequency (0.028 c/s) is hardly practical. Nor do mechanical filters offer an elegant solution, though one could certainly be built. An active R-C filter, on the other hand, is a simple solution. One such filter, which realizes the function of equation 4, is shown in Fig. 4(D). This network appears to have the disadvantage, when compared with that of Fig. 4(B), that drift in gain affects not only the calibration of the period meter, but also the shape of the frequency-response curve and the value of the resonant frequency. These effects are not important, however, in a circuit that is as highly damped as this one, and the difficulties with calibration remain the most serious. For example, a 25% increase in K would lower the resonant frequency of the circuit by 10% and would decrease the damping enough to give an overshoot on ramp response of 7%. Neither effect is very important, and the network would remain an effective differentiator and filter. The 25% error in calibration would, however, need to be corrected.

Many other active R-C filters could be designed to realize the function of equation 4. Kinariwala's interesting paper[4] includes a bibliography with important references.

Experimental Measurements of Transient Response

Experimental System

In order to observe the transient response of a physical period-measuring circuit, and to confirm, if possible, earlier conclusions regarding period meter design, an experimental period-measuring system was constructed on an analog computer. A log-diode circuit was used, followed by a differentiating network with a frequency function of the type given in equation 3. An exponential generator was used to provide various exponential inputs of current. A reactor simulator was also used, in place of the exponential generator, in order to study the response of the period-measuring system to ramp disturbances of reactivity.

The experimental system is illustrated schematically in Fig. 5. When used with a pulse input, from a neutron-detecting device, the log-diode circuit is preceded by a 50-pf (picofarad) "bucket" capacitor, aud the input pulses are 30 volts in amplitude. As a result, 0.0015 microcoulomb is dumped onto C for each neutron detection; this is the charge Q, introduced in equation 15. For the experimental study of transients, the bucket capacitor was by-passed, and a continuous-current input, $i(t)$, was provided to simulate the desired counting rate, according to the relation

$$i(t) = nQ \tag{23}$$

The current-voltage relationship of the log diode is given by

$$e_b = A \ln Bi_b \tag{24}$$

and the constant A, so defined, was equal to 0.1 volt/neper. Other system parameters are listed as follows:

$C = 0.5$ microfarad
$AC/Q = 33.3$
$R_1 = 1.33$ megohms
$C_1 = 3$ microfarads
$R_2 = 10$ megohms
$C_2 = 0.4$ microfarad

The two amplifiers shown in Fig. 5 were elements of the analog computer. They had extremely high gain (about 10^8), high input impedance, and negligible output impedance in this application. When connected as shown, each provided a voltage transfer function that was the quotient of the impedance in the feedback loop divided by the series input impedance. The amplifier in the count-rate meter thus provides a simple voltage gain

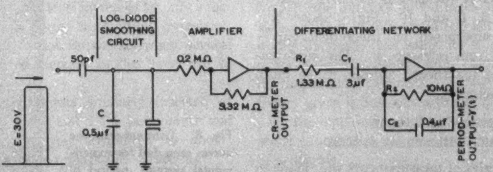

Fig. 5. Experimental system used for transient-response studies

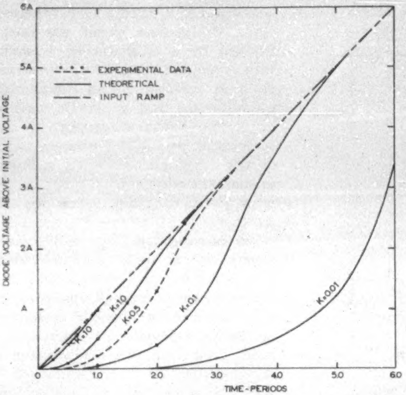

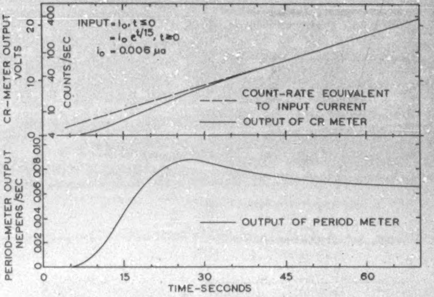

Fig. 6(left). Response of log-diode smoothing circuit to exponentially increasing currents

Fig. 7 (above). Transient-response curves recorded for experimental system; period of 15 seconds

of 46.6. The differentiating network has a transfer function that reduces to

$$E_{\text{out}}(s)/E_{\text{in}}(s)=R_2C_1s/(R_1C_1s+1)(R_2C_2s+1) \quad (25)$$

which is the expression of equation 3 with a numerator constant equal to 30 volts output per volt/sec input. The ramp response function of the differentiating network was measured and found to agree very closely with equation 8, with $a_2=0.25$/sec.

The growth-factor output, $\gamma(t)$, is a voltage, and may be displayed on a voltmeter or used as a control signal in a feedback-control loop. The diode voltage resulting from an input growth factor of one neper/sec (period of one second) is a ramp with a slope of 0.1 volt/sec. Therefore the output of the *CR* meter is a ramp with a slope of 4.66 volts/sec, and the output from the differentiating network is 140 volts, corresponding to a growth factor of one neper/sec. This is the required calibration constant.

TRANSIENTS IN THE LOG-DIODE CIRCUIT

Exponential-current inputs of the type

$$i(t)=i_0e^{t/T} \quad (26)$$

were impressed on the log-diode circuit. Measurements were made with the parameter K (defined as i_0T/CA) equal to 0.1, 0.5, 1, and 10. Fig. 6 shows test data superposed on theoretical curves taken from reference 2. The confirmation of the theory appears to be quite satisfactory.

TRANSIENTS IN ENTIRE PERIOD-MEASURING SYSTEM

A series of measurements was made to determine how well the entire period-measuring system would respond to exponential inputs, suddenly imposed. For example, a current input corresponding, by equation 23, to

$$n=4e^{t/15} \quad (27)$$

i.e., to a 15-second period (growth factor 0.067 neper/sec) initiated at 4 counts/sec, was imposed. The results of this test are shown in Fig. 7. One observes that the output transient, in measured growth factor, has decayed to within 10% of final value by the time n has reached 90 counts/sec. The overshoot in growth factor reaches a maximum of only 0.086 neper/sec (12-second period), far from saturation. This response indicates considerable improvement over period meters built previously.

In the experimental system, spurious noise limited the largest detectable period. Response to a 100-second period could, however, be measured and in this case only about 30 seconds were required to reach steady state.

To check short-period performance a current input corresponding to

$$n=4e^{t/3} \quad (28)$$

i.e., to a 3-second-period transient, was used.

The experimental result is shown in Fig. 8. The three recordings are, from top to bottom, the exponential current

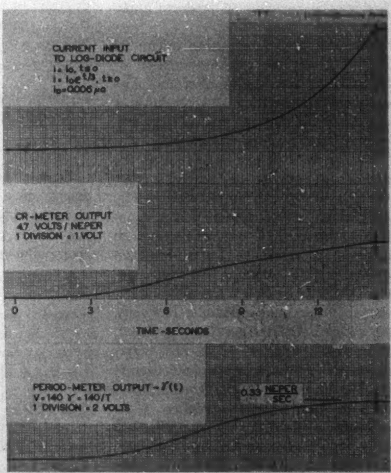

Fig. 8. Transient-response curves recorded for experimental system; period of 3 seconds

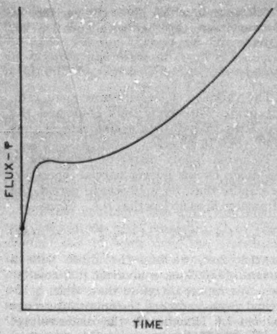

Fig. 9. Growth of reactor flux following step increase in reactivity

input, the amplified log-diode voltage (the parameter K equals 0.36 for this case), and the differentiating-network output (measured growth factor). The exponential generator was limited to about two decades, but measured growth factor reached 90% of steady state within these two decades, i.e., within 14 seconds. It is also clear from the measured curve that overshoot would be very small, less than it was with a 15-second period. This happens because the curve of diode voltage, though more distorted, approaches the straight-line asymptote more quickly (in only 9 seconds), and because the very distortion, with an excessive slope for a short time, shortens the differentiating-network transient. It is clear that periods somewhat shorter than 3 seconds could be measured accurately.

Although the effect of distortion in the diode-current transient can be beneficial, K should not be allowed to become less than unity, approximately, for periods of the order of the differentiating-network solution time. If, for example, a 12-second period is initiated from 1 count/sec, the form of the diode transient will be as above (K again equal to 0.36). From Fig. 6 it appears that a too steep slope in diode voltage will persist for longer than one period, i.e., for longer than 12 seconds. A much too high growth factor will thus be indicated by the period meter, and "scram" may be called for when all that was needed was patience. To avoid this type of response when operating with a reactor, a bias current, equivalent to two to four counts per second, should be kept on the diode.

Transients with Reactor-Simulator Input

Determining the response of the period measuring system to exponential inputs is useful for the basic insight it gives into the working of the system. Period control in a reactor, however, is often effected by control rods that either remain stationary or move at constant speed, according to some control signal, and it is therefore of considerable practical interest to study the response of the period meter to ramp inputs of reactivity, $\delta k/k$, to a reactor. Here the effect of prompt neutrons is found to play an important part in overcoming the delay introduced by a period-measuring system.

Fig. 9 shows the flux response to an input step of reactivity. The instantaneous growth factor ($\dot{\varphi}/\varphi$) is initially very large, then becomes small and finally assumes a nearly constant value as the flux begins to grow exponentially. The effect is to give the period-measuring system a hard "push" somewhat in advance of the appearance of the period that will shortly be present.

A series of measurements was made, accordingly, with the exponential-current generator replaced by a reactor simulator. For these tests the diode was fed a constant bias current of 0.006 μa, the equivalent of 4 counts/sec, to insure that transient response of the log-diode circuit would not be too sluggish. Fig. 10 shows test data simulating a start for a reactor just gone critical. Reactivity is inserted at 1%/minute for 17 seconds. Thus 0.28% $\delta k/k$ is inserted. Power level in the simulator, which is recorded also, eventually begins to increase with a stable 15-second period. In the third record the output of a fast period meter is shown, giving a nearly instantaneous record of the growth factor of power level. This meter lacks the time delays needed in a practical system to smooth out the noise from the neutron counting. According to this measurement, the "true" growth factor rises to a peak of about 0.13 neper/sec (period of 8 seconds) before settling down to a steady value of about 0.067 neper/sec (period of 15 seconds).

The measured growth factor, given last, rises to a peak of about 0.10 neper/sec, and requires about 20 seconds after the "true" growth factor has settled down to reach an accurate steady-state measurement. This is not alarming, however, for the power level increases by only a factor of four during the spurious overshoot, and this is not important when several decades of increase in flux level are to follow.

Reactivity was similarly inserted at rates of 0.5% and 1.5% per minute and the results were evaluated as above. There were no remarkable variations.

Finally, a test was run to see how quickly the period-measuring system would trip a 5-second-period alarm for various rates of shim-rod withdrawal. When reactivity was inserted at a rate of 6% per minute, the system signaled alarm after only 1.5 decades increase in power level.

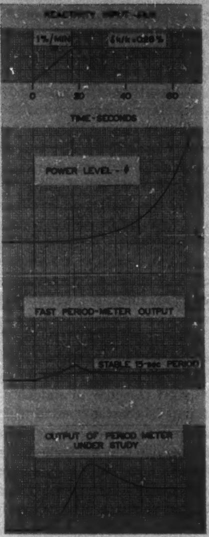

Fig. 10. Transient-response curves recorded for experimental system operated with reactor simulator

Conclusions

The foregoing analysis of linear differentiating networks rounds out the earlier work published on this subject, at least as applied to period-meter design. The curves given make it possible to judge whether, where electrical differentiation of a signal obscured by wide-band noise is required, the improved filtering performance of the slightly more complicated differentiating networks justifies their use. Although a quantitative analysis is given only for period meters using a log-diode circuit, the relative advantages of the various types of differentiating networks would be nearly the same for a period meter using a multiple-pump circuit for its logarithmic element. Though the theory given is basically a theory of analysis, the equations are simple enough to make practical a cut-and-try procedure of synthesis.

The experimental study was, in fact,

a check of just such a "synthesis" procedure, which had indicated that a log-diode circuit with AC/Q equal to about 30, followed by a differentiating network with a solution time of 15 seconds, would have adequate transient response for use in controlling startup on 15-second period. Transient response for a 3-second period and for longer periods was measured and found to give good confirmation of the theory, both for the log-diode circuit itself and for the entire period meter. It appears that periods as short as half a second would produce a satisfactory "scram" indication (*not* steady-state) if initiated at a count-rate lower than 100/sec.

The experiments with a reactor simulator are of particular interest, for they show that a period meter designed to have good response to suddenly imposed inputs of constant period will also respond well to the more complicated transient periods that are met when control rods are moved in a manner appropriate for an actual startup. The ability of the meter to detect short periods in a reactor is surprisingly good, because the prompt rise of reactor flux due to any disturbance of reactivity supplies a lead characteristic that tends to counter the time lags of the period-meter filters. Even when reactivity is inserted at a rate several times faster than normal, the "scram" indication provided by the period meter comes early enough for safety.

Appendix

The following example illustrates the use of the theoretical results in the analysis of a tentative design.

Two fixed-position fission chambers are cascaded, as shown in Fig. 11(A), to detect neutron density over a span of 8 decades. They are to be used in logarithmic count-rate and period meters designed to be effective over as much as possible of the 8-decade range. The proposed configuration is shown in Fig. 11(B). Each fission chamber is followed by a pulse-forming circuit and then by a log-diode circuit of the type discussed above. The diode voltage is amplified and fed to a meter, to indicate count rate, and also through a differentiating network to another meter, to indicate growth factor. When fission chamber 1 saturates, at 10^5 sec^{-1}, a relay operates to switch both the count-rate and period meters to the circuits associated with fission chamber 2.

The logarithmic element chosen for this application is a thermionic diode with a current-voltage characteristic that is logarithmic over about 5 decades, up to a current of 0.15 ma. Over this range the plate voltage changes by 0.10 volt per neper change in current (parameter A).

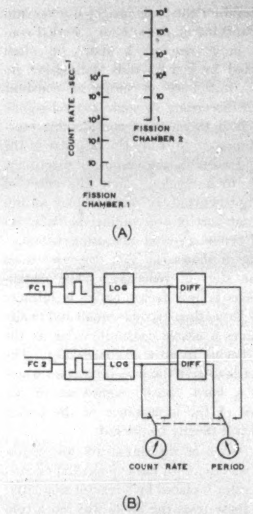

Fig. 11. Possible arrangement using fixed-position fission chambers cascaded to cover a wide range

Since the maximum diode current is 0.15 ma, and the maximum counting rate for the fission chamber is 10^5 sec^{-1}, the charge per pulse must be made equal to 0.0015 microcoulomb (parameter Q). This may be accomplished, as in Fig. 5, with 30-volt pulses and a 50-pf coupling capacitor.

Let us assume that the system is to be used, ordinarily, to help control startup on 15-second period, and that periods as short as 10 seconds shall be measured without perceptible transient during the transition from chamber 1 to chamber 2. This means that when an input of 10-second period is suddenly applied to the channel associated with chamber 2, the resulting output transient must decay before the count rate reaches 100/sec, i.e., before chamber 1 has saturated and switchover takes place.

In the design of the channel associated with chamber 2 the primary consideration must be fast transient response, for two reasons: 1. If transients too rapid to measure occur at higher flux levels they are potentially more dangerous than if they occur at low levels; 2. Noise at low count rates is not important because the output is connected to the indicating meter only at count rates greater than 100/sec. To insure fast response in the log-diode circuit we choose

$$AC/Q=20 \qquad (29)$$

This, with Q and A set as above, fixes the smoothing capacitor C, Fig. 5, as follows:

$$C=20Q/A=(20)0.0015/0.1=0.3\ \mu f \qquad (30)$$

To estimate the random fluctuation in the count-rate meter we use equation 33 of reference 2, which gives the variance of diode voltage, together with equation 29, above.

$$var\{e_b\}=AQ/2C=A^2Q/2AC=A^2/40 \qquad (31)$$

The variance of logarithm of count rate, not diode voltage, is thus 1/40, and the rms error in indicated count rate is thus $1/40^{1/2}$ or 0.16 neper.

To avoid highly distorted transients in the diode circuit during normal operation we require that, for a 10-second period, the parameter K be no less than 0.1. Since

$$K=i_0T/CA=n_0QT/CA=n_0/2 \qquad (32)$$

for this case, we bias the diode with a current of 0.003 μa, equivalent to 2 counts/sec. We expect therefore that, when a 10-second period reaches the count-rate range covered by chamber 2, the diode-voltage transient will be no more distorted than that shown in Fig. 6 for a K of 1.0. This transient has a too low slope for one period, then a too steep slope, and finally it settles down before 2.5 periods, or 25 seconds, have elapsed. Actually, with a bias current present, the transient is smoother than that for a K of 1.0, since under these conditions there is not a sudden step into a 10-second-period input, but the input follows a smooth transition, lasting over several periods, from the condition of no growth to that of exponential growth.

For a differentiating network we choose the configuration shown in Fig. 4(D), but with R-C decreased to 2 seconds. This has the effect of setting a_3 equal to 0.167/sec, and results in a solution time of only 11 seconds.

In predicting the transient performance of the period meter, we can make the assumption that steady-state is not reached at the output until a solution time of 11 seconds has elapsed after the diode-response curve of Fig. 6, for K equal to 1.0, has approached the ramp asymptote. Thus if a solution time of 11 seconds is added to the 25 seconds required by the diode circuit, a total elapsed time of 36 seconds, or 3.6 periods, is needed. This represents an exponential growth by a factor of 37, which implies that steady state would be reached by the time the count rate had reached 74 counts/sec. Thus, even a conservative calculation leads to the conclusion that the transient dies out before switchover at 100 counts/sec. The actual transient will be much shorter (see Figs. 7 and 8) because the differentiating networks will begin to respond before the transient in the log-diode circuit has died.

To get an idea of the magnitude of the random fluctuations to be expected in the neighborhood of the switchover point, we turn to equation 20, calculating for $N=2$ and for $N=5$ ($n=40$ and $n=100$, respectively). This gives

$$var_3\{\gamma\}_{n=40}=0.95\times10^{-4}$$

$$\text{standard deviation } (n=40)=0.0097 \text{ neper/sec}$$

$$var_3\{\gamma\}_{n=100}=0.43\times10^{-4}$$

$$\text{standard deviation } (n=100)=0.0066 \text{ neper/sec} \qquad (33)$$

Strictly, equation 20 holds only for

constant count rates, but, as stated in reference 2, when the count rate changes during the solution time of the differentiating network, the range of count rates may be examined to set bounds on the expected fluctuation of period-meter output. Thus we may estimate that the rms error of period-meter indication immediately after switchover will be between 0.007 and 0.009 neper/sec. Since the periods met in normal operation will be about 15 seconds (growth factor 0.07 neper/sec), this noise should cause no difficulties.

Different considerations affect the channel associated with chamber 1. This channel has to work over the transition between infinite period and 15-second period, and it has to be capable of indicating period at low counting rates, where noise is most important. Therefore lower noise than was needed with channel 2 must be obtained, even at the cost of slower transient response.

The parameters A and Q will be the same for both channels, however, since the former depends on the diode only and the latter depends on the diode and on the count rate at which saturation is to occur. The pulse-forming circuits will also be the same. There remain three system parameters to choose: value of the smoothing capacitor C, value of the diode bias current i_0, and solution time for the differentiating network. A proper choice depends on the reactor dynamics, rate at which reactivity is to be inserted, level of residual flux, etc. Without precise knowledge of these, we may however assume that the worst transient to be measured is no worse than a 15-second period beginning at 2 counts/sec. Thus we may set bias current as before and increase C to 0.45 μf, making AC/Q equal to 30. A still larger value of C might prove desirable, but might lead to overshoot because of the effect of the prompt neutrons; see Fig. 10. Similarly, the desire to provide more noise rejection without slowing response too much leads to a choice of the differentiating network of Fig. 4(D) as shown, with a 15-second solution time.

Calculation of response to various transients and of noise at various count rates may be made as indicated above for channel 2.

A Digital Start-up Control for Air-Cooled Nuclear Reactors

SAMUEL N. LEHR
MEMBER AIEE

VERNON P. MATHIS
NONMEMBER AIEE

IN BRINGING a nuclear reactor up to power, the flux level goes through as many as 8 to 10 decades from the off position through full power. Somewhere within this range of power the reactor goes critical (effective multiplication factor equals one). This point where criticality is reached may be 7 decades below the full power point. In most stationary water-cooled reactors, this total spread is divided into three ranges of control. The start-up range normally covers 3 to 4 decades; the intermediate range, 4 to 5 decades; and the power range, 1 to 2 decades.

For a mobile reactor, it is advisable for simplicity to control the flux through only two ranges. These are the automatic start-up range covering about 6 or 7 decades and the power range covering 2 decades.

The rate of power increase in the start-up range is controlled by actuating control rods so that the period (time for the reactor power to increase by a factor of *e*) is always above the minimum safe value. If the reactor period decreased below this value, a start-up accident could occur and the reactor could run away.

There are many pieces of equipment now available to control the reactor through this range by analog methods. The outputs of various sensors are converted to electric voltages or currents and actuate relays, alarms, recorders, or meters which the operator continuously monitors. For an automatic start-up control, this method appears inefficient. The outputs of the sensors are already digital signals consisting of discrete pulses. The outputs of the controls are also digital in form—an on or off relaying action to the control rods. It appears that a method that would calculate and record the number of pulses and their time-variations (the reactor period) digitally will have an advantage over the analog system.

This paper describes a study made of such a system, the various system parameters required for a stable system, the safety functions necessary to prevent a nuclear accident, and a digital pulse-counting and period computation system.

It is desirable to review some of the principal reasons for preferring an over-all digital system for the start-up control. Primarily, digital circuit techniques result in a mode of operation of the active devices, i.e., transistors, that immensely increases the effective reliability of those devices. They are either off or on. Relatively large variations in gain, leakage current, or impedance level of the transistors have no effect on the ability of a properly designed circuit reliably to indicate yes or no. The operation is precise and positive and lends itself readily to many techniques of calculation. Digital methods, furthermore, may readily be adapted to exploit the precision and reliability of the input information to the fullest extent, thereby achieving the ultimate in system accuracy with no basic changes in system philosophy for improved models.

The preference for a digital display of level and period information is easy to understand. The analog meter reader concerns himself with less than 1% of the panel area occupied by his instrument. A digital indicator can provide much greater panel space efficiency and simultaneously simplify the problem of transferring indicated information to the operator's mind.

The use of a digital system will very likely result in an ultimate reduction of the logic requirements involved in the safety and control functions. Digital techniques incorporate, within the computation circuits, on-off processes that verify or correspond to many of the signals required in present malfunction networks. The very operation of the digital computer may be made to be, in some respects,

The Count Rate Circuitry

Computing Scheme

The problem of level indication consists of determining the level of the reactor and providing means for display of this information. It is required to indicate the level of the reactor over a power range of 6 decades with an accuracy of at least half a decade. If this range is broken up into octaves and each of these is explicitly indicated, then the accuracy, to the nearest octave, will be within 1/3 of a decade. There will be 20 indications of interest, each corresponding to a doubling of reactor power with respect to the previous indication. A doubling indication, i.e., level indication using the radix 2 instead of *e*, has several notable advantages.

First, the concept of doubling lends itself readily to binary instrumentation as well as being an easy concept to understand from the operator's point of view. Second, the fortunate fact that there are approximately 10 octaves in 3 decades simplifies considerably the problem of display for the level indication since each nuclear sensor may be used to cover 10 of the 20 octaves. Assuming that this octave system is used, then the reactor level over the entire 6 decades may be indicated with sufficient precision by the decimal numers 0 to 19 corresponding exactly to the 20 octaves of reactor power in the start-up range.

Malfunction Signals and Pulse Standardization

Referring to Fig. 1, consider the sensor malfunction logic and the pulse standardizing circuits. These parts of the system are included to check the operation of the nuclear sensors, to discriminate the pulses to be counted, to supply necessary amplification of the signal, and to deliver uniform pulses to the digital circuits that follow. It is desirable to detect sensor malfunction with as little intervening circuitry as is possible to reduce the probability of malfunction detector failure.

The sensor malfunction logic is intended to check the output of each sensor for proper registration with the previous sensor output before information is accepted from it for delivery to the counters. A malfunction signal is capable of preventing the level counter signal from causing the sensor selector to switch to a new sensor. Proper operation signals for the sensors may be generated by noting that a certain count has been attained. A simple *RC* integrator operating on the raw input signal or a 2- or 3-stage magnetic core counter operating on the standardized pulses may be used to note the proper counting rate.

To generate standard pulses the signal may first be amplified to the extent necessary to furnish pulses of reasonable size from a differentiator. Since the signals arrive on a low impedance coaxial line, a common-base transistor may be used as a uniform gain voltage amplifier. This may be followed by emitter-follower stages to provide power gain.

Such a mode of operation minimizes the effects of transistor parameters on circuit gain. After differentiating the signal, to obtain a pulse for each fast rise time observed, the pulses are applied to a Schmitt trigger circuit. This includes the discrimination function if the input capacitor is chosen so that the circuit triggers only for pulses exceeding a prescribed energy level.

Sensor Selector and Gate Logic

In order to effect an over-all reduction in system complexity it is desirable that the two sensors share the use of as many of the start-up control circuits as possible. This implies ideally that a signal commutation scheme should be employed with respect to all of the circuits with the exception of the malfunction indicators. These should monitor each sensor at all times and indicate faulty operation as soon as it develops.

The sensor selector and gate logic network is incorporated into the system as early as possible to perform the switching or commutation function. It consists of several transistor gates and logic circuits operated by signals from the level counter and the malfunction logic block. The sensor selector is capable of passing the signal from the selected sensor into the level counter through Gate 1. Actually the chamber selector must also provide for passing a different signal from the second sensor to the period computation circuitry during the overlap interval when both sensors are in use. This operation will require a few additional logic elements.

Fig. 2 illustrates one commutation scheme. The gates, one on each sensor line, allow no signal to pass through unless both gate control lines have the proper signal. Assume that the 2-stage counter is always set to the state 00 when start-up begins. Then the gate on line 1 is the only one that allows pulses to enter the level counter. The level counter continues to accept pulses from sensor 1 until a predetermined count rate is reached, e.g., 131,072 pps (pulses per second).

The attainment of this value of count generates a pulse that is fed to the 2-stage counter, changing its state from 00 to 01. The gate on line 2 now is activated. The level counter also generates signals for the low count, e.g., 64 pps. Then if the reactor level should decrease so that the count falls below 64 pps, a "reverse-one-unit" signal is applied to the 2-stage counter. This switches in the lower sensor line. Finally, the condition 10 of the 2-stage counter activates a third gate that supplies a signal to the effect that the power range has been attained.

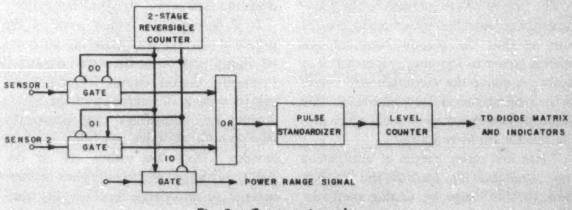

Fig. 2. Commutation scheme

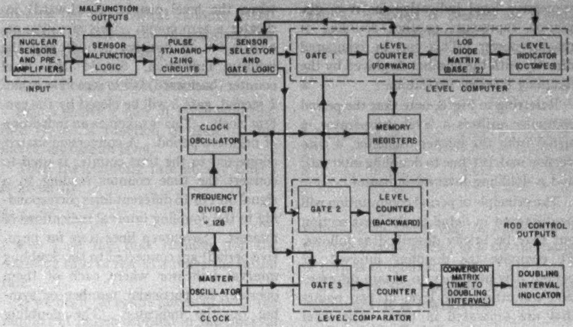

Fig. 3. Digital level and period computer

LEVEL COMPUTER

The level computer, shown in Fig. 1, operates as follows. Assume that the sensor selector allows a signal from sensor 1 to pass to gate 1. Gate 1 is operated by the clock oscillator at a repetition rate of 1 second, for example. The duty time is arranged so that gate 1 is open, allowing pulses to enter the level counter, for practically the entire second. A time of about 10 microseconds is ample for clearing the level counter at the end of each clock interval. The gate is therefore open almost all of the time and serves to mark the end of each second so that the reactor level, in terms of pulses per unit time, may be read out.

The log matrix converts the reading of the 17-stage level counter into a signal on one of 10 possible output lines corresponding to 10 successive doublings of counting rate, i.e., 10 different ranges of readings of the level counter. Thus a particular output signal, corresponding to one particular range of input pulse repetition rate over the sampling period is fed to the level indicator. Here, each of the 10 lines is capable of activating a particular number on a decimal digital-display device.

For example, if the reading of the level counter happens to lie between 1,024 and 2,047 counts when the gate closes at the end of some particular second, the log matrix will activate line 4 corresponding to the decimal digit "3." The number "3" would be displayed as the level indication and would be retained by suitable electrical or mechanical memory techniques until renewed or changed at the end of the next second. This number is interpreted as an indication of a particular range of neutron flux.

Suitable counting circuits employing transistor flip-flops may be designed in a straightforward manner for the frequencies of interest here. They are tolerant of transistor parameters and highly reliable.

The diode matrix is properly connected to the counter flip-flops to take the logarithm of the level count. The matrix is arranged primarily to supply a signal that lights the next indicator bulb the first time the next higher order flip-flop operates. Since the operation of flip-flop corresponds to a multiplication by 2, a logarithmic level indication results. Approximately 50 diodes are required for this matrix in an actual system.

It is seen that the level counter and log matrix are capable of activating 10 decimal digits corresponding to 10 octaves (3 decades) of reactor power. The entire range to be covered is 20 octaves. Therefore a "tens" column is required for the complete indicator as well as a "units" column. This may be done by utilizing signals from the sensor selector circuit to activate the required digits in the tens column.

For example, the tens indicator will be arranged so that if sensor 1 is being gated into the level counter, no tens digit will appear and the over-all indicator can show only the digits 0 to 9 in the ones column, corresponding to the first 10 octaves of power. When sensor 2 is gated in, a signal is fed to the indicator that displays a "1" in the tens column of the indicator. This, together with the ones column, gives octaves 10 to 19.

Note that there is a feedback path from the level counter to the sensor selector and gate logic block. When the level counter fills in the sampling interval to a predetermined value a signal is generated that can switch the sensor selector to the higher sensor. This switching operation is arranged so that it occurs if and only if the next sensor is operating properly as evidenced by the state of the sensor malfunction logic circuits.

The sensors are calibrated so that the high count of sensor 1 registers properly with the low count of sensor 2 and the high count of sensor 2 registers with the power range sensor; hence the registration of a particular count within a decade remains the same from sensor to sensor.

The counter readout circuits and the sensor selector circuit operate in either direction. That is, accurate level indications are produced whether the counting rate is increasing or decreasing. Therefore, the actual power level is always displayed and the display is revised each second.

The Period Circuitry

PERIOD COMPUTER

The problem of reactor period computation is fundamentally concerned with measuring the rate of change of reactor level. It is required to indicate the period of the reactor over a positive period range of, say, 3 to 30 seconds. Indications of specific selected values between these two extremes are also required as well as specific indications of positive period, negative period, and infinite period.

The accuracy of the measurements must increase as the period becomes shorter to a maximum accuracy of 5% for the very short periods. The delay time inherent in the instrumentation before a change in period is indicated should be small when compared to the time values of the periods of interest.

The period of the reactor at any power level is defined as the time required for the reactor power level to increase by a factor of e, i.e., 2.718. A considerable simplification in a binary digital system results if the factor "2" is employed as a multiplier rather than e, because the doubling operation is explicit in a binary system. For example, in a counter, the triggering of each successive flip-flop corresponds to a doubling of the count, i.e., a multiplication by 2. It is convenient, then, to think in terms of the doubling interval rather than the period.

The required values of period are easily converted to corresponding values of doubling interval. In addition, it is desirable that the "period" indication actually be displayed to the operator in terms of the doubling interval. This allows the operator, if he so desires, to check on whether the period computer is operating properly by simply timing the interval between level changes since each successive level indication, as it is displayed, represents another doubling of reactor power. This can be compared directly with the number displayed by the doubling interval indicator.

Referring to Fig. 3, note that the period computer utilizes a level comparator, a signal from the master oscillator, a conversion matrix (time to doubling interval), and a doubling interval indicator.

The principle of period computation will be discussed in detail in the next section but may be briefly described as follows. To compute the doubling interval, or period, it is necessary to obtain information concerning the level at two points that are separated in time. The level counter (forward) supplies an initial value of level at the end of each second, timed by the clock oscillator. It will be recalled that the initial level count was determined by adding, one by one, each of the pulses supplied by the sensor; the level being represented by the total number of counts obtained in one clock interval. To obtain information necessary to compute the doubling interval the pulses arriving from the sensor at the second point in time are used to reduce the level counter contents to zero by subtracting one count for each input pulse.

This count-back operation corresponds to using the level counter as a level comparator. The time required to empty the level counter at the new input pulse rate is compared to the fixed time required to fill the level counter initially in the forward direction. The time required to zero the counter by this method is related to the period of the reactor. For example, suppose that the period is infinite; that is, that the level has remained constant. In this case the level counter, having reached its initial count in just one clock interval, would be counted backward to zero in just the same amount of time. Considering the clock to be operating at 1 second for definiteness, a count-back time of 1 second would then always correspond to a period of infinity regardless of the value of the initial count. If the counter fails to count back to zero in 1 second or less, at the new pulse rate, the period is negative; that is, the level, as evidenced by counting rate, must have decreased. For all values of count-back time between zero and 1 second the period is positive, each value of time corresponding to a particular period regardless of level.

In the system shown in Fig. 3, the master oscillator supplies pulses to the time counter of the level comparator whenever gate 3 is open. The gate is opened by the clock oscillator and closed when the level counter (backward) indicates a zero count. This circuitry accounts for all positive periods and the infinity indication. Should the level counter (backward) fail to zero in less than 1 second, gate 3 will be closed by the system clock. This is taken as an indication of negative period. A conversion matrix connected to the time counter is used to convert the time counter reading to a signal on 1 of 16 different lines corresponding to the doubling interval indications of interest. Seventeen lines (one for negative period) are connected to the doubling interval indicator where each of them operates its particular number or symbol on the indicator. The doubling interval indicator is capable of holding each indication until the next clock cycle when the display is changed or renewed. The display may be similar to the level display, if desired, or of a different form. Five values of doubling interval are chosen to activate the five levels of operation and safety of the reactor. Rod control outputs are produced directly from these five selected indicator lines.

The function of the memory registers is to reduce the effect of the statistical variations of the nuclear sensor pulse rate and to increase the precision of the time counter indication. It is desirable to delay the count-back operation for as long a time as possible so that the time required to zero the level comparator counter will be appreciably different from 1 second even for large values of doubling interval. On the other hand, it is required that the doubling interval indications recur frequently as compared to the shortest doubling intervals of interest.

The memory registers are used to achieve this dual result in the following manner. Assume that the forward level counter has just reached its reading and that the level indicator has been triggered by the clock, giving up-to-the-second information on reactor level. The contents of each flip-flop of the counter are quickly shifted at this time to the first memory register and held there for one clock interval. The counter meanwhile is being refilled with new level information. This in turn is fed to the first memory register at the end of the next clock interval while the contents of register 1 are shifted to the second memory register.

Finally level information is shifted into the level comparator counter where it is counted back at the current counting rate. This results in a new doubling indication each second, based on what the reactor level was in that last second, but compared with level information obtained several seconds ago. System considerations will dictate an optimum number of these 17-bit memory registers. Two such registers, each consisting of 17 magnetic core elements, seem to offer a maximum advantage.

The problem of avoiding a delay while the memory registers fill when switching to the next sensor is solved by allowing a small amount of sensor overlap. Thus gate 2 continues to be fed from sensor 1, for example, as long as the level comparator counter is being supplied with sensor 1 information from the memory registers. The line feeding gate 1 switches to sensor 2 when the level counter so indicates and level information based on sensor 2 begins to move down the memory registers toward the level counter (backward) in the comparator. At the time that the comparator is to receive its first charge of in-

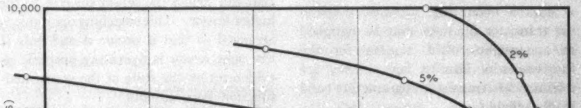

Fig. 4. Probability, sample size, and per-cent accuracy

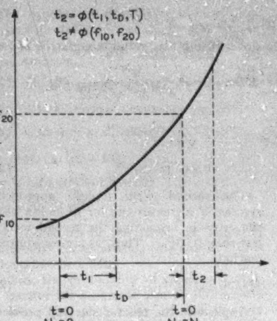

Fig. 5. Pulse counting rate versus time

formation from sensor 2, the line feeding gate 2 switches to sensor 2. Thus the countback always occurs at a rate determined by the sensor that supplied the count then present in the level comparator counter.

The fact that the sensor input information is statistical in nature means that the level counter will not read exactly the same value each time even for a fixed reactor level. Curves showing the total count necessary to produce a desired probability of an individual answer that is correct to a prescribed per cent are shown in Fig. 4.

The conclusion to be drawn from these curves is that the pulse information will be sufficiently precise for the level indication and the resulting period computation. For example, if the total count is 1,000, then the probability that any individual level count will be in error by more than 5% is only 0.1. Thus a clock interval of 1 second could be used, if desired, and a counter with enough stages to count to about 200,000 would be required to accommodate the maximum input pulse repetition rate.

Since the control rods are driven by outputs from the doubling interval indicator, it is desirable to include an extra feature in this indicator circuit to be certain that it does not respond to occasional drastic random variations in sensor pulse rate. To accomplish this a digital statistical weighting circuit may be included in the doubling interval indicator. The reactor period is known to vary smoothly and relatively slowly. The weighting circuit takes advantage of this by incorporating transistor and diode logic networks that prevent the period indicator from changing more than plus or minus one doubling interval increment per second. This technique effectively smooths out any radical random variations that remain in the information after the previous processing.

PERIOD COMPUTATION SCHEME

Fig. 5 shows a plot of pulse counting rate (f) as a function of time (t) for increasing reactor level.

Then the counting rate at any time t is given by

$$f=f_{10}e^{t/T} \tag{1}$$

where T is the time required for the counting rate to rise to e times the initial rate.

If we begin to count pulses at $t=0$, the number of pulses counted in the interval t_1, is:

$$N=\int_0^{t_1} f_{10}e^{t/T}dt \tag{2}$$

$$N=f_{10}T(e^{t_1T}-1) \tag{3}$$

If we wish to count this same number of pulses (N) after a certain delay time, t_D, the time interval, t_2, required to count N pulses may be determined by:

$$t_2=\frac{N}{\bar{f}_2} \tag{4}$$

where $\bar{f}_2$ is the average counting rate in the interval t_2.

$$\bar{f}_2=\frac{1}{t_2}\int_0^{t_2} f_{20}e^{t/T}dt \tag{5}$$

$$\bar{f}_2=\frac{f_{20}T}{t_2}(e^{t_2/T}-1) \tag{6}$$

Substituting equations 3 and 6 in equation 4, we have:

$$t_2=\frac{f_{10}T(e^{t_1/T}-1)}{f_{20}T(e^{t_2/T}-1)}\cdot t_2 \tag{7}$$

Hence

$$\frac{f_{20}}{f_{10}}=\frac{e^{t_1/T}-1}{e^{t_2/T}-1} \tag{8}$$

But, from equation 1, we have

$$f_{20}=f_{10}e^{t_D/T} \tag{9}$$

$$\frac{f_{20}}{f_{10}}=e^{t_D/T} \tag{10}$$

Combining equations 8 and 10:

$$e^{t_D/T}=\frac{e^{t_1/T}-1}{e^{t_2/T}-1} \tag{11}$$

Solving for t_2:

$$t_2=T\ln[e^{-t_D/T}(e^{t_1/T}-1)+1] \tag{12}$$

This is the basic relation of interest in computing the period. It states that for any given period and time delay there is one and only one corresponding value of t_2. Thus, a measurement of t_2 uniquely determines the period. The choice of values for t_D and t_1 may be optimized to produce a large spread in t_2 for the range of periods of interest.

Table I. t_2 Spread in Seconds for Various Values of t_1 and K

K	t_1 0.64	 1.00	 1.28
1	0.11	0.23	0.35
2	0.18	0.39	0.57
3	0.25	0.51	0.72*
4	0.31	0.60	0.82
5	0.34	0.64	0.86

To solve the equation by computer techniques, it is rewritten as

$$t_2=T\ln[e^{-Kt_1/T}(e^{t_1/T}-1)+1] \tag{13}$$

where

$$kt_1=t_D$$

Multiplying and factoring gives

$$t_2=T\ln[e^{-(K-1)t_1/T}(1-e^{-t_1/T})+1] \tag{14}$$

In the form of equation 14, t_2 was computed for values of T ranging from 3 to 30 seconds, corresponding to integral values of doubling interval ranging from 2 to 20 seconds; K from 1 to 5; and t_1 for the three values: 0.64 second, 1 second, and 1.28 seconds.

A measure of the spread in t_2 obtained by utilizing each of the above combinations of t_1 and K is the difference in countdown time between that corresponding to a doubling interval of 20 seconds and the value corresponding to 2 seconds.

The results obtained are tabulated in Table I, which shows that longer values of counting interval (t_1) and larger values of delay time (K) results in a larger time spread in t_2. Since the values of t_2 are used to compute the doubling interval, a greater spread in t_2 can contribute to more accurate indications of doubling interval. A value of $t_1=1.28$ seconds and $K=3$ are considered to be optimum for the present system; this is indicated in Table I by asterisk. t_1 cannot be chosen too large for it represents the elapsed time between readouts; K cannot be too large since it corresponds to the length of the memory and is related to the required amount of sensor overlap. The particular value 1.28 seconds was selected because it can be counted by just filling a 7-stage time counter using a master oscillator of 100 cps (cycles per second).

It should be noted that the derivation of equation 12 was in terms of the period, T, defined as the time required for the level to reach e times its initial value. Table I is presented in terms of the doubling interval, D, defined as the time required for the level to double. The explicit equation corresponding to equation 12 for t_2 in terms of D is:

$$t_2 = \frac{D}{\ln 2} \cdot \ln[2^{-t_D/D}(2^{t_1/D}-1)+1] \tag{15}$$

The entire derivation thus far assumes only that the pulses are increasing exponentially with a fixed period. The assumption of constant period is justified by considerations of the physical system to which the analysis is to be applied. The problem of the statistical variation in the pulse rate is considered in the Appendix. This serves, however, only to impose on the foregoing analysis a certain probability of obtaining an answer correct to the desired accuracy.

Conclusions

Some important conclusions arrived at after a careful consideration of the results of the study are noted below:

1. An over-all digital system, using solid-state devices, for performing the functions of the start-up control is definitely feasible. This includes an all-digital computation technique for level and for period, a digital display of level and period, and the replacement of relay logic by semiconductor logic.
2. The bulk of the problem in applying solid-state digital techniques to the control lies in the level and period computation problems. The amplifiers, pulse shapers, and logic circuits can be approached with the aid of circuit techniques already in use. It is noted, however, that perhaps half of the total number of circuit components are required just to duplicate exactly the present safety and control interlock circuits.
3. The over-all digital system does not require many more components than the analog system. The difference becomes insignificant if digital display is desired regardless of the computation scheme employed.
4. The use of solid-state devices in the start-up control will result in great size, weight, and power reduction and an increase in reliability. Important extra reliability, thermal insensitivity, and component interchangeability will result from the use of an all-digital system.

Appendix

Statistical Considerations

The use of the Poisson distribution to describe the statistics of nuclear events has been justified by both theory and experiment.[1,2] This function may be written as:

$$f_p = \frac{M^n e^{-M}}{n!}$$

where

f_P = the value of the probability for a given M and n

M = the arithmetic mean, or average count for a large number of trials

n = the particular number, or count, observed in one trial

Feller[1] states that "For any fixed M, the simplest physical assumptions lead to the Poisson distribution as defined above as the probability of finding exactly n events within a fixed interval of specified length." This corresponds exactly to the problem in the present study.

Pollard[2] justifies the use of the Poisson distribution by quoting the experimental agreement of count data with the results predicted by the theory. He goes on to point out that a fluctuation of count "as great as the square root of the number of particles counted in any one observation" can be expected and remarks that a relation between probability, sample size, and accuracy exists.

The theory developed in this Appendix verifies Pollard's statements and results in useful quantitative data regarding the inter-relations of probability, sample size, and accuracy of measurement.

Mean Deviation (From the Mean) of a Poisson Distribution

The Mean Deviation (from the mean) for a Poisson distribution is of considerable interest because of its rather simple relation to the arithmetic mean.

The Mean Deviation (MD) is defined as follows[3]:

$$MD = \sum_n f_i \frac{(n-M)}{N} \tag{16}$$

Where M is the arithmetic mean, N is the total weight or probability, and f_i is the value of the probability n units from the arithmetic mean.

For a Poisson distribution f_i is given by the following relation.

$$f_P = \frac{M^n e^{-M}}{n!} \tag{17}$$

Substituting this value of f_i in equation 16:

$$MD = \sum_n \frac{M^n e^{-M}}{n!} \frac{(n-M)}{N} \tag{18}$$

Making the approximation that the distribution is symmetrical about the arithmetic mean, it is convenient for purposes of computation to consider only those values of n less than M. Consequently N, the total probability, will be 0.5 and equation 18 becomes

$$MD = 2e^{-M}\left(\sum_{n<m} \frac{M^n}{(n-1)!} - \sum_{n<m} \frac{M^{n+1}}{n!}\right) \tag{19}$$

$$MD = -2e^{-M}\left(\frac{M^{M+1}}{M!}+1\right) \tag{20}$$

An approximation to $M!$ is given by Sterling's equation[4]:

$$M! = e^{-M} M^M \sqrt{2\pi M} \tag{21}$$

Substituting this value in equation 20,

$$MD \simeq -2e^{-M} \frac{M^{M+1}}{e^{-M} M^M \sqrt{2\pi M}} - 2e^{-M} \tag{22}$$

$$\simeq -2\frac{M}{\sqrt{2\pi M}} - 2e^{-M} \tag{23}$$

$$\simeq -0.8\sqrt{M} - 2e^{-M} \tag{24}$$

The second term rapidly approaches zero as M increases and for M as low as 10 the error in neglecting the second term is less than 0.03%. Thus, as a close approximation:

$$MD \simeq 0.8\sqrt{M} \tag{25}$$

Applied to the reactor start-up problem, this means that for nominal mean counts of 10 pulses per second, 100, 1,000, 10,000, and 100,000 we may expect, respectively, average deviations from the mean of approximately 3, 10, 30, 100, and 300 counts. Thus the expected per-cent error goes down as the number of counts increases.

Probability, Sample Size, and Per-Cent Accuracy

The interrelations of probability, sample size, and accuracy are implicit in the Poisson distribution. It is not convenient however, to calculate the values leading to design curves by using the equation directly.

Waugh[5] presents a table entitled "Probability that an Item Chosen at Random from a Normal Distribution Will Lie at Least as Far From the Arithmetic Mean as the Stated Number of Standard Deviations." The table lists probabilities in terms of x/σ where x is the item chosen and σ is the standard deviation.

Before making use of this table it is necessary first to define a "standard deviation" for the Poisson distribution.

The Poisson distribution is given by

$$f_P = \frac{M^n e^{-M}}{n!} \tag{26}$$

and a normal distribution is given by

$$f_N = \frac{1}{\sigma\sqrt{2\pi}} \cdot e \frac{-(n-M)^2}{2\sigma^2} \tag{27}$$

Assuming that the curves have a similar shape in the region of interest we may equate 26 and 27, giving

$$\frac{M^n e^{-M}}{n!} = \frac{1}{\sigma\sqrt{2\pi}} \cdot e \frac{-(n-M)^2}{2\sigma^2} \tag{28}$$

Since we are particularly interested in the region near $n = M$, and since the result must hold for $n = M$, we may substitute n for M in equation 28. This gives

$$\frac{M^M e^{-M}}{M} = \frac{1}{\sigma\sqrt{2\pi}} \tag{29}$$

Applying Sterling's equation for $M!$,

$$\frac{M^M}{M^M \sqrt{2\pi M}} e^{-M} e^M = \frac{1}{\sigma\sqrt{2\alpha}} \tag{30}$$

And, simplifying,

$$\sigma \simeq \sqrt{M} \tag{31}$$

which is the required result.

Vol.
Pt. 1
196

The process of computing the relation between probability, accuracy, and sample size by Waugh's table may best be shown by an example.

1. Select a sample size, M, e.g., 100.
2. Select a desired accuracy, e.g., 20%.
3. Compute x, σ, and x/σ.

$\sigma=\sqrt{M}$, $(\sqrt{100}=10)$

$X=\%(M)$, $(0.2\times100=20)$

$X/\sigma=20/10=2$

4. Look up in the table the value of probability corresponding to $X/\sigma=2$. This is found to be 0.0454.

Thus, the probability of an error of 20% or greater for a sample size of 100 is only 0.0454. The probability of the correct answer, within 20%, is 0.9546—over 95% certain for each individual calculation.

This computation when repeated for other values of sample size and % accuracy leads to the family of curves shown in Fig. 4. These are used to anticipate computation accuracy and to determine required sample size for the start-up control problem.

The period error for a single calculation is estimated as 5% for a doubling interval of 2 seconds whenever the probability of the correct level indications exceeds 0.9.

Additional material in this area can be found in the list of references.

A High-Speed Microcurrent Amplifier

JOHN A. DEVER
ASSOCIATE MEMBER AIEE

LOUIS SICKLES
NONMEMBER AIEE

BY THE USE of feedback amplifier techniques considerable improvement has been made in the speed and/or stability of the familiar electrometer tube micromicroammeter. Simplicity and compactness have been retained. With 100 feet of input cable, the amplifier has a 150-millisecond time constant at 10^{-11} amperes full scale with 0.05% per day stability.

Control systems for nuclear reactors frequently call for operation of linear and logarithmic current measuring instruments down to levels of 10^{-11} amperes and below. This is especially true of those for research reactors and critical facilities. Amplifiers designed for these applications should be stable, insensitive to system disturbances, reliable and fast even with long signal cables. Good speed of response provides rapid indication and insures that safety functions are not compromised. A related consideration is the amplifier transfer function; bandwidth limitations can markedly affect the performance of a controller in a closed loop system where the amplifier serves as the flux measuring device. Also, broader usage as a laboratory or research instrument is likely to require the widest bandwidth that can be obtained.

The micromicroammeter to be described is the result of a study to find the practical limits on speed for the familiar electrometer tube d-c amplifier. Since simplicity and modest cost were deemed important, the more complex stabilized amplifier has not been considered. Instead, a single-ended input stage has been adopted in which drift is limited by single or double regulation of all important d-c potentials. What drift remains is made acceptably small by the choice of 100% feedback and a 10-volt span.

The problem of high speed and good transient response in a micromicroammeter raises design difficulties not usually encountered in feedback amplifiers. This is chiefly because the input time constant, created by capacity from the input terminal to ground, can vary over a range of 10^9 for the 8-decade region of operation extending from 10^{-11} to 10^{-3} amperes. The effect of this factor in determining amplifier stability can conceivably be offset by altering attenuation networks for each current range. However, this can be awkward and expensive to do; when easy conversion to logarithmic measurement is desired absolute stability everywhere in the frequency spectrum is a necessity. With this in mind, appropriate care is taken in gain and phase manipulation to arrive at an optimum combination of over-all gain and bandwidth.

Closed Loop Design

Fig. 1 contains all the parameters needed to characterize the micromicroammeter. The forward gain block consists of three stages of gain and a cathode follower output. C_{IN} represents stray, wiring, and cable capacity, and capacity of the chamber or other source producing the current I_{IN}. A certain amount of capacity, C_F, exists from output to input, intentionally or otherwise, and is generally associated with the feedback resistor, R_F.

Degenerative feedback applied as show causes the output drift to be equal to the amplifier drift referred to the input, reduces the input impedance to $=R_F/A(s)$, and reduces the output impedance to $=1/g_M A(s)$ where g_M is the transconductance of the cathode follower output stage.

The closed loop transfer function is

$$\frac{e_0}{I_{in}}=-\frac{R_f}{\dfrac{sR_f(C_{in}+C_f)+1}{A(s)}+sR_fC_f+1} \qquad (1)$$

where

$s=j\omega$

As a first approximation, assume that $A(s)$ is large and constant and equal to A_o. In every case we will consider, C_{IN} is much larger than C_F. Then

Manuscript submitted December 11, 1958; made available for printing February 9, 1960.

John A. Dever and Louis Sickles are with the Minneapolis-Honeywell Regulator Company, Philadelphia, Pa.

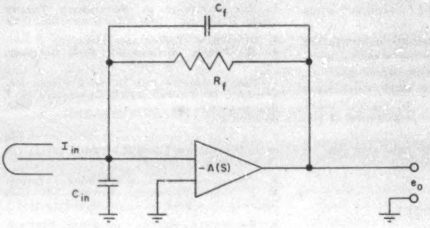

Fig. 1. Micromicroammeter system schematic

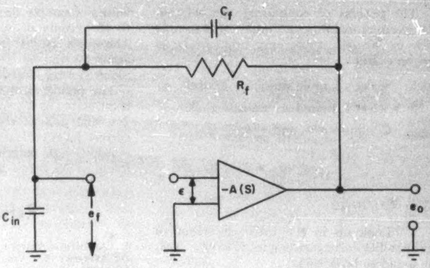

Fig. 2. Open-loop configuration of miromicroammeter

$$\frac{e_0}{I_{in}}=-\frac{R_f}{s\left(\frac{R_fC_{in}}{A_0}+R_fC_f\right)+1}=-\frac{R_f}{s\left(\frac{T_{in}}{A_0}+T_f\right)+1} \qquad (2)$$

where

$T_{IN}=R_FC_{IN}$

$T_F=R_FC_F$

$C_{IN}\gg C_F$

Obviously, as the gain gets very large, T_F becomes the limiting factor in obtaining wide bandwidth.

A somewhat more accurate description of the closed loop is possible by assuming $A(s)$ to be a simple lag, a fair approximation of the actual function.

$$A(s)=\frac{-A_0}{sT_a+1} \qquad (3)$$

Then

$$\frac{e_0}{I_{in}}=-\frac{R_f}{s^2\frac{T_{in}T_a}{A_0}+s\left(\frac{T_a+T_{in}+A_0T_f}{A_0}\right)+1} \qquad (4)$$

Examination of equations 2 and 4 leads to the following conclusions for the design of a wide band instrument.

1. Low-frequency forward gain, A_o, must be large to degenerate the input time constant.

2. C_F must be small on the lowest ranges in order that $T_F\leq T_{IN}/A_o$. On higher ranges the effect of T_F reduces because the gain $A(s)$ becomes less than A_o as the frequency increases.

3. The bandwidth of $A(s)$ must be as wide as possible, i.e., T_A must be small, for wide instrument bandwidth on the higher current ranges.

Open Loop Design

Equation 1 can be rewritten in the form

$$\frac{\theta_0}{\theta_i}=\frac{1}{\beta}\,\frac{A\beta}{1+A\beta}$$

giving

$$\frac{e_0}{I_{in}}=\frac{-R_f}{sT_f+1}\;\frac{\frac{sT_f+1}{sT_{in}+1}A(s)}{1+\frac{sT_f+1}{sT_{in}+1}(As)} \qquad (5)$$

Care must be exercised in identifying the relative importance of the various terms. The denominator $(1+A\beta)$, not β alone, controls the response in most instances. However, loop gain $A\beta$ is easily recognized and, referring to Fig. 2 for the physical interpretation, the open loop transfer function can be written

$$\frac{e_f}{\epsilon}=-A(s)\,\frac{sT_f+1}{sT_{in}+1} \qquad (6)$$

The time constant, T_{IN}, formed by the feedback resistor and the input capacity, is the dominant factor in determining the stability of the amplifier. This time constant is widely variable due to different cable lengths and range resistors and the corresponding break frequency can move throughout the frequency spectrum.

If the effects of both T_F and T_{IN} are taken into account, the examination of the open loop becomes complicated because both the coefficients are independently variable. For a basic analysis of the instrument, T_F can be assumed zero. Later, the proper variation of T_F can be calculated to get the maximum benefit from the lead effect.

Let T_F-0, then

$$\frac{e_f}{\epsilon}=-A(s)\,\frac{1}{sT_{in}+1} \qquad (7)$$

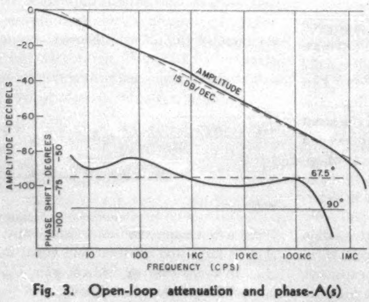

Fig. 3. Open-loop attenuation and phase-A(s)

Vol.
Pt. 1
1960

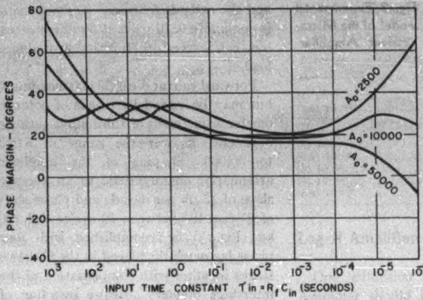

Fig. 5. Phase margin as a function of loop gain and input time constant

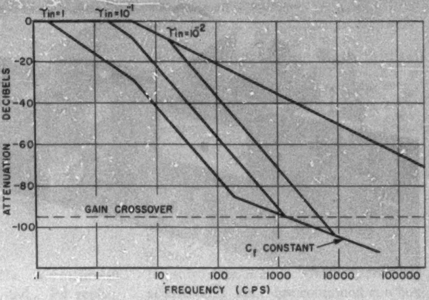

Fig. 6. Attenuation characteristic with C_F present

If no lead term exists, the phase shift of $A(s)$ plus $1/sT_{IN}+1)$ must not exceed 180° for all frequencies up to the frequency of unity gain to prevent oscillation. Actually, for acceptable transient response, 180° must not be approached too closely. Consequently, a phase margin of approximately 22.5° has been adopted. The function of $A(s)$ is shown in Fig. 3. Neglecting for the moment how this is obtained, notice that the average attenuation rate is 15 db (decibels) per decade, and the average phase shift is 67.5°.

Fig. 4 shows the lag term $(1/sT_{IN}+1)$ added to the attenuation curve of $A(s)$. The approximate resonant frequency of the closed loop function may be picked off the graph for a specific input time constant and loop gain.

For example, measuring 10^{-10} amperes full scale, a 10^{11}-ohm resistor is used which, with 1,000-$\mu\mu$f (micromicrofarad) input capacity, gives an input time constant of 100 seconds. If a d-c loop gain of 50,000 is employed, the approximate resonant frequency of the instrument is 20 cycles. If a gain of 1,000 is used, the resonant frequency is close to 1.4 cycles. Note that the resonant frequency of the instrument does not increase by the same factor as a reduction in the input time constant. If T_{IN} is changed by a factor of 10, for instance, by changing range with C_{IN} fixed, the resonant frequency changes by only a factor of 3.72.

Shown in Fig. 5 is the instrument phase margin for a specified loop gain neglecting any lead term in the feedback. This figure is constructed by adding the phase shifts of $A(s)$ and $(1/sT_{IN}+1)$ at the chosen value of loop gain. An input time constant of 10^{-6} is about the lowest which the amplifier normally encounters, e.g., on the 10^{-8}-ampere range with 100-$\mu\mu$f input capacity, $R_F C_{IN} = 10^{-6}$.

Although the instrument will be unstable with this value of T_{IN} and a gain of 50,000, a reduction in gain to about 20,000 will insure stability. Alternatively, 50 or more feet of cable or a 1,000-$\mu\mu$f capacitor at the input will maintain stability, since T_{IN} will be larger than 10^{-5} seconds.

With an amplifier characteristic of relatively constant phase, it follows that the phase margin is similarly fixed over wide variations of the input time constant. This means that the transient response stays fairly uniform through the entire current range of the instrument. Overshoot to a step input of current on any range is less than 30%. This type of response is adequate for most reactor instrumentation and control applications.

Returning to the effect of T_F in the feedback path, the case where this time constant becomes limiting on the closed loop response is of interest. Significant influence of this lead term is to be expected when it is located about as indicated on the open loop curves of Fig. 6 for representative input time constants. The result, of course, is increased phase margin and damping which would, in general, be selected for damping factors in the vicinity of 0.7: approximately the situation of the $T_{IN}=1$ curve.

A difficulty is immediately evident: note that as R_F is reduced by factors of 10, the instrument tends to become underdamped because T_F reduces by 10 while ω_N increases by only a factor of 3.72. Thus, a fixed value of C_F will not give optimum response on every range, but rather a separate fixed capacitor must be used for each range setting. Even this is not completely satisfactory because the response on a single range will change with input capacity.

Regardless of any need for it, damping will exist on the 10^{-11}-ampere range because a 10^{12}-ohm resistor is used in order that the output span be 10 volts. Ordinarily, insignificant circuit and resistor capacities of less than 1.0 $\mu\mu$f are now important in shunt across the feedback resistor. By special construction these have been reduced to 0.06 $\mu\mu$f so that the instrument time constant with minimum input capacity is about 60 milliseconds. With 2,000 $\mu\mu$f on the

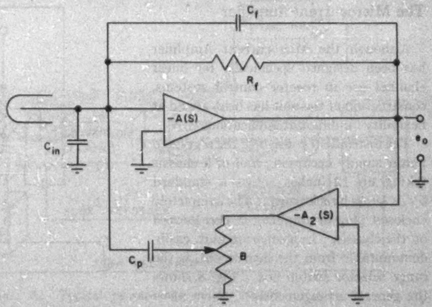

Fig. 7. System schematic for capacity cancellation with positive feedback

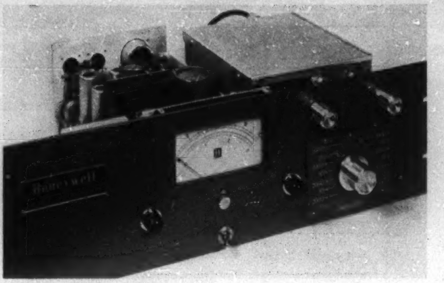

Fig. 8. Experimental model of the Microcurrent Amplifier

input the instrument time constant is less than 150 milliseconds.

For some laboratory applications wide bandwidth at lower current levels than 10^{-11} amperes full scale might be desirable.

If a 10^{13}-ohm feedback resistor must be used, the time constant in the feedback, even with only 0.06 $\mu\mu$f capacity, would be 600 milliseconds. Fig. 7 shows a scheme whereby the dominant lag in the feedback at these low levels might be cancelled out with positive feedback. The approximate condition for cancellation is

$$C_p = \frac{C_f}{A_2\beta}$$

If the positive feedback is made greater than that necessary to cancel the feedback time constant, the stability of the circuit will be decreased and the result is severe ringing or oscillation. This method is, therefore, only applicable for use with this amplifier on ranges lower lower than 10^{-11} because T_F is not, in general, the dominant term and because of the care that must be used in setting the amount of positive feedback as ranges are changed. Variations of C_F, C_P, A_2 and β set a limit to the degree of compensation over a period of time.

The Microcurrent Amplifier

Although the Microcurrent Amplifier has been designed specifically for linear channel use in reactor control systems, construction of the unit has been aimed at flexibility for different applications.

The instrument consists of the regulated power supply occupying half of a chassis taking up 12 inches across a standard $5^1/_4\times19$-inch rack panel. The completely enclosed plug-in amplifier is also located on the chassis. In a separate unit, easily demountable from the instrument, is the range selector switch box. Fig. 8 shows the general arrangement.

Amplifier

The amplifier proper is composed of four direct-coupled stages as shown in the circuit diagram of Fig. 9. Failure to demonstrate significant advantages in drift reduction by differential stages induced selection of a simple single-ended input stage configuration. Plate, screen, bias, and filament potentials are all doubly regulated for stability. The drift that occurs is largely that of electrometer tube contact potential which is not easily compensated or balanced due to variation from one tube to the next.

Two to 5 millivolts per day drift is common, becoming somewhat better with time, for normal variations in room temperature and an unregulated line. The first two stages and their associated components are built on a shock-mounted printed circuit board. Isolation from shock and vibration contributes both to low microphonics and prevention of aging cycles in the electrometer tube. Grid current drops to less than 5×10^{-14} amperes after a settling period of a few hours and open input peak-to-peak noise is below 1%.

A second printed circuit board is used for construction of the third stage of gain and the cathode follower. Output swing is nominally ±10 volts at 5 milliamperes, but can exceed ±20 volts at reduced load.

Forward gain at d-c is 50,000 maximum, but may be varied by means of potentiometer adjustment of third stage cathode degeneration over the range of 5,000 to 50,000. Shaping of the amplifier attenuation characteristic to an average slope of 15 db per decade and phase shift of 67.5 ±10° between 10 cycles and 100 kc (Fig. 3) is accomplished with four phase lag networks placed in the first two stages together with compensation of the interstage dividers. Before insertion of the networks the gain-bandwidth product of each stage was maximized and the interstage capacities reduced as far as possible. The use of a printed circuit was helpful in this regard.

Range Selector Box

Current range is selected by changing R_F, the feedback resistor, in steps of 1, 3, 10, etc. A short-circuiting 18-position 2-deck steatite switch was chosen for its general ruggedness, low leakage, and small strain on insulators during transfer from one position to the next. The last feature and the addition of charge dissipating resistors enables attaining ver low switching transients. Microphonics are substantially reduced by stoutness of construction and tying down most components. Shunt capacity and its damping effects are minimized by sielding switch decks and circuitry wherever feasible. A value of 0.06 $\mu\mu$f can be reached without great difficulty.

In the interest of flexibility a fixed 20-$\mu\mu$f capacitor is added from the summing point to the wiper of a potentiometer between output and ground. This yields a variable damping control for cases where only one or two ranges at a time are of

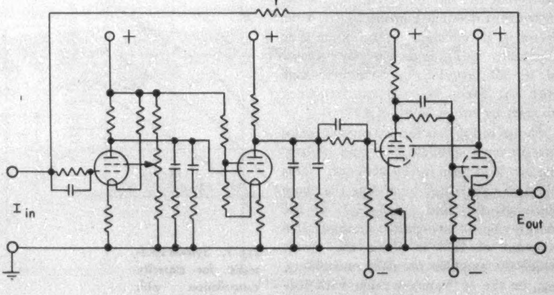

Fig. 9. Circuit of the Microcurrent Amplifier

concern. The entire assembly in its box can be demounted and moved to a remote location, for instance a console, when such is desired for operator convenience.

Performance

A summary of characteristics of the complete instrument is given in Table I. Lines (1) to (3) are for the standard arrangements with a 10-volt feedback span. Choice of a 1-volt span or less yields higher speeds at the expense of stability as shown by (4) and (4A), or lower ranges, as in lines (5), (6), and (6A). All data were taken with maximum gain and a 10-volt output span, i.e., reduced feedback spans were obtained with a divider at the output.

Table I. Characteristics of the Microcurrent Amplifier

Range, Amperes	R_F, Ohms	Feedback Span, Volts	Stability, Per Cent per Day	67% Response, Msec	C_{INB}
(1) 10^{-11}	10^{12}	10	0.05	80	50
(1A) 10^{-11}	10^{12}	10	0.05	150	2,000
(2) 10^{-9}	10^{10}	10	0.05	6	2,000
(3) 10^{-3}	10^{4}	10	0.05	0.025	2,000
(4) 10^{-11}	10^{12}	1	0.5	20	50
(4A) 10^{-11}	10^{11}	1	0.5	100	2,000
(5) 10^{-12}	10^{12}	1	0.5	800	2,000
(6) 10^{-13}	10^{12}	0.1	5	500	50
(6A) 10^{-13}	10^{12}	0.1	5	4000	2,000

Log-N Amplifier

One extension of the Microcurrent Amplifier should be noted. By replacing the range selector switch and resistor assembly with a logarithmic diode, a high-speed log-N amplifier results. Models have been built covering the same 10^{-11}-to 10^{-3} ampere current range with an accuracy of 2 % of full scale. Physically, the substitute circuits—diode, calibrating adjustments, etc.—are contained in a box fitting the same space as the range selector. A period meter and trip circuits are generally combined to furnish a complete intermediate channel.

Magnetic Automatic Power-Range Control for an Aircraft Nuclear Reactor

Synopsis: Control system philosophy for an aircraft nuclear power plant is discussed briefly. Advantages are presented for a power-range magnetic control system with a minimum number of moving parts. Control system elements and computing devices are discussed in detail. Performance of a breadboard version of the control system is evaluated.

THE POWER-RANGE reactor control system in a nuclear-powered airplane controls the usable power output of the power plant. In the nuclear turbojet engine being developed by the General Electric Aircraft Nuclear Propulsion Department, the reactor takes the place of the chemical-fuel combustor used in conventional turbojet engines. The reactor must supply the correct amount of heat, or power output, to satisfy the over-all engine demands. Therefore, temperature is the primary controlled variable upon which power plant control is based.

A secondary control loop based on reactor flux is integrated with the temperature control loop. If reactor reactivity were controlled by temperature alone, unstable operation could result. The unstable operation could result from an excessive time lag between the actual generation of additional heat in the fuel elements and the electrical signal from temperature sensors in the effluent. Fast response is desirable, and accurate control is essential to assure maximum utilization of the reactor.

A tertiary loop, a reactivity-controlling position loop, is driven from the flux-loop error signal.

The control system is shown in the block diagram of Fig. 1, in which some of the items require explanation. An integration appears between the flux-loop and temperature-loop error to bring the steady-state temperature error to essentially zero. The flux loop is logarithmic to maintain system gain relatively constant regardless of reactor "gain." One of the safety functions is shown, a device which prevents the operator from calling for withdrawal of the reactivity controller under certain conditions. A constant current reference supplies bias, demands, and reference current for the entire system.

Constant current, rather than constant voltage, is required for a magnetic-amplifier system since the control windings are

sensitive to ampere-turns. Ambient temperature variations in a constant-voltage system would not result in constant ampere-turns; thus reference points would be coupled directly to ambient temperature.

Implementation of Control System With Magnetic Amplifier

Choice of Magnetic Amplifier for the System

Magnetic amplifiers were chosen for this control system because of their extreme reliability. As stated, the power-range reactor control system is a vital part of the total control system for a nuclear aircraft engine. The requirements of aircraft reactor controls are necessarily different from those for non-air-borne reactors. The use of magnetic amplifiers can contribute to the reliability of the system.

When reliability is the foremost design consideration, a so-called "static" system results; i.e., a minimum of moving parts, sliding contacts, and switching contacts is used. A control system in a nuclear engine will be subjected to conditions that include radiation, high temperatures, high acoustic noise levels, shock, and vibration. Either magnetic-amplifier or transistor mechanization of power-range control could satisfy the requirement for a static system. A hybrid system is, of course, possible; however, transistors have not been proved sufficiently tolerant of a radiation environment. The magnetic amplifier thus appears to be a logical choice for mechanization of the control system, where feasible.

Extremely high reliability and ruggedness are inherent in magnetic amplifiers, as would be expected from its elements, which are an iron core, windings, and solid-state reactifiers. Any unreliability is more likely to arise from the circuit design, construction methods, and materials. These considerations are also the means by which the inherent high reliability of these devices can be realized, and a great deal of effort is being directed to this end.

In addition to the reliability aspects of the device, several other salient features substantiate its use for the power-range control system. The size and weight of a magnetic-amplifier system can be equal to or less than an equivalent electron tube implementation since no d-c power supply is needed. Extremely high power gains can be realized in one stage. This gain can be proportioned between voltage and current gain by proper choice of turns to meet the requirements. Many new circuit possibilities are presented by saturable core devices, such as counters, integrators, static switches, and storage elements, to name a few.

As for environment, the magnetic amplifier is quite tolerant of conditions that will be encountered in a nuclear aircraft. Vibration will not damage an encapsulated magnetic amplifier with suitable core cushioning. A newly encountered problem with large turbojets is high-level acoustic noise. Because of its inherent ruggedness the magnetic amplifier is not affected by the forces produced and frequencies encountered. However, in the design of the amplifier attention must be paid to a solid mounting and a low center of gravity.

The most serious problems in the environment of a nuclear aircraft control system arise from radiation and heat. The semiconductor diodes are the components most affected by radiation. A great deal of testing has been done to establish the performance of these devices under radiation, in the interests of improving their tolerance, and of designing the magnetic-amplifier circuits to be more tolerant of the radiation-produced diode changes. Component parts used in these magnetic circuits are capable of operation in ambient temperatures of 125 degrees centigrade.

Encapsulation and wire-combinations have been tested under radiation and temperature. Complete amplifiers have been irradiated to estimated aircraft doses, and changes have not been significant. Circuit developments have recently increased tolerance considerably beyond this radiation level. In view of such testing, the magnetic amplifier appears to be well suited to the specialized environmental conditions encountered in a nuclear aircraft engine control system. Unencapsulated units incorporating the latest circuit developments are shown in Fig. 2, and an exploded view of the same type of device in Fig. 3.

Growth potential of magnetic devices is good, considering the more rigorous radiation and temperature environments of the future. Advanced development of magnetic circuitry without the use of semiconductors is being carried on, as well as significant improvements in the semiconductors themselves. New developments in high-temperature semiconductors will also extend the capabilities of magnetic devices greatly.

Advantages of Magnetic Amplifiers

In general, the magnetic system can be packaged in half the volume of a corresponding electron-tube system with power supplies. The weight comparison shows the magnetic circuitry to weigh in the order of one third the weight of a comparable tube system.

An electron-tube circuit which is used in a complex control system usually requires three or more extrenal sources of power, an a-c filament supply, and two or more high-voltage d-c supplies. The magnetic amplifier is powered by one alternating voltage source (in the case of military aircraft, 115 volts, 400 cycles). There is no need for voltage or a-c to d-c conversion, with the exception of certain center-tapped circuits that require a small integral transformer.

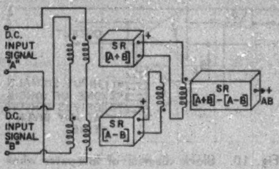

Fig. 4. Block diagram of magnetic relay

To make a comparison of the various power losses and efficiencies between a tube circuit and a magnetic amplifier, it is desirable to look at a particular circuit requirement where power losses become significant. In the control system under discussion, the torque motor valve amplifier, which delivers 3 to 5 watts, is an example.

This particular design has power losses in the copper windings, a bias resistor, and a resistor in series with gate windings. The efficiency of the device, defined as the ratio of power to the load to power taken from the line, is about 70%.

An equivalent d-c tube amplifier delivering 3 to 5 watts and operating class A or class B can be expected to operate at 30% to 50% plate efficiency. When one considers the total power taken from the line, including filament power losses in the power supply and filters, the over-all power efficiency of the amplifier and its associated circuitry is quite small, perhaps 5% to 20%.

The question of optimization arises if heat generated is a problem. A magnetic circuit for high power requirements can have high efficiency. However, a tube circuit, by its physical nature, can obtain a moderately low efficiency.

UNUSUAL CIRCUIT FEATURES

There are some unusual circuit features of magnetic devices that are put to good use in this system. First, it is possible to have multiple electrically isolated inputs to an amplifier. This arrangement is used in the flux amplifier, the temperature amplifier, and the feedback amplifier around the integrator. Each of these amplifiers is at a summing point in the circuit, and through the use of these multiple inputs, the summing can be done without danger of interaction between the various signal circuits. Another feature of magnetic devices closely related to this one is that it is possible to have feedback around an amplifier and still have the input isolated electrically from the output. This method of feedback was used in many places throughout the system.

Magnetic amplifiers also can have very low input resistance, which makes them excellent thermocouple amplifiers because good impedance matching can be had. This property is used in the temperature loop.

Another useful feature of one type of magnetic amplifier, a half-wave amplifier, is that it can sum a-c and d-c signals at the same time. Thus, a-c position feedback around the position loop amplifiers is summed with the d-c demand, and the necessity of demodulating the a-c transducer signal is eliminated (an a-c transducer is the most reliable position sensor).

Particular Circuits and Devices

COMPUTING FUNCTIONS

Continuously Variable Comparative Limiter

The circuit under discussion selects the smallest signal from two input signals, and doubles it. The logic of the circuit is based on the mathematical fact that if the absolute value of the difference between two quantities is subtracted from the sum of the same two quantities, the result is always twice the smaller: where B is the smaller

$$|A+B|-|A-B|=2B$$

Because of the absolute value signs, if A is smaller, the result is

$$|A+B|-|B-A|=2A$$

This logic is implemented by the circuitry shown in the block diagram of Fig. 4. Saturable reactors are ideal for the summing and subtracting since their output is always of one polarity and hence represents the absolute value of the sum or difference. One saturable reactor is used to sum the two input signals and another identical saturable reactor is used to subtract the same signals. The outputs of these two saturable reactors are fed into a third, where the difference is taken, and the output of this reactor is proportional through some gain factor to the lower signals.

It is easily seen that this circuit makes an ideal limiter for either a fixed limit or a continuously variable limit. If one input signal is set at some fixed level, the output of the circuit will follow the variable signal from zero up to the level of the fixed signal. There the output will cease to follow the increasing variable signal and instead stay at the level dictated by the fixed signal. This action is shown in Fig. 5. Since the output of the circuit always follows the lower of the input signals, some variable limit signal can be fed into one input and thus cause the maximum output to stay at a level below or equal to that dictated by the limit signal.

Signal Comparison

It is necessary in the control system to perform many switching operations where one signal A, being larger than another B, will cause the switching to occur, but signal B, being larger than A, will not. Furthermore, in many cases it is desired that the differential signal that causes switching be very small, in the μamp (microampere) region, if the signals are currents.

The magnetic relay circuit was developed to perform just such switching operations; the circuit diagram is shown in Fig. 6. Briefly, the circuit operates as follows: The magnetic amplifier raises the input signal from the μamp region into the milliamp region. A diode gives unipolarity switching. The saturable reactor a-c output drives a ferroresonant trip circuit. The magnitude of this alternating voltage is controlled by the direct current in the saturable reactor control winding. The ferroresonant circuit is a bistable device that trips at a certain value of alternating voltage. When the circuit is tripped, its impedance becomes very low and a large current is allowed to flow through it and the relay coil in series.

This circuit has a trip point that is independent of the relay trip point and line voltage frequency, and can be compensated for temperature. It can switch on a differential current of as low as 1 μamp and can be made to trip on signals of only one polarity (providing opposite polarity signal does not exceed 20 to 25 milliamp). Removal of the series rectifier allows switching action from any polarity of signal.

Current Blocking

A device is needed in the control system that blocks currents of one polarity while passing those of opposite polarity. This device must have a current input versus current output characteristic that is linear from zero input to some maximum input. This requirement eliminates the use of a diode because at least 0.4 to 0.5 volt across it is required to open it.

The magnetic rectifier was developed to meet the need for such a device. This circuit consists of a square circuit magnetic amplifier modified for d-c output. The output curve is shown in Fig. 7 as curve *A*. By appropriate shunting of diodes, the knee of the curve can be shifted to the zero axis, curve *B*. The input current is fed through a resistor in series with the output. The polarity of the voltage across this resistor is such that it subtracts from the output in the "back" or nonconducting region and adds in the forward direction. The output curve is rotated to its desired form, curve *C*, which approximates a perfect rectifier.

The magnetic rectifier will block currents of one polarity (maximum "leakage," 5 μamp) and pass current of the opposite polarity. The forward characteristics are quite linear from 0.0 to 0.8 milliamp. Fig. 8 compares a diode, curve *A*, with the magnetic rectifier, curve *B*.

Integrator

The control system requires an integrator with a linear integrating action, with respect to time, that will hold at the particular level reached if the input signal is suddenly removed. This integrator must also be capable of acting as a straight amplifier under certain control conditions.

The circuit meeting these requirements is shown in Fig. 9. A full-wave center-tap magnetic amplifier is used as the computing amplifier and has considerable positive feedback to provide essentially infinite gain. The integrating action is controlled by the resistance-capacitance combination across the input, the product *RC* determining the rate of integration for a particular input. If the signal is removed, the circuit provides holding action, since capacitor charge leaks through the amplifier windings in a direction that causes the amplifier output to oppose capacitor discharge. The output is taken from the amplifier terminals.

This circuit arrangement also has the advantage that very little current flows in the input winding of the amplifier because of the electrical feedback of the output. The circuit will "servo" in to the point where the current into the input winding is essentially zero. The output is also forced by this arrangement to follow the charging of the capacitor, giving quite linear integrating action over a certain range.

To cause the integrator to perform as an amplifier, the circuit of Fig. 10 is used. It is a simple servo loop in which the amplifier *K* detects the error between the integrator output and the auxiliary input, amplifies it, and feeds it back into the input of the integrator. Thus, the integrator output, operating as an amplifier, is constrained to follow the input signal. The loop has a time constant of less than 0.1 second. When it is switched back to integrator operation, it instantaneously holds the same level of output that it had when operating as an amplifier.

Log Conversion

The forward characteristic of an ordinary silicon diode has a nearly logarithmic *E-I* curve approaching a true logarithmic curve between 10 μamp to 10 milliamp. This inherent property is exploited to generate a computing function with the following relationship:

$E = K_1 \ln i + K_2$

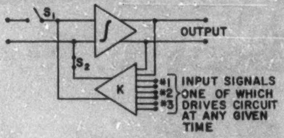

Fig. 10. Block diagram of integrator when switched to act as an amplifier

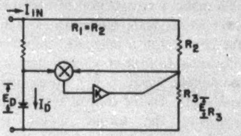

Fig. 11. Log conversion bridge

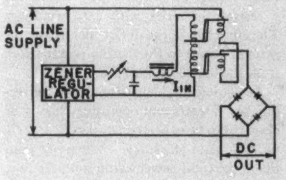

Fig. 12. Constant current reference

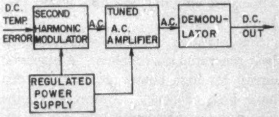

Fig. 13. Temperature amplifier

The magnetic amplifier following the diode must not disturb the *E-I* relationship of the diode by loading and must furnish power to the next stage.

Because of the low level of diode input current and susceptibility to noise, the diode is operated in a bridge circuit, shown in Fig. 11.

When current I_D flows through the diode, a voltage E_D is generated. This is compared to the magnetic-amplifier output voltage E_{R3} by a sensing coil across the bridge. The sensing coil is the input to a magnetic amplifier with very high gain. When E_{R3} equals E_D, the bridge is balanced and the diode is not shunted. The amplifier is, however, delivering power to the next stage at a voltage equal to the diode voltage:

$I_D = 1/2\ I_{in}$

Since the input current to the bridge

Vol.
Pt.
196

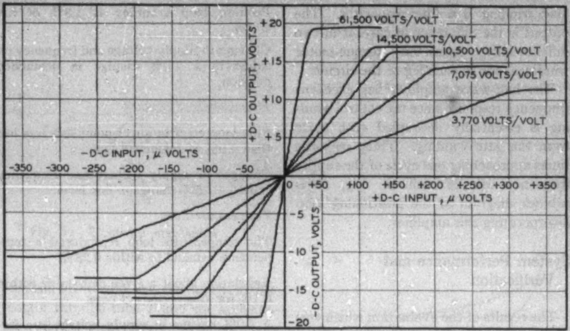

Fig. 14. Second-harmonic modulator electronic d-c amplifier. Performance curve showing various amounts of negative feedback

splits between R_1 and R_2, the voltage-current relationship now becomes

$$E_{R3}=E_D=K_1 \ln 1/2\, I_D+K_2$$

But

$$\ln 1/2\, I_D=\ln I_D+\ln 1/2$$

Now, let

$$K_3=K_2+\ln 1/2$$

Then

$$E_{R3}=E_D=K_1 \ln I_D+K_3$$

This relationship holds for 2.5 to 3 decades of input current.

OTHER MAGNETIC DEVICES

Constant Current Reference

The basic element of the constant current reference is the saturable reactor with a bridge rectifier in its output. It has the property of proving a direct current independent of the load resistance and small changes in line voltage and frequency; it is controlled only by the input current.

The transformed current ratio is an inverse function of turns ratio only. Current gains of the order to 5 to 20 are very easily obtained.

The control winding of the saturable reactor is driven by a regulated small current supply, such as the output of zener diode. The total components form an open loop and furnish a large current output independent of changes in line voltage supply, line frequency, and load resistance limited by

$$I_0\, R_L=1/2\, E_{\text{gate}}$$

By optimizing each unit, current regulation of 0.005% can be obtained; see Fig. 12.

Temperature Error Amplifier

The difference of temperature demand and feedback is amplified by the temperature error amplifier. The zero and gain stability of this amplifier is such that it could be used directly in the temperature feedback line. However, if this is done, the variations in gain and zero of the amplifier cannot be differentiated from the true feedback signal. This would result in changes in the controlled variable to compensate for these variations. An error amplifier causes only a change in accuracy of the loop by a change in gain. Zero drift in the amplifier will again cause error in the controlled variable to compensate for it, but less error than if it were in the feedback. A more stable and accurate loop will thus result from using the amplifier as an error amplifier.

This particular design more than adequately meets requirements by employing magnetic and electronic devices. Fig. 13 is a block diagram of the amplifier.

A second-harmonic magnetic modulator modulates the incoming d-c error to an 800-cycle signal which is then amplified in a tuned a-c amplifier. The a-c output is demodulated by a phase-sensitive rectifier, and appears as direct voltage again in the output. The d-c is fed back through a second winding in the modulator as over-all negative feedback. The entire amplifier is driven from a self-contained saturable-transformer-regulated supply.

The second-harmonic modulator provides considerable power gain, besides performing the modulating function, and in addition it has extremely low null drift. The theoretical minimum detectable signal of a magnetic second-harmonic modulator approaches 10^{-13} watt. About 10^{-14} watt has been achieved in this design. The a-c amplification, of course, does not add any null drift. Very small errors can be sensed consistently to provide excellent loop sensitivity with little drift. Loop accuracy with this amplifier is held to better than 0.25% of the controlled variable. A side feature, which is unnecessary in an error amplifier but useful in other applications, is the linearity of the amplifier with and without feedback. This is shown in Fig. 14, where several values of feedback have been set. The gain may be set from 61,000 volts per volt to 3,800 volts per volt. It is of interest to note that when magnetic feedback is used, there is no galvanic coupling between the output and input, resulting in freedom from grounding and isolation difficulties. It has been found that the modulator is capable of accepting an overload of greater than 100 times its normal maximum input with no permanent effects.

The open-loop gain does not vary more than 1.0% or 2.0% from 107 to 125 a-c input. Response time with nominal negative feedback applied is approximately 15 milliseconds. The drift of the entire circuit over a period of 24 hours was measured as approximately 2 μvolts referred to the input.

Voltage Current Conversions

When a 2-input-winding full-wave magnetic amplifier is connected as shown in Fig. 15, a closed-loop servo is formed. This arrangement provides an output affected only by the varying input voltage signal. Hence

$$N_1\, I_1=N_2\, I_2$$

independent of R_2, provided I_2R_2 does not exceed one fourth gate voltage. By decreasing N_2 the output current must increase to maintain balance and therefore a current gain can be obtained. An applied voltage at the input terminals can thus generate a constant current in the load, independent of load resistance (within limits, as already mentioned) but

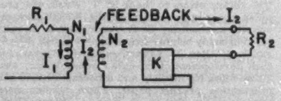

Fig. 15. Voltage current conversion circuit

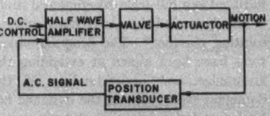

Fig. 16. Position loop block diagram

directly proportional to the applied voltage signal.

Valve Torque-Motor Drive

The torque-motor valve amplifier is a half-wave amplifier used in a closed-position loop. The device has two input windings. The input or demand is a d-c position demand signal. The second winding accepts an a-c signal from a linear differential transformer feedback, a function of output position. This circuit compares an a-c signal to a d-c signal without the use of demodulators. A half-wave amplifier, except for a difference in gain, will operate an a-c or d-c input.

The circuit itself consists of two cores arranged in a half-wave half-bridge. Each core has a gate winding and a reset winding. Common to both cores are the d-c and a-c control windings and a negative feedback winding. Across each load winding is a filter capacitor. The output is the difference in current in two differentially connected torque-motor windings, one in each leg of the circuit.

The half-wave amplifier has excellent frequency response since the control winding is essentially decoupled each cycle from the gate winding. Thus, response times approaching one cycle of the supply frequency can be realized. Fig. 16 is a block diagram of the positioning loop incorporating this amplifier.

System Performance and Verification

The results of the evaluation which was conducted on the magnetic-amplifier power-range control system are summarized below.

Position Loop

Position loop noise is 0.1% of full travel.

Position loop accuracy is 1.3% of full travel.

Changes in supply voltage and frequency resulted in a 1.0% change in demanded position.

Flux Loop

Flux loop error in an 11-point test was less than 1.0% of demanded flux.

Changes in supply voltage and frequency caused a 1.5% change in flux level.

Temperature Loop

The temperature loop reproduced a temperature demand to within 0.28%.

Regulation about a given demand is within 0.1% for long periods of time.

A 5.0% change in supply voltage and frequency caused an error of 1.4% of demanded temperature.

The control system fulfilled the transient requirements imposed on it by the desired reactor dynamics.

Instrumentation for Experimental Reactor Kinetic Studies

EDWARD L. GARDNER
NONMEMBER AIEE

REACTOR POWER excursions involving stable periods ranging from a few seconds to 2 ms (milliseconds) have been experimentally investigated in the course of the Kinetic Experiments on Water Boilers (KEWB) program conducted by Atomics International for the U.S. Atomic Energy Commission. Reactivity introduction, power and temperature measurement, and data analysis have imposed some unique requirements in instrumentation and special apparatus.

Early experimental investigations of the dynamic behavior of the water boiler type of reactors were conducted on the SUPO reactor at Los Alamos by Kasten,[1] and on the Livermore reactor by Flora, and others.[2] These experiments included reactivity relase up to a maximum of only about 0.4%, resulting in minimum reactor periods of about 6 seconds.

The present efforts on KEWB were initiated as a full-scale experimental study of the dynamic behavior of homogeneous solution reactors.[3] The program objectives have been aimed at extending the knowledge and understanding of the dominant parameters in the dynamic behavior and the safety of these types of reactors. The operating parameters which bear directly on the transient behavior of the reactor and which are under investigation include the amount of reactivity released, the initial fuel temperature, the initial core pressure, and the initial power level.

The approach in the program has been to construct a prototype reactor with the special provisions required for the experimental transient studies. This prototype reactor is installed in a special test facility, which includes an underground building to house the reactor test cores with reflector, gas-handling system and associated equipment, a waste disposal system, a small building containing amplifiers and power supplies, and the control building, some 200 feet from the test building. A comprehensive description of the facility is contained in reference 4. The instrumentation, control, and data treatment aspects of this program which are considered unique are discussed in this paper.

Reactivity Mechanism

Two means are used to insert reactivity into the KEWB reactor. The safety and control rods are withdrawn singly or in groups of two, three, or four. The low rate of reactivity insertion by this means limits its usefulness to effective step inputs of up to 0.7% or to ramp reactivity studies involving insertion rates of 0.12%/sec (per second). Reactivity releases approaching 4% produce reactor periods down to 2 ms, so that it is necessary to insert reactivity as nearly approaching a step input as possible. To achieve this rapid reactivity insertion in the KEWB a pneumatic accelerator is used to eject a poison rod from the core. This device can insert 4% reactivity in 20 ms. This near-step reactivity release places the reactor on a stable period of 2 ms and could be satisfactorily used to produce even shorter periods.

The pneumatic accelerator, Fig. 1, is comprised of a poison rod P attached to an air-driven piston p, a compressed air reservoir R provided with a solenoid S operated valve V_0, and a cylinder C fitted with various valves. The poison

The author wishes to thank M. T. Webb, who provided the original design of the KEUB fast reactivity mechanism; D. P. Gamble and R. K. Stitt for their many helpful suggestions for circuit design; and R. J. Allen, D. Vawter, and R. B. Wimmer for their development of the data readout device; also J. W. Flora for his help and encouragement in the preparation of this paper. These studies were conducted for the U. S. Atomic Energy Commission under Contract *AT(11-1)-GEN-8*.

Vol.
Pt. I
196

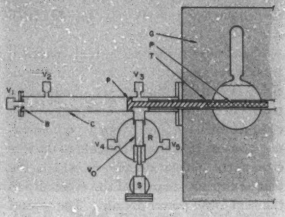

Fig. 1. Reactivity mechanism

rod and its piston are contained in the reactor through-tube T and the accelerator cylinder respectively. The through-tube, and therefore the poison rod, pass through the core on a horizontal diameter.

The piston is driven by compressed air released into the cylinder from the reservoir. It draws the poison rod completely out of the reactor reflector G, then stops the rod on an air buffer.

As the piston is driven outward by the compressed air from the reservoir, it compresses the air in the cylinder ahead of it. This air compression acts as a buffer to slow down and stop the piston. The compressed buffer air would also drive the piston and the attached poison rod inward in such a manner that the piston and rod would oscillate on an air spring if some means were not used to prevent it. The spring-loaded valve V_2 bleeds off the buffer air, allowing the piston to travel outward with the least possible deceleration while the poison rod is inside the reflector. The size of the valve orifice determines in large measure the rod travel characteristics. If the orifice is too large the piston will strike the end of the cylinder. On the other hand, too small an orifice will cause the rod to rebound into the reactor. The appropriate orifice size was determined with the aid of Fastax camera films of trial ejections and was selected to give the least ejection time compatible with a rebound limited to 6 inches, which does not allow the poison rod to re-enter the reflector. The pressure of the drive air, although reduced, overcomes the rebound and again drives the piston outward and holds it against a rubber bumper B, which prevents the piston from striking the metal end of the the cylinder.

The poison rod is reinserted into the reactor by introducing compressed air at 8 psi (pounds per square inch) into the cylinder on the buffer side of the piston by means of a valve V_1. The spring-loaded dump valve remains closed against this pressure and the piston drives the poison rod gently into the reactor until it reaches a remotely adjustable mechanical stop. The air trapped between the piston and valve V_0 during the reinsertion operation is released through valve V_3, which opens simultaneously with V_1. The position history of the poison rod during an ejection is provided by a magnet carried by the piston. The magnet generates a voltage as it passes under a series of pick-up coils located at 2-inch intervals along the cylinder.

A panel located in the control room console provides for the complete remote control and supervision of the reactivity mechanism.

The piston can withdraw the poison rod from its farthest inserted position to where the rod clears the reflector (30 inches) in 60 ms. The rod withdrawal time and maximum velocity are varied by adjusting the pressure of the air in the reservoir. The rod position traces in Figs. 2 and 3 show the maximum rod velocities to be 800 and 600 inches/sec respectively, which were produced by reservoir air pressures of 80 and 60 psi respectively.

It is necessary from the experimental standpoint to establish the stable reactor periods at as low a reactor power as possible and, in cases involving effective step changes in reactivity, the stable period must prevail for at least one dec-

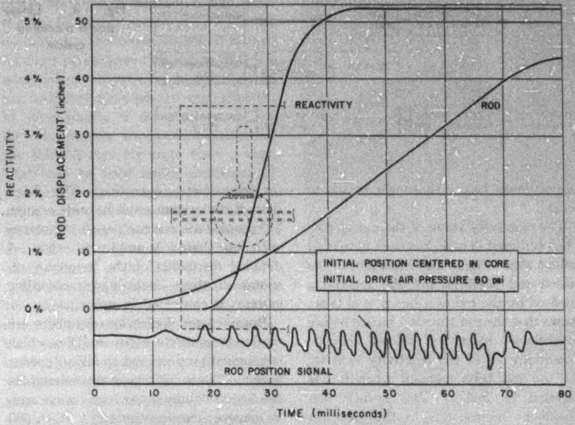

Fig. 2. Poison rod position versus time

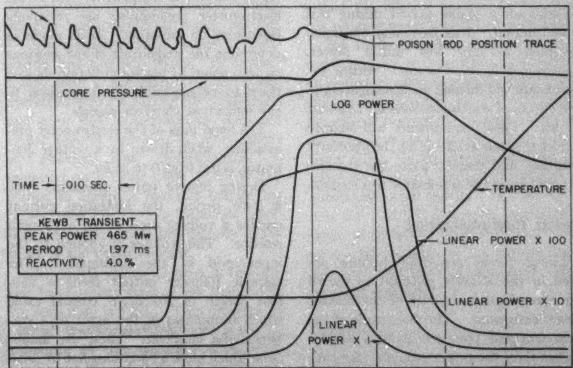

Fig. 3. Power transient oscillogram

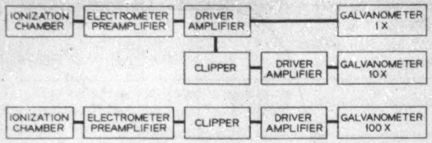

Fig. 4. Linear power recording system

ade of power before shutdown begins to occur.

The reactivity value of the poison rod, when centered in core, has been measured to be 5.2%. Fig. 2, which is a plot of the poison rod position and the reactivity released by the rod as a function of time, shows that the rod travels 4 inches before appreciable reactivity release begins. Essentially all of the reactivity held by the rod has been released when it has traveled 22 inches. The 22-inch displacement corresponds to the eleventh rod position pulse, which is indicated by an arrow in Figs. 2 and 3.

Since the KEWB core is loaded to 4% reactivity, the reactor is not critical until the rod has moved out 8 inches. During this 8-inch travel the rod is accelerated to nearly maximum velocity. This permits the mechanism to insert the 4% reactivity in 20 ms.

Fig. 3 is an oscillogram of a typical reactor power excursion with a 2-ms reactor period. It may be noted that the eleventh pulse, which indicates full reactivity insertion, occurs 43 ms before peak power. An inspection of the more sensitive linear power traces shows that the reactor power was rising with a constant period until 10 ms prior to the power peak. The time increment between these two events, i.e., reactivity fully inserted and onset of shutdown, is 33 ms. The reactor power increased a little over 7 decades on a stable period during this time interval. This particular excursion involved a very low initial power, approximately 10^{-4} watts. Future experiments will include an investigation of the effects of starting powers up to about 25 kw. These experiments will sharply reduce the time available for the reactivity addition, and thereby place the greatest demand upon the accelerator mechanism.

Power Instrumentation

Linear power recording systems are used in the KEWB program to record the three highest decades of the reactor power excursions. The magnitude of the excursion peak powers is about 4 decades higher than the power available for calibration. The usable dynamic ranges of the electrometer should cover 5 decades for convenient operation. The band pass of the system must be wide enough to record 2-ms reactor period excursions with less than 5% amplitude error. A detailed discussion of the frequency response of these linear power recording systems is contained in reference 5.

Boron-coated ionization chambers are used to measure the n (neutron) flux which is assumed proportional to instantaneous power. The sensitivity of these chambers is 8.5×10^{-15} amp/n/sec/cm^2 (where amp = ampere; cm = centimeter). With 600 volts applied to these chambers, 150 μamp can be drawn without saturation effects. Such a current would flow when the flux at the surface of the chamber was 2×10^{10} n/sec/cm^2. Since the flux in the reactor room at the peak of the highest power excursions is 2 or 3 decades greater than 2×10^{10} n/sec/cm^2 the ionization chambers are shielded by cadmium and water-cadmium attenuators.

The electrometer preamplifiers are designed to operate in the reactor room and are connected to the ionization chambers with 4 feet or less of coaxial cable. Fifteen-range resistors in the preamplifier have values starting at 10^8 ohms, and descending to 10^3 ohms. Each decade is split at 5x, 2x, and 1x.

Regulated positive and negative high voltages are supplied from a nearby instrument room through 50 feet of cable. All of the circuit components used in the electrometer preamplifier are relatively insensitive to radiation. Tests made to determine the magnitude of the spurious signals caused by reactor radiation showed them to be negligible in comparison to the ionization chamber signals.

The band pass of the electrometer preamplifier, when driven by a voltage generator, is flat from 0 to 35 kc.

During reactor power transients with a 2-ms period, the ionization current creates a voltage drop across a 10^4-ohm resistor. This voltage is applied to the input grid of the preamplifier. The cathode follower output feeds a 250-foot length of *RG 62/U* coaxial cable which terminates in the input of a stabilized d-c amplifier. These d-c amplifiers, which have a band-pass flat to ±0.3 decibel from zero to 5 kc, are used as driver amplifiers. The galvanometers used have a frequency response flat from zero to 1,200 cycles/sec.

Four linear recording systems are used to measure the reactor power during transient operation. They are grouped in pairs to provide self-monitoring. One channel in each pair drives two galvanometers so that one of the galvanometers covers the power decade in which the transient peak occurs and the other covers the next lower power decade. The second channel of each pair covers the second lower power decade. Block diagrams of the circuits are shown in Fig. 4. In this manner the three upper decades of the power excursion are linearly recorded. It will be noted in Fig. 3 that the two more sensitive linear power signals are clipped to prevent overloading the galvanometer driver amplifiers and to limit the galvanometer currents to safe values.

Temperature Instruments

As energy is released in the water solution of uranyl sulfate, the temperature of the core rises. If the reactor period is short enough, the heat distribution is adiabatic, and until bubble formation causes movement of the solution this temperature distribution in the core is a good indication of the flux distribution. The temperature history during a transient provides data on that part of the intrinsic reactor shutdown due to temperature reactivity compensation. Dynamic measurement of the temperature presents several problems.

The temperature-sensing elements must withstand immersion in the core solution,

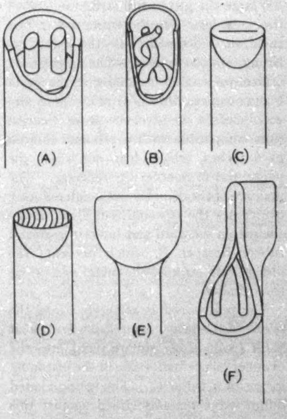

Fig. 5. Thermocouple fabrication sequence

Fig. 6. Digital oscillogram readout system

which is highly corrosive. It is composed of 0.75 molar UO_2SO_4 and 0.5 molar H_2SO_4 in distilled light water. The pH of this solution is 0.7. If the thermocouples are to survive in the core they must be made of corrosion-resistant metals or be protected from direct contact with the fuel solution. The first thermocouples used in the KEWB were 0.005-inch iron and constantan wire insulated with MgO enclosed in a type *347* stainless-steel sheath. The outside diameter of the sheath was 0.040 inch. A suitable length of flawless stock was cut and polished to remove tool marks. The MgO insulation was sandblasted out to a depth of 0.020 inch or more; see Fig. 5(A). The wires were twisted around each other and pressed down 0.005 to 0.010 inch below the end of the sheath, which was closed over the wires with the use of a dull diagonal cutting plier, Fig. 5(C), and sealed by heliarc welding without the use of extraneous metal, Fig. 5(D). The welded tip was polished and inspected for MgO filled pits or other flaws. The good tips were flattened by introducing about 0.060 inch of the sheath between the specially shaped and polished jaws of a vise. This flattening enclosed the thermocouple junction in a blade 0.007 inch thick, 0.1 inch wide, and 0.1 inch long; see Fig. 5(E). After a final polish and inspection, the thermocouples were given electrical tests. Fig. 5(F) shows a section of a completed thermocouple.

Satisfactory thermocouples were then connected to a cold junction and a recording oscillograph. The thermocouple was plunged into a beaker of hot water and the time for the couple to respond to 63% of the final temperature change was measured. This method of obtaining response time is acceptable when dealing with time constants longer than about 5 ms. Time constants of 20 ms were obtained with the best thermocouples produced in this manner.

From the temperature trace of the oscillogram of Fig. 3 it may be seen that the temperature rise in a 2-ms period power excursion is virtually a step function for these thermocouples. While the usefulness of the thermocouples is limited for short-period power transients, they are adequate if the period is longer than 90 ms, and they have proved very effective in other phases of the program. They have resisted the adverse environment of the KEWB core for more than a year. They can be used under conditions of high temperature and pressure as well as as in a corrosive medium. Their response is faster than any commercially available thermocouple which has been offered for use in the KEWB.

A 2-ms period reactor excursion requires that the thermocouples have a time constant of 0.3 ms if the reported temperatures are to be within 10% of the true value at all times. A continuing development program has demonstrated that bare wire thermocouples can be fabricated which have time constants at least as short as 0.5 ms. The useful lifetime of these thermocouples is now being investigated.

Data Reduction

To expedite the detailed reduction of occasional oscillograms under circumstances which are not appropriate for routinely employed digital computer techniques, an oscillogram trace displacement readout device was developed. There are 10 to 15 traces, depending on the experiment, which are recorded on a KEWB oscillogram. These include linear power, log power, temperature, and pressure traces. Ease of operation, accuracy, and digital readout in terms of parameter units were the important design requirements.

The readout device consists of a linear potentiometer, a voltage supply scaling network, and a digital voltmeter; see Fig. 6. The precision linear motion potentiometer has a 5-inch travel. Its repeatability error is less than 1.0% full scale; hysteresis does not exceed 1.0% full scale; and error due to nonlinearity does not exceed plus or minus 0.5%, independent of position. The potentiometer is mounted on a lucite plate which is machined to accept a movable magnifying cursor; see Fig. 7. To eliminate backlash the cursor is attached directly to the slider of the potentiometer.

The digital voltmeter used in this system has linearity error of less than 0.3%. Its resolution is 0.2%. This provides an over-all system precision which is limited primarily by the accuracy with which the cursor is located on the oscillogram trace.

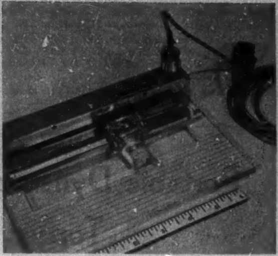

Fig. 7. Readout head showing linear potentiometer and cursor

The output potential may be adjusted to be proportional to power, pressure, temperature, or strain by properly scaling the voltage supplied to the ends of the potentiometer element. The voltage source, which has coarse and fine adjustments, is contained in a compact control unit. The calibration data pertinent to the trace under inspection is used to determine this voltage. The voltage controls have arbitrary scales, and they are adjusted until the desired scale factor, in parameter units per inch, appears on the digital voltmeter. During calibration exactly one fifth of the potentiometer supply voltage, which corresponds to precisely 1-inch trace deflection, is delivered to the voltmeter. The value of any point on the trace is thereafter displayed directly by the voltmeter when the cursor is positioned.

The control unit also provides a bias source which permits the reader to adjust the voltage at any arbitrary displacement of the cursor to zero. This allows the deflection of the trace to be read relative to its own base line without having to adjust the relative position of the readout potentiometer and the oscillogram.

The readout circuit of this device is controlled by a 3-position foot switch. In its first, or normal, position, the calibration factor appears on the voltmeter. Repetitive reading of the scale factor insures against error resulting from instrument drift. In the second position, the value of the trace deflection appears in parameter unit values. In the third position the net deflection potential is made available to auxiliary devices such as a Clary printer or an International Business Machines Corporation card-punching machine.

Portable Dynamic Electronic Speed-Torque Indicator

HERMAN R. WEED
MEMBER AIEE

Synopsis: The concept of instantaneous observation of the complete speed-torque characteristic of a motor while it accelerates from standstill to full speed is based on the assumption that a large percentage of the torque is utilized in acceleration of the inertia if the motor is otherwise unloaded. The basic instrument needed is an accelerometer with dynamic response capable of indicating the true starting torque and the transient cusps of the torque curve. This paper discusses the application of a 2-phase a-c instrument tachometer and active high-gain operational amplifiers to the design of a portable speed-acceleration instrument. The tachometer utilizes a drag-cup rotor and produces a constant frequency carrier output that has a minimum of ripple with frequency proportional to speed, thus eliminating the problem at low speeds of ripple amplification by differentiation encountered when using conventional tachometers. The constant frequency carrier output simplifies the problem of amplification and noise found with the homopolar-type generator. The use of stabilized operational amplifiers for differentiation and amplification after demodulation both provide the necessary dynamic response for the torque signal and virtually eliminates the problem of drift in the d-c stages. Operational applications of the instrument including torque versus speed, acceleration versus time, and speed versus time are included from the engineering laboratories of Robbins and Myers, Inc., Springfield, Ohio.

THE CONCEPT of instantaneous observation of the complete speed and torque characteristics of a motor while it accelerates from standstill to full speed has been the subject of papers by many competent authors.[1,2] The technique might be summarized as the accurate determination of the instantaneous speed during acceleration, the differentiation of this speed signal, and the assumption that during the acceleration period the major portion of the developed motor torque is used to accelerate the inertia. Thus, the acceleration term is considered proportional to torque. The speed and acceleration signals may then be displayed on the vertical and horizontal axes of an oscilloscope to plot the conventional speed-torque characteristic. The system is thus an accelerometer in basic operation.

Speed and Differentiation Problems

Although simple in concept, the previously stated principles are somewhat more difficult to instrument. Two problems overshadow the others. The first is that of speed measurement. Since only a fraction of a second may be required for the entire acceleration process, the tachometer must be of such nature as to provide an accurate instantaneous indication of speed during this time. This suggests very low inertia and very short electrical time constants. This is particularly true if the instrument is to be portable and not permanently attached to the motor shaft, thus permitting it to function properly other than in the laboratory. The second problem also affects the first. Since the speed signal is to be differentiated to produce the acceleration term, ripple voltages on the speed signal will be emphasized and may easily overshadow the acceleration term itself. This ripple voltage term is difficult to overcome if it has a frequency proportional to speed. In order that the system be capable of indicating cusps in the torque curve, it would be necessary for any filters used to have little attenuation over most of the speed range; thus the emphasized ripple term might be comparable to the torque term. Various types of tachometers have been utilized, such as photosensitive devices measuring the

number of light pulses, magnetic devices measuring voltage pulses, homopolar generators having no commutation ripple but considerable noise, and conventional a-c and d-c tachometers, always with the two problems of low inertia and ripple voltage in mind.

The second problem of differentiation also presents the question of how the differentiation will be accomplished. Until recently, sufficiently stable d-c amplifiers were not available to permit other than approximate differentiation with passive circuit components and the associated limitations in initial values and frequency response. If a torque signal was desired down to zero speed, d-c amplifiers of some design were still required with their associated problems of drift, calibration, and stability.

More or less successful solutions to these problems have been devised and some of the authors previously mentioned discuss workable systems. It is the purpose of this paper to present a solution that more adequately meets all of the requirements than any other system previously designed.

Two-Phase A-C Tachometer with Operational Amplifiers

The two basic problems previously discussed are solved in this unit by the use of a 2-phase a-c tachometer with drag-cup rotor, a phase-sensitive detector, and chopper stabilized active operational amplifiers. The drag-cup rotor of the tachometer presents so little inertia to the system that the unit is easily portable and driven from a handheld rubber cone. It may be successfully driven from very small motors without noticeable loading effects. Also, if properly balanced, there is essentially no output voltage with a frequency proportional to speed, and thus no ripple problem other than that of the carrier excitation voltage which may be made appreciably greater than the highest frequency necessary to reproduce the transient cusps. Thus, a very high transient frequency response is possible without interference due to noise or low-frequency ripple proportional to speed.

The use of chopper stabilized active operational amplifiers makes possible the attainment of near perfect differentiation and provides true initial values of acceleration or torque. It is also possible to utilize these operational amplifiers to produce very sharp cut-off filters so that a true response may be obtained nearly up to the carrier frequency. The chopper stabilization of the d-c amplifiers essentially eliminates the drift problem, and the associated recalibration requirements.

System Analysis

Operation

The over-all system operation is best understood by reference to the block diagram of Fig. 1. The 2-phase a-c tachometer with drag-cup rotor is supplied with a 1,500-cps (cycle per second) voltage from a fixed frequency oscillator. The resulting output of the tachometer is a

Fig. 5. Simplified operational amplifier circuits

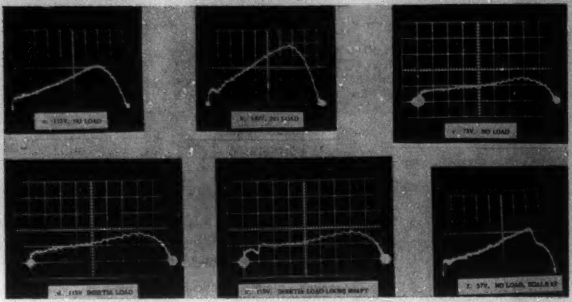

Fig. 6. Torque versus speed, 115-volt, 1-phase capacitor-start motor

1,500-cps voltage with magnitude proportional to speed and a 180-degree phase reversal for reversed rotation. This voltage is fed into a conventional a-c preamplifier. The output of the preamplifier is supplied to a frequency-doubling phase-sensitive detector. Thus the output of the detector is a d-c component of voltage proportional to speed and with polarity indicative of direction of rotation. The ripple voltage on the d-c output has a fundamental of 3,000 cps which is filtered out by an underdamped −12 db (decibel) per octave filter with a sharp corner at 700 cps.

This fairly clean d-c signal is proportional to speed and has a dynamic frequency response somewhat above 700 cps. This signal is split into two channels, one leading to conventional amplification using chopper stabilized operational amplifiers and the resulting adjustable speed signal. The other channel leads to the differentiator. A small amount of additional filtering is accomplished by a conventional R-C (resistance capacitance) filter with its corner near 1,500 cps. The differentiation is accomplished by use of a chopper stabilized operational amplifier and the differential output is supplied to an operational amplifier serving the combined function of providing a −18 db per octave filter and amplification. The additional filtering is necessary because of the amplification by ω of the ripple term in performing the differentiation. A potentiometer is used to provide a variable output for the acceleration term. Unfortunately, this system was troubled with a certain amount of 60-cycle pickup in spite of the careful shielding and this 60-cycle term is emphasized by the differentiation. Since this is a frequency in the desired pass band of the system, a narrow-band parallel-T blocking filter tuned to 60-cycles is used at the acceleration signal output terminals.

All d-c power is supplied from regulated power supplies to provide greater stability for both the oscillator and the operational amplifiers. Provision is made for zeroing the phase-sensitive detector and observing the drift of the operational amplifiers separately from the front panel.

TACHOMETER AND PHASE-SENSITIVE DETECTOR

The tachometer used is a type *10047-2A Eclipse-Pioneer*, 400-cycle 2-phase servomotor with one winding excited from an audio oscillator source of 1,500-cps voltage. The output of the second stator winding is a 1,500-cps voltage with magnitude proportional to speed and 180-degree phase position dependent on direction of rotation. The output is essentially linear with speed to above, 3,600 rpm. A slight quadrature component of voltage is observable at zero speed, but by proper choice of tachometer may be made small enough to have negligible effect.

The tachometer is encased in an aluminum hand-held unit with tapered rubber cone or tip drives; see Fig. 2. A variety of cones or rubber tips may be used to accommodate a range of shaft diameters and center hole sizes.

The 1,500-cps speed-modulated carrier is fed into an a-c preamplifier with adjustable signal level to assure maximum undistorted output for a particular tachometer unit. The output of the a-c amplifier is transformer coupled to a frequency-doubling phase-sensitive detector using silicon diodes. The output of the detector is a d-c signal with magnitude proportional to speed, polarity indicative of rotation, and a fundamental ripple frequency of 3,000 cps. The circuit is shown in Fig. 3. The ripple components are effectively removed by a

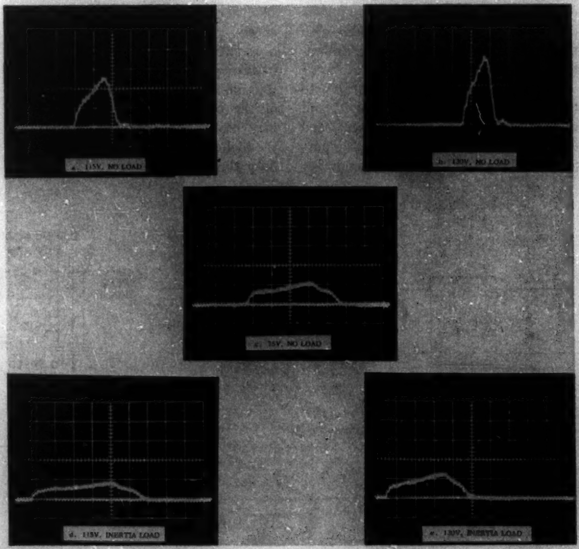

Fig. 7. Acceleration versus time, 115-volt 1-phase capacitor-start motor

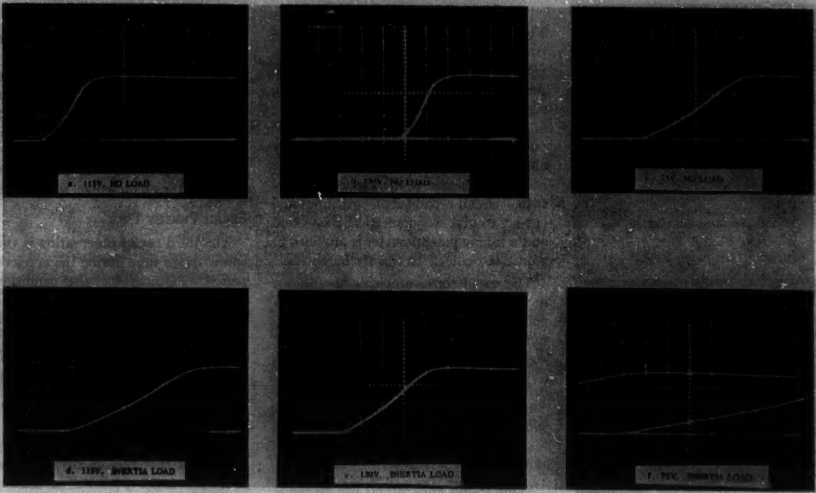

Fig. 8. Speed versus time, 115-volt 1-phase capacitor-start motor

slightly underdamped −12 db/octave R-C filter with a corner frequency of 700 cps. Thus, the speed output signal has a flat pass band up to slightly above 700 cps. A virtual zero speed may be set at any level as well as making adjustment for d-c drift of the detector by a metered d-c null adjustment brought to the front panel. Details of design are straightforward and follow conventional electronic methods.

OPERATIONAL AMPLIFIERS, DIFFERENTIATOR, AND FILTER

The chopper stabilized d-c operationl amplifier is the center of the differentiator, filter, and high-gain d-c sections. It is only by use of these amplifiers that the required initial conditions of the acceleration signal and the absence of d-c drift in both speed and torque outputs can be obtained. The amplifiers used in this unit are type *K2-X* plug-in Philbrick units with type *K2-P* plug-in chopper stabilizers. These have a transient frequency response of over 250 kc. The slight offset of the outputs is easily compensated by scope position adjustment and thus the amplifiers require no zeroing or external adjustment. Three such amplifier sections are used; one for differentiation, the second for amplification and filtering of the acceleration signal, and the third for amplification of the speed signal.

An important problem is the ability of the differentiator to produce an accurate measure of the acceleration while the speed signal is still essentially zero. Consideration will be given to the comparison of a differentiating circuit using an operational amplifier with one using passive R-C components. Consider the two circuits of Fig. 4. Each circuit is subjected to a unit step function of voltage of slope K at time $t=0$.

The passive circuit operational equation is:

$$\frac{e_0}{e_i}=\frac{-RCp}{RCp+1} \quad (1)$$

or

$$e_i=\frac{-1}{RC}\int e_0 dt-e_0=-\left(1+\frac{1}{RCp}\right)e_0 = Kt\mu(t) \quad (2)$$

By differentiating,

$$K=-\left(p+\frac{1}{RC}\right)e_0 \text{ for } t>0 \quad (3)$$

Thus

$$e_0=-KRC+A\epsilon^{-t/RC} \quad (4)$$

If

$$e_0=0 \text{ at } t=0+$$

$$0=-KRC+A \text{ or } A=KRC \quad (5)$$

Thus

$$e_0=-KRC(1-\epsilon^{-t/KC}) \text{ for } t>0 \quad (6)$$

From this

$$\frac{de_0}{dt}=-K\epsilon^{-t/RC} \quad (7)$$

and at

$$t=0+$$

$$\frac{de_0}{dt}(0+)=-K \quad (8)$$

Thus, the passive circuit has a response limited in initial slope to that of the signal. This is plotted in Fig. 4(A).

By comparison, the active circuit equation assuming a perfect amplifier may be written as

$$e_0=-RCpe_i=-RC\frac{d}{dt}(Kt\mu(t)) \quad (9)$$

Thus

$$e_0=-KRC \text{ for } t>0 \quad (10)$$

Also, from equation 9,

$$pe_0=-RCp^2e_i \quad (11)$$

At $t=0+$, it is assumed that $p^2e_i\to\infty$; thus

$$pe_0(0+)=-\infty \quad (12)$$

This has assumed a perfect amplifier. Since the amplifier response is known to be about 250 kc, the actual slope of e_0 at $t=0+$ is limited to approximately 150×10^6 volts per second. A typical response is shown in Fig. 4(B).

Thus, the operational amplifier is limited only by its own frequency response and maximum output values in producing a perfectly differentiated signal. The passive circuit with accompanying amplifier limits the acceleration signal to an

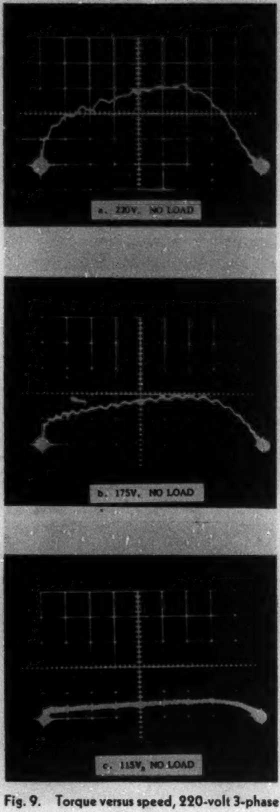

Fig. 9. Torque versus speed, 220-volt 3-phase 3,500-rpm motor

initial slope equal to that of the signal being differentiated for equal voltage output and is incapable of providing an initial torque signal at the moment of zero speed and finite acceleration. A simplified version of the differentiating circuit is shown in Fig. 5.

The torque amplifier and filter shown in Fig. 5 make use of the high input impedance of the operational amplifier together with its feedback properties to produce amplification of the desired signal and an −18 db per octave filtering of harmonics at the same time. The potentiometer adjusts output sensitivity ahead of a parallel-T sharp-tuned filter used to eliminate 60-cycle pickup. The twin T circuit is padded on both input and output to give a symmetrical pass band and a tuning potentiometer is provided to adjust the cut off to exactly 60 cycles.

The speed signal amplifier also shown in Fig. 5 has a fixed gain of 10 with a potentiometer output for variable sensitivity. It is a straightforward chopper stabilized operational amplifier in all respects.

Results

SPEED VERSUS TORQUE

Many useful applications can be made of the instrument described in the preceding paragraphs. The three more apparent ones are the observation of speed versus torque or acceleration, acceleration versus time, and speed versus time. The recording of speed versus acceleration will be considered first. Typical results of the unit are shown in Fig. 6 by use of pictures of the instantaneous trace displayed on an oscilloscope. These pictures were recorded while the motor was undergoing a normal starting acceleration with various voltages and external loads. As such, they represent the transient torque versus speed relationship at the shaft of the motor. Values of initial torque, maximum torque, full-load speed torque are easily observed and may be correlated with the linear speed co-ordinate. A switching cusp is apparent in Fig. 6. It is also possible to observe the acceleration versus speed relationship of a loaded motor under normal starting conditions. The curve of Fig. 6 is for an inertia load and demonstrates the net torque available for acceleration.

ACCELERATION VERSUS TIME

A second useful result is the observation of the acceleration versus time of a motor either unloaded or loaded during its starting period. Fig. 7 demonstrates the acceleration versus time relations for most of the acceleration versus speed plots of Fig. 6. A linear calibrated time axis is produced by the internal sweep circuit of the oscilloscope; see also Fig. 9.

SPEED VERSUS TIME

The third useful observation is that of speed versus time during the acceleration period. Pictures for the condition of Fig. 6 are shown in Fig. 8. These results give the time necessary for the motor to attain any fraction of full speed under any desired load condition. Again a calibrated linear time scale is supplied by the oscilloscope.

Conclusions

It is felt that this instrument provides the first truly portable instantaneous speed-torque recorder to the motor manufacturing industry. Its stability and simplicity of operation, combined with its ease of application, make it equally useful in the laboratory or on the production line. With this instrument it is possible to determine in a matter of seconds the complete torque-speed characteristic including cusps due to harmonics or switching and to obtain this without the motor being loaded. Thus, it is a vital tool in the experimental verification of new or modified designs, in production line quality control, and for on the spot trouble shooting. Only with the recent availability of stabilized operational amplifiers and high precision servo components has such an instrument been feasible at a reasonable price.

The Relative Merits of Incremental and Conventional Digital Computers in Air-Borne Real-Time Control

S. M. SHACKELL
NONMEMBER AIEE

J. G. TRYON
NONMEMBER AIEE

IN THE conventional or general-purpose digital computer, operands are tranferred in their entirety from one functional block to another. The inputs and outputs of such a block are simply the values of the constants and variables concerned. In the incremental computer, however, only portions of the operands are transferred. The inputs and outputs of a functional block are increments of the quantities concerned; the digital differential analyzer is one example.[1]

In these definitions, a functional block is an operation, e.g., multiplication or limiting. An operand is one of the quantities being calculated or entering into a calculation, i.e., a multiplier, or a quantity to be limited.

The purpose of this paper is to evaluate the relative merits of the two designs in air-borne real-time control. These designs are also used extensively in industrial process control. However, the experience of the authors is in air-borne systems, and the opinions expressed here will be confined to this field.

In real-time control, the computer guides some physical system along a prescribed path. The inputs to the computer are the positions, velocities, and other quantities that describe the state of the system; the outputs are signals that control the system. An autopilot is an example. Here the system is the aircraft, and the computer outputs control ailerons, elevators, and rudder.

First, observe that the two designs are related, differing in the way in which changes in variables are handled, and that both have sufficient potential capability. After defining the air-borne real-time control problem, this study will compare actual computers, concluding that each machine has its place, and that the place of the incremental is limited.

Kinship Between Incremental and Conventional Computers

In the first incremental machines increments could have only two values +1 and −1. In later "ternary" machines, improvement was obtained by increasing the number of possible values to three, +1, 0, and −1. A dual-mode incremental computer has been considered in which the number of different values is increased still further to five, +32, +1, 0, −1, −32. It is obvious that the number may be increased still further until the increments may take on all possible values that operands may attain.

If more and more possible values of increments are allowed, changes in operands can be transferred in fewer steps. It is obvious that if increments can have all possible values of any number in the machine, any change can be transferred in a single step. Such a computer is merely a conventional computer.

From this it may be seen that the general-purpose computer and the digital differential analyzer are the opposite extremes of a single class of computers. Indeed, the conventional design is the limiting case of the incremental design.

An Essential Difference

Much understanding may be gained by studying an essential difference between the incremental and the conventional machines. A common characteristic of all real-time control computers is that they have inputs and outputs which are functions of time. As the inputs change with time, the computers cyclically recalculate correspondingly changed values of the outputs. Furthermore, as their calculations proceed, all computers evaluate intermediate quantities. Although these intermediate quantities are necessary to the calculation of the outputs, they are not outputs.

The essential difference is that, in the incremental computer, the intermediate quantities and outputs are retained from cycle to cycle and brought up to date in each cycle. Changes in the inputs since the most recent calculation are propagated through the calculation as changes in the intermediate quantities to become changes in the outputs. In the conventional computer, on the other hand, the intermediate quantities and outputs of one cycle are discarded and have no use in the next recalculation. Each quantity is recomputed afresh in each cycle; there is no essential holdover from previous cycles. (Certain exceptions will be discussed.)

The two computers are very like two people of different temperaments who are given new values to plug into a set of formulas with which they have just been working. One (the conventional) tears up the old work sheet in disgust and starts over. The other (the incremental) patiently computes the change required in the first entery on the work sheet, erases the old entry, puts down the new, and continues on in the same fashion across the page.

For example, suppose that the calculation is $q=wxy+z$, where w, x, y, and z are inputs, and q is the output. Let (wx) be the intermediate quantity and let i indicate the cycle. The conventional computer might use the computation equations

$$(wx)_i=w_ix_i \tag{1}$$

and

$$q_i=(wx)_iy_i+z_1 \tag{2}$$

The incremental might use

$$\Delta w_i=w_i-w_{i-1}$$

$$\Delta x_i=x_i-x_{i-1}$$

$$\Delta(wx)_i=w_{i-1}\Delta x_i+x_i\Delta w_i$$

$$(wx)_i=(wx)_{i-1}+\Delta(wx)_i \tag{3}$$

and

$$\Delta y_i=y_i-y_{i-1}$$

$$\Delta(wxy)_i=(wx)_{i-1}\Delta y_i+y_i\Delta(wx)_i$$

$$\Delta z_i=z_i-z_{i-1}$$

$$\Delta q_i=\Delta(wxy)_i+\Delta z_i$$

$$q_i=q_{i-1}+\Delta q_i \tag{4}$$

Compare equations 1 and 2 with equations 3 and 4 respectively. Note that values from the $(i-1)$th cycle do not

---

Paper 60-120, recommended by the AIEE Computing Devices Committee and approved by the AIEE Technical Operations Department for presentation at the AIEE Winter General Meeting, New York, N. Y., January 31–February 5, 1960. Manuscript submitted November 2, 1959; made available for printing January 29, 1960.

S. M. SHACKELL, deceased, was with Stevens Institute of Technology, Hoboken, N. J., and J. G. TRYON, formerly with the Bell Telephone Laboratories, Inc., Whippany, N. J., is with the University of Alaska, College, Alaska. The work was supported by the U. S. Air Force, Air Material Command, and was a part of the TRADIC Computer Research Project at Bell Telephone Laboratories. The opinions presented are those of the authors and do not necessarily reflect Air Force opinions or attitudes on the subject.

appear in the conventional equations. Note that in the incremental equations, the input changes Δw_i, Δx_i, Δy_i, and Δs_i are propagated through the calculation. They first appear as a change $\Delta(wx)_i$ in the intermediate quantity wx, and later as a change Δq_i in the output q.

Calculations where conventional computers do not start afresh in each cycle are the exceptions already mentioned. They are only partial exceptions and do not destroy the difference just observed since in each the phenomenon of propagation of changes in inputs through changes in intermediate values to become changes in outputs is missing.

Some of the exceptional calculations are integration and differentiation with respect to time, servoed solutions (a form of successive approximation), and prediction.

For example, in time integration, both computers approximate the integral

$$s=\int_0^t y dt \tag{5}$$

by

$$s_i=s_{i-1}+\Delta s_i \tag{6}$$

and

$$\Delta s_i=y_i T \tag{7}$$

where i indexes the cycle and T is the period. Here the conventional design by the very nature of things must go back to the previous value of the integral s_{i-1} to compute the present value s_i, and so is to some extent incremental. However, it does not go back to the inputs or intermediate quantities of the previous cycle in computing y_i, and so the calculation is emphatically not an incremental one.

In summary, it may be said that in real-time control: 1. The incremental computer retains previous intermediate quantities and results and corrects them to allow for changes in the inputs (it does this by propagating the changes through the calculation), and 2. the conventional computer discards previous intermediate quantities and outputs, except where they are necessary to the calculation. There is no propagation of changes.

Logical Capabilities of Incremental Computers

Incremental computers often are considered to have very limited logical capabilities but this is not necessarily true. In the matter of abstract logical design, what the conventional computer can do, the incremental can also do. The capabilities of economical machines are quite different.

Historically speaking, the incremental computer evolved from a rather restricted design. In the original digital differential analyzer, every calculation was reduced to integrations (and additions), which in turn were represented by finite summations. As difficulties were found, the design evolved until now the incremental is far more than a digital version of a differential analyzer. Integration is no longer the primary operation. Rather, the type does arithmetic in a particular, incremental fashion. This arithmetic is just as valid as that done in a conventional digital computer; only the method is unusual.

EXACT INCREMENTAL COMPUTATION

The belief that incremental computers are not exact is based on the awareness of certain weaknesses of the early models. Actually, incremental calculation can be made as exact as may be desired.

First, incrementals may be equipped with exact algorithms. Indeed, multiplication has long been exact; see equations 3. Division is usually done by servoed multiplication, and is therefore not exact. It may, however, be done as follows. To solve $q=x/y$, use the incremental equations:

$$y_i=y_{i-1}+\Delta y_i$$

$$r_i^*=r_{i-1}+\Delta x_i-q_{i-1}\Delta y_i$$

$$\Delta q_i=\left[\frac{r_i^*}{y_i}\right]_{\text{rounded}} \tag{8}$$

$$r_i=r_i^*-y_i\Delta q_i$$

The solution must be started with

$$q_0=\frac{x_0}{y_0} \text{ and } r_0=0 \tag{9}$$

It is then exactly equivalent to the division equation of the conventional machine:

$$q_i+\frac{r_i}{y_i}=\frac{x_i}{y_i} \tag{10}$$

where r_i is the remainder. Here r_i^* is a temporary remainder, i indexes the cycle, and subscript zeros indicate initial conditions.

To achieve exact calculation, it is also necessary that the increments be able to take on a variety of values. If each successive output value is to be exact, the computer must be equipped to handle any change in value that may occur. The full change must be processed to full precision.

Incremental computers have never been constructed with this feature. The necessary extension is perfectly straightforward in theory. Instead of a machine in which increment values are restricted to +1, 0, −1, a design must be provided in which: 1. the largest permissible increment is larger than any expected change in any input, intermediate value, or result, and 2. increments are expressed with a sufficient number of digits to achieve the desired accuracy.

The dual-mode incremental computer already mentioned marked the beginnings of such a design. In it increments could take on the values +32, +1, 0, −1, −32. A better set of values would be +32, +31, +30, +29, . . ., +2, +1 0, −1, −2, . . ., −31, −32. Such increments would be expressed as 6-digit binary numbers.

It should be noted that an exact incremental must do actual multiplication and division in the course of the algorithms. Multiplication occurs in the formation of $w_{i-1}\ \Delta x_i$, $x_i\ \Delta w_i$, $q_{i-1}\ \Delta y_i$, and $y_i\ \Delta q_i$. Division occurs in

$$\Delta q_i=\left[\frac{r_i^*}{y_i}\right]_{\text{rounded}}$$

These multiplications are not simple gate-and-add operations as in the digital differential analyzer. They are multiplications of, for example, 16-bit numbers by 6-bit numbers. Similarly, division requires that the quotient be carried to perhaps six bits.

Exact computation also requires that accurate equations be used. It has been customary in digital differential analyzers to evaluate many functions by integrations, where of course the integrations are approximate by finite summations. The classic example is the computation of sine and cosine which is done by the cross-coupled integrations

$$\sin\theta=\int\cos\theta d\theta \tag{11}$$

and

$$\cos\theta=-\int\sin\theta d\theta \tag{12}$$

Much work has been put into this method and it can be very satisfactory. However, it can also be quite inaccurate, i.e., if the increments are too large.

Exact evaluation may be obtained by expanding the function in an appropriate series, e.g., a power series. This series will be made up of multiplications, divisions, additions, and subtractions and so can be evaluated exactly using the algorithms already suggested.

It should be obvious from the above that an exact incremental computer is an expensive extension of the old digital differential analyzer. Cost considerations, however, should not obscure the present issue. There is nothing inherent in the logical principle of incremental calculation that limits accuracy; the incremental can be just as exact as the conventional computer.

Because of finite word length, increment size, and computation rate, there is, of course, no such thing as a perfectly exact computer, conventional or incremental. In the interest of simplicity, this point has not been emphasized in the foregoing. A review of the analysis will show that in every respect, however, the accuracy of an incremental design may be made identical with that of a conventional design.

DECISIONS

Real-time control involves decisions e.g., when an output must be limited or when one calculation must be substituted for another. Such decisions have been rare in incremental designs. There are two ways, however, in which they can be handled, one corresponding to address modification in the conventional machine, and the other to transfer of control.

A decision element or limiter has appeared in several incremental designs. Straightforward generalization suggests a functional block, called selection, corresponding to address modification. The block is essentially a single-pole double-throw switch. It is designed to select between the changes in two quantities just as address modification in a conventional machine may select one of two quantities. The selection is made on the basis of the sign of a third quantity, the criterion. Stated exactly, the block performs

$$q_i = q_{i-1} + \Delta q_i$$

$$\Delta z_i = \Delta x_i \text{ if } q_i \geq 0$$

$$= \Delta y_i \text{ if } q_i < 0 \qquad (13)$$

Here, Δz_1 is the output increment, and Δx_1 and Δy_i are the input increments between which selection is made. The quantity q_i is the criterion on which selection is made; it is kept up to date by addition of the third input which is Δq_i. As before, i indexes the cycle.

Selection would typically be used in changing of the value of a coefficient in the calculation upon the change in sign of a key quantity. Two servo functional blocks and a selection block would be required.

Regarding equipment cost, the selection operation is no more expensive than other operations. However, its use may involve expensive delays. Whenever the selection action triggers off a large change in some quantity, a slewing time must elapse before the change is complete. The slewing time is determined by the magnitude of the change and the largest increment possible in the machine; it may be long or short.

The foregoing shows how the incremental computer may accomplish the equivalent of conditional address modification, and thus substitute one number for another. Where one calculation must be substituted for another, the incremental needs a conditional jump operation analogous to that of the conventional machine, e.g., in an autopilot it might be necessary that a different program be used above a specified altitude.

To accomplish a conditional jump, the incremental must: 1. sense that a jump is needed, 2. reload all registers with initial values associated with the new program, and 3. switch to the new program of instructions. Reloading may be done by the regular loading circuits, which must read from the initial-value bands on the drum that are appropriate to the new program. Switching to the new program is done by switching reading heads on the drum. The process is sequenced by a flip-flop circuit which is set in action by the condition calling for the jump. This may be a change in the sign of some criterion, or it may be an intervention by the operator.

Equipment cost for the scheme includes extra initial-value and program tracks. There must be the sequencing circuit, and sufficient equipment to detect the need for the jump. Equipment cost is probably not too high; the serious cost is in slewing time. After every jump there will be a hiatus during which quantities work their way from initial to up-to-date values.

One way to reduce slewing time is to provide large increments, as has already been suggested. Another is to maintain all calculations simultaneously, switching only the final outputs. A third is to provide a conventional computer that supports the incremental by providing it with up-to-date initial values. All are expensive.

It may be noted that the "red-tape" decisions of conventional computers have no counterpart in incrementals. This is because subroutines and loops are impractical in incremental calculation.

If both forms of decision are provided, the authors believe that the incremental computer can, at least in principle, make all decisions that conventional computers can make.

CORRECTION OF ERRORS

At first glance it appears that correction of errors is difficult or impossible in an incremental computer. Since every calculation is of the form

$$x_i = x_{i-1} + \Delta x_i \qquad (14)$$

it appears that an error in the present calculation propagates into all future calculation and can never be wiped out. Actually, the appearance is not necessarily true. Once the computer has been provided with the conditional jump facility just described, it can correct any error that it can discover. This places it on a par with the conventional machine.

The proposed scheme is as follows: Error-detecting checks will be maintained. On receiving an alarm from one, the conditional jump facility will be used to reload initial conditions. After sufficient time has elapsed to cover slewing, the calculation should be in good shape again.

All the standard error-detecting checks are possible. Parity checks on the storage, reading, and/or transmission of both full quantities and increments may be provided; also overflow checks on the magnitude of quantities may be provided. Tests for the continuity (smoothness) of quantities are easy, since the rates of change of all quantities are available as the increments. Arithmetic may be checked by providing duplicate circuitry or by repeating the calculations.

The cost of this scheme is in the check circuitry and the jump facility. The slew time which must elapse before an error is repaired may be significant. The cost will be large or small depending on the thoroughness with which errors are detected.

The operation of the scheme requires two arrangements which have been a part of incremental design for some time. The first is the permanent recording of the initial conditions; the second, the provision for what is called "no loss of reference," i.e., bringing into the computer a complete new value of each input in each cycle. These new values are compared with the computer's versions, and the changes in the inputs are calculated accordingly.

SUMMARY

It appears that as far as logical capabilities are concerned, the incremental design is a very powerful one. Indeed, it seems that two computers, one incremental and the other conventional, may be externally equivalent. Both can produce the same outputs when fed the same inputs.

The choice between the arithmetic and incremental principles cannot therefore be made on the basis of capability of the logical design; it must rest on equipment cost, maintainability, convenience in programming, and similar factors.

Real-Time Control Problem

In air-borne real-time control, some systems must be steered or otherwise directed in response to physical stimuli. Action must be fast enough and accurate enough to achieve the required degree of control, whatever it may be.

The work of the computer begins with the conversion of the inputs. Typically, these are continuous physical quantities such as air speed, acceleration, and target range. Each must be sampled repetitively and thus converted to a sequence of digital values.

The problem continues with the actual calculation, which is a cyclical affair. The same calculation is repeated again and again, once for each new sampling of input values. The results are the outputs. These appear first as sequences of digital values and then, after conversion, as continuous physical quantities.

The problem concludes with this conversion. The output sequences are converted to continuous physical signals, like shaft positions, which in turn control the physical system.

For present purposes, attention should be concentrated on the calculation itself. Input and output conversions are difficult; however, they tend to have the same realizations in both designs. Ever since the addition of the no-loss-of-reference feature to the digital differential analyzer, there has been little difference between the input-output equipment of the two types.

The typical calculation is made up of co-ordinate conversion, smoothing and prediction, time integration, evaluation of arbitrary functions (usually approximated by polynomials), and general calculation. These computations, which involve algebra, trigonometry, and calculus, are realized by programs of arithmetical operations. In the case of the conventional computer, the operations are those of ordinary arithmetic; in the case of the incremental, they are those of the special incremental arithmetic.

Besides arithmetic, the calculation sometimes involves decisions (conditional transfers of control). For example, a bombing calculation must determine the moment for dropping the bomb. Such decisions are not frequently encountered within a single individual calculation; they are, however, common in the routines which assemble individual calculations into a system and in routines for control of error.

It is noteworthy that the calculations deal with quantities which are continuous functions of time. Not only are the functions continuous, but their derivatives are bounded by physical limitations.

Capabilities of Actual Computers

The capabilities of typical machines will now be compared. To be specific, consider: 1. a simple incremental, 2. an incremental with provision for fast slewing, and 3. a conventional computer. Here "typical" means well proportioned for the class of control jobs for which the type is suited. No attempt will be made to compare equivalent computers, for to do so would be unfair to at least one. The types are suitable for quite different jobs; to consider equivalent computers would be like trying to decide the relative merits of a baseball team and a football team on the basis of their showings at soccer.

This discussion continues to be limited to air-borne computers. Numerical estimates are given where possible, in order to indicate orders of magnitude. They should be correct to within a factor of 3. They are based on transistor circuitry and on magnetic-drum storage in the case of the incremental computers and core storage in the case of the conventional (all circa 1956).

The simple incremental is the incremental with increment sizes limited to +1, 0, −1. It is usually called a digital differential analyzer. The incremental with provision for fast slewing is a machine with multiple increment sizes, e.g., +32, +1, 0, −1, −32.

SPEED

The calculation must be done with sufficient speed. Speed has two aspects: First, it is necessary that the initial solution of a new problem be delivered with reasonable promptness. This requires that large changes in variables be processed in each computation cycle, since the computer must move promptly from whatever state it finds itself in to the state demanded by the problem. (The time required for such motion is known as "slewing time.") Second, the problem must be solved frequently enough to keep up with whatever high-frequency changes in inputs occur. This calls for frequent recalculation rather than for the handling of large changes. (Frequency of recalculation is measured by calculation or iteration frequency. It determines the bandwidth that the computer can handle which is in practice about one eighth of the calculation frequency.)

The incremental computers typically have the better computation frequency. Both simple and fast-slewing incrementals deliver as many as 200 solutions/sec (per second). Contrast this with the 10 or 20 solutions/sec that are delivered by the typical conventional machine. The incrementals are an order of magnitude better. They are satisfactory in a control system requiring a bandwidth of about 25 cps (cycles/sec), whereas the conventional computer can work up to only about 2.5 cps. The incremental machines gain this advantage by the efficiency of their arithmetical operations, which involve many fewer elementary logical operations. This efficiency is so great that the circuitry of an incremental moves at a very lazy rate. Both types could be speeded up by using more or faster equipment, but the relative advantage would remain with the incremental.

With regard to slewing time, however, the conventional machine is the better computer. Starting from any state, it can produce the first correct result in one computation time, or about 0.1 or 0.05 sec. The simple incremental may require 300 sec for the same achievement. The incremental with fast slewing needs perhaps 10 sec. The conventional machine is faster by two or three orders of magnitude, an impressive advantage which is rooted in the basic logical principle of the conventional computer. It recomputes each quantity anew in every cycle, and so can establish completely new values of all quantities in one cycle of calculation.

The poor showing of the incremental computer is also rooted in the basic logical design. The incremental propagates changes in its variables through the calculation, and gains its impressive simplicity by sharply limiting the magnitude of the changes which can be made in each cycle. However, by adding more equipment, as in the incremental with fast slewing, the increments can be made larger and the disadvantage reduced. The cost is high, and our work suggests that the cost of a conventional machine is reached long before the slewing time of the machine is approached. (Workers on the West Coast have used two computers in the same system; a conventional machine to handle slewing and an incremental to handle the continuing calculation. This has promising possibilities.)

In another view of the matter, it may be observed that the incremental machine is rate-limited. Although it can process a great many changes in a quantity per second, the changes are quite small. Conventional machines, on the

Vol.
Pt.
196

other hand, are frequency-limited. Although they can process very large changes in a quantity, they do so only with limited frequency.

Considering still another aspect of speed, it may be said that the delay in a conventional computer is a constant. Being of the order of the computation period, it is perhaps 0.05 sec in a fast computer. The delay in an incremental machine is a function of the magnitude of the changes being processed. It is as low as 0.005 sec (the iteration period) when changes are small; it may be up to 10 or even 300 sec (the slewing time) when changes are very large.

LOGICAL AND MATHEMATICAL CAPABILITIES

Although incremental and conventional designs have the same abilities in principle, their logical and mathematical abilities are very different in practice. The difference arises from the following facts:

1. Less time and equipment are required by incremental machines to carry out repetitive algebraic and trigonometric calculations on continuous quantities. Time integrations and the evaluation of polynomials are natural operations for the incremental.
2. Far less time is required by the conventional machine to implement decisions.

With regard to the first point, in repetitive calculation, the incremental computers capitalize on the fact that real-time control deals with continuous quantities. They work with the changes in these quantities, rather than the entire quantities, thus saving both time and equipment, for the changes are of limited magnitude and the operations are thereby simplified. The conventional computer, however, is fundamentally unable to capitalize on continuity, since it recomputes all values in each cycle. It takes more equipment to do the same calculation, as well as more time.

On the other hand, conventional computers implement decisions promptly. Since each new cycle of calculation produces new values of all quantities, only one computation time is needed to get started on a new path. As already mentioned, this time may be as low as 0.1 or 0.05 sec. The incrementals are slow in implementing decisions because they must drop the old calculation and start up the new one. To do so requires going from an arbitrary state (the state of performing the old calculation) to a different arbitrary state (the new one). In the course of the change, each quantity must work its way to the new value, one increment at a time. To do so may require one slewing time, which may be 10 to 300 sec depending on the amount of equipment that has been spent on fast slewing.

The incrementals have no difficulty in making a decision; this is done promptly and cheaply by a selection block. Their difficulty lies in getting started on the work required by the decision. If it is desired to improve the incrementals in this respect, one may maintain all possible calculations simultaneously in the computer and implement the decision by switching outputs, which is an expensive process. The conventional design, therefore, has the advantage when decisions requiring appreciable changes in the calculation are to be made; the incremental with fast slewing comes next; and the simple incremental is a poor third.

ACCURACY

Both designs work to the same accuracy in real-time control. There is no difficulty in obtaining the needed accuracy, and no gain in providing more.

As accuracy is increased, the computation time of the conventional computer increases more sharply than that of the incremental. This is because multiplication time in the conventional machine tends to go as the square of the word length, while in the incremental it goes about as the first power.

GENERAL INFORMATION PROCESSING

Real-time control does not now include general information processing (by which is meant nonalgebraic nontrigonometric work such as sorting, collating, logical analysis, and the processing of "noisy" data of low correlation). However, large real-time control systems are beginning to require a tremendous amount of this sort of work. Accordingly, it is noteworthy that the conventional design can handle general information processing. It is not very efficient, but it can do the job.

The incremental computer is quite unable to handle this type of calculation. Some basic change in principle would be necessary before it could complete such a job in acceptable time. "Noisy," uncorrelated data cannot be accepted by the internal registers of an incremental; sorting and logical analysis are equally impossible. The difficulty is that all the data-processing operations involve large changes in the content of registers in every cycle of calculation, and these the incremental cannot achieve.

Physical Characteristics

In describing physical characteristics the discussion will continue in terms of a simple incremental computer, an incremental with fast slewing, and a conventional computer. Discussion is still limited to air-borne problems.

By physical characteristics is meant weight, size, and number of parts. Weight and size determine some of the indirect costs of the computer. All three factors tend to determine the manufacturing cost.

The simple incremental machine is lighter and smaller than the conventional machine. It is perhaps only half as heavy and half as voluminous. The two reasons for this difference are that: 1. the incremental is efficient in the simple problems for which it is suited, and 2. the conventional, being the one which can handle the larger, more involved problems, is assigned the bigger problems. Thus, since it does more, it is larger and heavier.

The sinple incremental is also less complex, having about one quarter as many individual parts. The same two reasons again apply, and a third, very powerful, factor appears. The incremental is built around a magnetic drum which it uses with great efficiency. Furthermore, the logical circuitry is highly efficient, much of it being used for several purposes.

The characteristics just described apply to the plain incremental computer with the very high slewing time, in which increments have the values +1, 0, −1. If the more complicated incremental computer with better slewing time is considered, the weight, volume, and number of parts approach those of the conventional design.

The most striking physical characteristic of incremental machines is that they all use a magnetic drum. They are built around the drum, gain their advantages from it, and would be quite impractical without it. It is conceivable that an incremental machine could be built around some other storage device; indeed, one of the authors has started a machine using magneto-strictive delay lines.

Designability and Maintainability

The description now turns to those characteristics which, although nonphysical, are by no means imaginary. Designability and maintainability are very real items in the description of a computer; the former determines much of the cost of building the machine; the latter fixes the cost of running it.

In this area, opinions vary, but the matter is of sufficient importance that consideration is necessary, and for this reason the authors' opinions are included here.

Incremental designs are not clean-cut, and are difficult to understand and explain. Many of their features and much of their economy are obtained by low cunning. It is difficult to predict their behavior in dynamic situations. Their designability is therefore not considered good.

The conventional design is also not clean-cut but it is more so than that of the incremental. While it is difficult to understand and also is tainted with low cunning, it is, the authors believe, not so much so as the incremental. Its behavior in dynamic situations can be predicted somewhat more easily since one need not allow for rate-limiting; therefore, the designability is somewhat better.

More significant than original designability is the designability of changes. Often, and indeed, usually, when a real-time computer is more or less finished, it is necessary to change the design to allow for some change in the system in which the design is employed. Such changes may even have to be made after production is started. Here the conventional machine is much more flexible and much easier to work with.

When maintainability is considered, the authors believe that even the simple incremental must again take second place to the conventional. Although it has fewer parts, it is harder to troubleshoot. There seems to be no basic reason for this; however, as commonly designed, incremental machines are untidy and inconvenient to work on. In particular, the extensive time-sharing of circuits that makes them so compact also makes them hard to troubleshoot.

There seems to be no reason why incremental computers cannot be designed for easy maintenance; however, it is to be expected that a good deal more equipment would have to be added. It is important to differentiate between maintainability and reliability: maintainability measures the ease with which an existing fault may be found; reliability measures the rate at which faults are generated.

If the incremental computer has poor maintainability, so does the conventional. However, the conventional does seem to be easier to repair than the incremental because: 1. step-by-step operation is easy, 2. a break-point facility is easy, 3. time sharing does not complicate the circuits excessively, and 4. diagnostic programs may be conveniently used.

Reliability

Reliability means the ability of an equipment to perform satisfactorily throughout a specified period of operation, provided that it is in good shape at the start. Two kinds of trouble occur in any digital computer. One is malfunction, the transient trouble that appears, does its damage, and departs, leaving behind it an error which may or may not propagate. The other type of trouble is the failure, the permanent trouble, e.g., a burned-out transistor.

The simple incremental computer has fewer failures because of its fewer components. (It should be remembered that it needs fewer components, in part because it tackles easier problems, and in part because it uses its components very efficiently.) It is reasonable to guess that the typical simple incremental machine has only one quarter as many failures as the typical conventional machine. This is a large advantage. The incremental with fast slewing has almost as many parts as the conventional, and so will have as many failures.

It is observed that the simple incremental computer also has the fewer malfunctions. However, the errors from these malfunctions are "devilish." Because of the basic nature of an incremental each error remains indefinitely. This, it will be remembered, is because the incremental carries over old values into new calculations. Even so, perhaps one half of the malfunctions cause negligible trouble because they affect only one increment, because they occur in an unimportant calculation, etc. The remaining half, however, spoil the performance.

In the conventional computer, by contrast, most malfunctions cause no more than a temporary inconvenience. A check of one computer, for instance, indicated that only one tenth of all its malfunctions would cause serious errors. This is because the machine recomputes almost all values afresh in each cycle, and it is only where the problem being solved involves carry-over of information from one cycle to the next that errors are not wiped out promptly.

The net result is, apparently, that the simple incremental and conventional computers are about alike in the number of performances spoiled by malfunctions. The incremental computer with fast slewing is in a much poorer position. It has almost as much equipment as the conventional and therefore has almost as many malfunctions, which all have lasting effects, and about half of them will be serious enough to spoil performances.

Thus far computers without special error-correcting facilities have been discussed. The best error-control schemes known to the authors are based on programmed detection and correction, rather than on the use of redundant equipment, which is prohibitively expensive. These schemes detect errors by mathematical means, and correct them by repetition of the calculation. It is reasonable to expect that they will catch and deal with two thirds of all malfunctions.[2]

Now, it is easy to add programmed error control in the conventional computer. A few extra operations, perhaps 100, must be added to the calculation to be checked. It is equally easy to add the equivalent control program to either incremental. The additional operations are added in straightforward fashion. However, before the control program is effective in an incremental, short slewing time must be provided. The control program, to be effective, must be able to discard the faulty solution and slew in a new one from the permanently recorded initial values, all in a short time. Hence, it is impractical to use an error-correcting program in the simple incremental.

It thus appears that, with respect to calculations lost because of malfunctions, the best machine is the conventional computer with error control. The conventional computer without error control, the simple incremental without error control, and the incremental with fast slew and error control follow close behind. The incremental with fast slewing but no error control places far behind the others.

To arrive at a picture of over-all reliability, both failures and malfunctions must be considered. Malfunctions occur about 10 or 20 times as often as failures, so the malfunctions dominate and the ranking just given holds for over-all reliability.

In the following it will be assumed that the conventional computer and the incremental with fast slewing are provided with error-control programs. To build either machine without error control would be poor design. That the simple incremental has no such control will be assumed.

Comparative Evaluation

It is clear that no one of the designs is superior to the others. Rather, each is suitable for a different class of problems. The air-borne problems for which each design is appropriate will now be described.

PROBLEMS FOR THE SIMPLE INCREMENTAL COMPUTER

The incremental computer with limited increment sizes (and hence long slewing time) has these advantages:

1. Very high computation frequency.
2. Very good capacity for repetitive calculations upon continuous quantities.
3. Small volume, low weight, fewer elements.
4. Excellent reliability with respect to failures.

Balancing the advantages are these disadvantages:

1. Very long slewing time.
2. Poor ability to implement decisions or do general information processing.
3. Not very good designability and maintainability.
4. Adequate reliability with respect to malfunctions.

This design is therefore suitable for the elementary real-time control problems, e.g., in an autopilot. Such problems can use all of the advantages of the simple incremental and, indeed, may demand some of them. The computer which rides in and controls a missile, for example, will unquestionably require small volume, low weight, and excellent reliability with respect to failures. It may also require very high computation frequency for stability.

The elementary problems involve no general information processing. Decisions are few and involve no abrupt changes in the calculation, so the weaknesses of the incremental in this regard are immaterial. Any deficiencies in designability and maintainability can be overlooked. Reliability with respect to malfunctions is satisfactory.

However, the simple incremental cannot be used where fast slewing is required. This eliminates any problem in which the computer gets little warning, and in which it must produce results immediately after the first data are supplied. The simple incremental is therefore a poor choice for defensive fire control in a bomber, for example, where only a few seconds may be allowed for engaging the target. This is regrettable, since its high computation frequency is exactly what is needed for fast response after the target is engaged. It is, however, at no disadvantage in handling the missile because it can be started on the problem ahead of time.

The simple incremental is not suitable for compound problems in which first one and then another calculation must be undertaken.

PROBLEMS FOR INCREMENTAL COMPUTER WITH FAST SLEWING

When the incremental is provided with multiple increment sizes so that slewing time is reduced at the price of more equipment, the result has these advantages:

1. Very high computation frequency.
2. Very good capacity for repetitive calculations upon continuous quantities.

The result has an intermediate position, neither very good nor very poor, with respect to many of the other factors, specifically:

1. Moderate volume, weight, and number of elements.
2. Satisfactory reliability.
3. Acceptable slewing time.
4. Sufficient ability in implementing decisions to handle a few.

Clearly, its disadvantages are:

1. Poor ability in general information-processing.
2. Poor designability and maintainability.

The design, therefore, is appropriate where very high computation frequency is needed for dynamic response and where general information processing is not necessary. A suitable problem appears to be defensive fire control, which requires both high computation frequency and short slewing time.

However, since this design is weak in general information-processing and can handle only a few decisions in reasonable time, it is not suited for compound problems. The weaknesses in its designability and maintainability also limit its usefulness.

PROBLEMS FOR CONVENTIONAL COMPUTER

The conventional design is strong in these points:

1. Very short slewing time.
2. Excellent ability to implement decisions and to do general information-processing.
3. Excellent designability.
4. Better reliability.

It is entirely satisfactory in these qualities:

1. Adequate capacity for repetitive calculations upon continuous quantities.
2. Reasonable volume and weight.
3. Reasonable maintainability.

Its weaknesses are:

1. Moderate computation frequency.
2. Larger number of elements.

From this recapitulation one may conclude that conventional computers are strong in the compound real-time control problems. These are the problems that involve several elementary calculations. The central computer in a modern weapon system faces such a problem. The capacities of the conventional computer are even more necessary when the problem includes general information processing.

Designability is an extremely important asset in these compound problems. The large, complicated systems change rapidly as they are developed and tested. The computer which can be adapted to these changes easily and quickly is much to be preferred. Modern

Table I. Comparison of Typical Computers in Air-Borne Real-Time Control

	Type of Computer		
Characteristics	Simple Incremental Computer, DDA*	Incremental Computer with Fast Slewing: Increments 0, ±1, ±32†	Conventional Computer, GP‡
Bandwidth, cps	25	25	2.5
Slewing time, sec	300	10	0.05
Fundamental speed limitation	Rate-limited, 1 part in 300/sec	Rate-limited, 1 part in 10/sec	Frequency-limited, 2.5 cps
Precision	1 part in 1,000	1 part in 1,000	1 part in 1,000
Relative volume and weight	1/2	3/4	1
		3/4	1
Relative number of parts	1/4	1½	1
Maintainability, hours down per failure	1/2		
Malfunctions per 1,000 hours			
Total	10	40	50
Serious	5	7	2
Failures per 1,000 hours	1	4	5
Reliability in unsatisfactory performances per 1,000 hours	6	11	7

The numbers are estimates, but should be correct to within a factor of 3.

* Suitable problem for simple incremental computer: Guidance of single-stage missile; a small, single problem requiring light weight but no fast slewing.

† Suitable problem for incremental computer with fast slewing (increments 0, ±1, ±32): Defensive fire control; a moderate-sized problem requiring large bandwidth and fast slewing.

‡ Suitable problem for conventional computer (GP): Central computer in bomber; a large, compound problem including decisions, data-processing, and fast slewing.

systems are built hurriedly, and there is no time to spare for redoing computers.

In the big problems, the chief handicap of the conventional computer is its modest computation frequency. When the work accumulates, the machine may not recycle fast enough for good dynamic system response.

The better reliability of conventional computers is a mixed blessing. It is composed of good reliability with respect to malfunctions and poor reliability with respect to failures. The weakness with respect to failures may be a significant handicap. However, maintainability is good.

In simpler problems, the conventional design is less desirable. Its strongest virtues are unnecessary, and its complexity is a drawback. However, where slewing time must be short, its appropriateness is indicated.

Table I summarizes the comparisons given. The numbers are estimates only. It is to be expected that actual values will be up to three times larger or smaller. They should not, however, be off by factors much larger than 3.

The Mainstream of Computer Development

The computer industry is working almost exclusively with conventional computers and will continue to do so. This is to be pondered in weighing relative merits. The industry is a large one; it produces inventions and designs, component parts, engineers and maintenance men, programs, techniques, and a literature. Much of this output cannot be used in an incremental computer without extensive modifications. An incremental project will therefore have to proceed alone to a great extent; it will find itself out of the mainstream of computer work. This argues strongly for the conventional machine.

Critical Discussion

A very real effort has been made to avoid bias in forming the opinions in this article and, though no change is apparent, a possible major change in circuit technique might of course, affect the conclusions.

A hybrid machine, part conventional and part incremental, is a tempting possibility. The conventional portion would do the general information-processing and deciding; the incremental would do the repetitive calculation upon continuous quantities. On starting up, detecting an error, or making a decision requiring a change in the course of the calculation, the conventional would provide the incremental with a new solution. Therefore the hybrid would have both short slewing time and high computation frequency. At least one such machine has been built, and is reported to be successful.

Again it should be stated that this discussion has been limited to the air-borne problems. A similar analysis for industrial process-control would be timely and it is hoped that this paper may be helpful in such an analysis.

Forecast

Considering the trend to more and more complicated systems with more and more functions done automatically, the severe limitations on the simple incremental, the small advantage gained at much cost in the incremental with multiple incremental sizes, and the course of the computer industry, it is felt that the place of the incremental computer in air-borne control is limited. It seems predictable that the conventional computer will be very generally used. Incremental techniques may be used where they can provide functions which are unnatural to the conventional computer.

The Existence of an Electric Analog of a Magnetic Circuit Established by the Basic Laws Defining Magnetostatics

ELDO C. KOENIG
ASSOCIATE MEMBER AIEE

EQUIVALENT circuits have been established by Kron and others who used finite-difference and integral forms of Maxwell's equations and equations of mathematical physics in general, and in many cases applied them to actual problems in obtaining solutions. Examples of application are to problems of compressible and incompressible fluid, electromagnetic fields, elastic fields, and heat flow. See references 1 through 19.

This paper is concerned with the special case of the equivalent circuit of magnetic fields of static current circuits where flux is represented by current, and mmf (magnetomotive force) by emf (electromotive force). The equivalent has been applied in analyzing magnetic circuits containing saturable material. The analog computer used has previously been described;[16,17] it contained nonlinear resistance elements whose nonlinearity gave an ampere-versus-voltage curve of the same shape as the saturation curve of steel. This type of equivalent circuit, exemplified in Fig. 1, is to be compared with a second type.

The second type of equivalent circuit, the one most generally used,[9,14] is shown in Fig. 2. The magnetic field which is simulated in both the first and second types, is that produced by equal currents flowing in opposite directions in two conductors normal to the *xy* plane; see Fig. 3. The medium surrounding the conductors extends to infinity but only the network in the vicinity of the conductors is shown. Here, known currents are injected into or taken from the network at the junctions, and flux densities are represented by the difference of potentials between the junctions.

The first type of circuit, with which this paper is concerned, is believed to be of greater significance than the second, and deserving of added consideration for several reasons:

Paper 56-118, recommended by the AIEE Basic Sciences Committee and approved by the AIEE Technical Operations Department for presentation at the AIEE Winter General Meeting, New York, N. Y., January 30–February 3, 1956. Manuscript submitted March 28, 1955; made available for printing February 18, 1960.

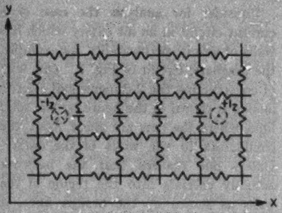

Fig. 1. Equivalent circuit with lumped resistances for magnetostatic field of Fig. 3 with battery in each circuit element at location of branch cut

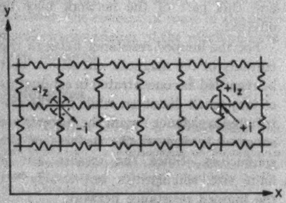

Fig. 2. Second type of equivalent circuit for magnetostatic field of Fig. 2 with currents injected into and taken from network at location of magnetic circuit conductors

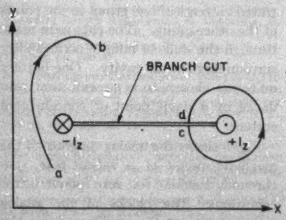

Fig. 3. Simple 2-dimensional magnetostatic field with branch cut between conductors

1. When the same basic laws are applied to magnetostatics and to current density flow, the results reveal directly the mmf-emf and flux-current correspondence.

2. The concept of the mathematical branch cut used in classical solutions is clearly perceptible in the equivalent circuit and serves as a guide in reducing the circuit to the simplest form.

3. When sketches of lines of equimagnetic potential rather than tubes of flux are made of magnetic circuits (such as those of electric machines), armature reaction, slot leakage, etc., are more easily visualized.[19] The equivalent circuit with the mmf-emf and flux-current correspondence may be easily constructed from such a sketch, and the significance of the terms related to the magnetic circuit is retained in the analog.

Establishing the Equivalent Circuit

Consider for analysis the simple 2-dimensional magnetostatic field, as shown in Fig. 3, produced only by the currents indicated which are of equal magnitude and flowing in opposite directions in two conductors normal to the xy plane. Throughout the region outside the conductors a scalar potential exists. The scalar potential U is made a single valued function of position by inserting a branch cut between the two conductors, and thus a Riemann sheet is established. Two parallel lines are shown in Fig. 3 as representing the two edges of the cut. The cut prevents the complete encirclement of the current in the calculation of the line integral:

$$\oint_a^b \mathbf{H}\cdot d\mathbf{s} = \oint_a^b \frac{1}{\mu}\mathbf{B}\cdot d\mathbf{s} = U_a - U_b \qquad (1)$$

where a and b are any two points in the open region bounding the two conductors and the cut. For the special case of a and b located on opposite edges of the cut, such as c and d in Fig. 3, the magnetic potential differences by Stoke's theorem equals the current flow in the circuit, or

$$U_c - U_d = I_z$$

To establish the analog consider a sheet of material of conductivity σ in the xy plane, as shown in Fig. 4. Circular holes are cut in this sheet at the location of the conductor of Fig. 2 and of the same diameter. A cut is made between the two conductors following a line of equimagnetic potential and the edges of the cut are plated with a material of infinite conductivity. The terminals of a battery are connected to the plated edges. Then, by the density flow equation for steady current,

$$\oint_a^b \frac{1}{\sigma} i\cdot d\mathbf{s} = V_a - V_b \qquad (2)$$

By comparison of equations 1 and 2 it is noted that magnetic potential U corresponds to electric potential V magnetic induction $\mathbf{B}$ to current density i, permeability μ to conductivity σ, and flux Φ to current I.

The same analysis applies to three dimensions where the path of the integral is a space curve. A magnetic field produced by current flowing in a single-turn conductor is shown in Fig. 5. The periphery of the cut follows the contour of the conductor. For the equivalent circuit the surfaces of the cut are coated with material of infinite conductivity and the terminals of the battery are connected to the two surfaces.

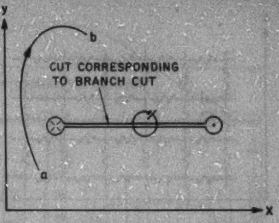

Fig. 4. Equivalent circuit of magnetostatic field of Fig. 3 consisting of sheet of conducting material with battery connected across cut

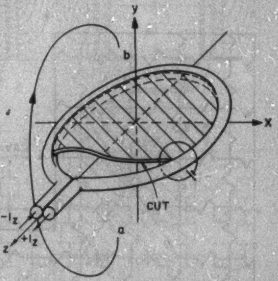

Fig. 5. Three-dimensional magnetostatic field with cut in plane of looped conductor

Equivalent Circuit with Lumped Resistance

For general application it is desirable to use a lumped resistance circuit rather than a sheet of conducting material representing distributed resistance. Fig. 1 shows an equivalent circuit of lumped resistance for the magnetic circuit of Fig. 3. The cut representing the branch cut is made along a line of equimagnetic potential in the same manner as before for the distributed resistance circuit of Fig. 4 and the ends of the resistance elements on either side of the cut connected to the terminals of batteries. It is evident that the sum of the voltage drops of any chosen mesh is equal to zero except when the mesh includes a conductor of the simulated magnetic circuit in which case the sum of the voltage drops equal the battery voltage. This is true, regardless of the manner in which the cut is made between conductors. Fig. 6 shows another way of making the cut for the same magnetic circuit.

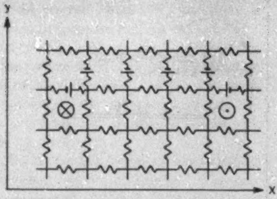

Fig. 6. Second arrangement of batteries for equivalent circuit of Fig. 1, where simulated branch cut does not follow line of equimagnetic potential

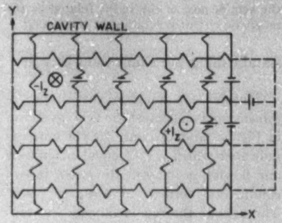

Fig. 7. Electric analog of magnetic circuit for conditions of static current circuit in air cavity with walls of infinite permeability

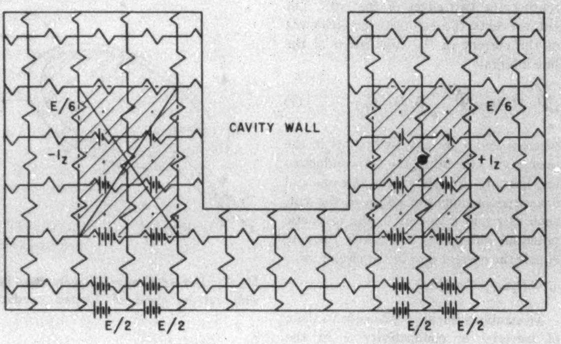

Fig. 8. Electric analog of magnetic circuit for conditions of coil, large relative to mesh size

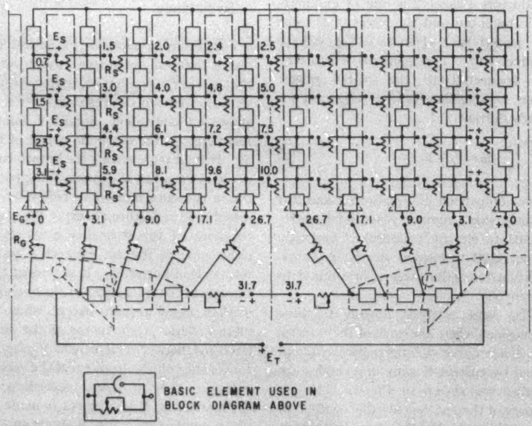

Fig. 9. Analog diagram of magnetic circuit of salient-pole synchronous machine for zero power factor conditions assuming that only teeth and pole head saturate

Consider for analysis the case of a current circuit in an air cavity which has walls of infinite permeability, for example, the magnetic circuit of Fig. 7. One way of constructing the 2-dimensional electric analog is shown in the figure by the solid lines where the cuts are made from the conductors to the walls of the cavity. Unless one realizes that the network actually extends into the region of the walls as shown by the broken lines, it would appear that the branch cut as suggested by the location of the emf was discontinuous at the edge of the cavity. Because the permeability of the material of the cavity walls is infinite, the mesh elements have zero resistance and this part of the network may be omitted.

For the lumped resistance network the currents of the magnetic circuit can best be regarded as concentrated in conductors of very small diameter, while for the distributed resistance circuit the currents are assumed to flow at the surfaces of the conductors. Since the meshes are of finite size, singularities are avoided in the lumped resistance network.

The example circuit of Fig. 8 illustrates how current in a group of conductors may be considered to be concentrated at a number of points in the center of the meshes of the analog. Cuts are made from each of these six points of concentrated currents of one group to the points of the other group. The cuts were made through the walls of infinite permeability surrounding the air cavity. One battery unit was chosen to represent mmf produced by a single point of concentrated current.

Fig. 9 shows the analog diagram of the magnetic circuit of a salient-pole synchronous machine for zero power factor conditions. The blocks of the analog circuit represent the nonlinear basic elements for simulating magnetic saturation of the stator teeth and pole tips. The cuts are made in such a manner as to agree with the sketch of lines of equimagnetic potential (ampere-turn lines) of Fig. 10, and the emf E_s and E_g are placed in the network at these cuts. The significance of such terms as armature reaction and leakage reaction remain perceptible in the analog circuit. The approximate relative magnitudes of the emf are written on the network drawing.

By sectioning the air gap with the aid of a rough sketch of the field, it is possible to reduce the number of resistance elements of the network in this region. The average dimensions of the resulting odd-shaped sections are normally taken in calculating the resistance values. When odd-shaped sections of saturable material are considered, such as the pole tip sections, it may be desirable to adjust the width from the average value according to the degree of saturation or to use a finer mesh circuit. For 2-dimensional fields the depth is normally taken as unity.

Fig. 11 shows another arrangement of emf for the analog of the magnetic circuit of Figs. 9 and 10, in which case the cuts in the network corresponding to the branch cuts are made from the slot conductors to be bottom of the slots and on through the core, which is assumed to have infinite permeability. It is seen that the number of emf have been reduced and that those eliminated are of the largest magnitude; however, the concept of some of the electrical characteristics of the machine have been obscured.

A New Ceramic Triode for VHF Applications

J. D. CAMPBELL
NONMEMBER AIEE

FOR SOME TIME, the need has been apparent for a high-performance receiving tube to operate in the very-high-frequency (vhf) region up to 450 mc (megacycles per second) and to bridge the gap between available receiving tubes and high-performance transmitting tubes. This tube should be capable of operating as an oscillator, amplifier, or frequency multiplier. Desirable features of such a tube are that it have a low input power requirement, withstand high ambient temperatures, and be as small as possible. A reliable method of connecting the tube electrodes to lumped constant circuit components with minimum capacitance, should be provided.

There are several high-performance transmitting tubes designed for use in coaxial circuits in the ultrahigh-frequency (uhf) region. One such tube is type *6442*, which was selected as a reference for evaluating the *Z-2664*.

One method of estimating performance of grounded-grid radio-frequency (r-f) amplifiers is by the gain-bandwidth figure of merit of $G_m/2\pi\sqrt{C_{in}C_{out}}$. By increasing Mu for the *Z-2664* and thereby increasing the G_m-to-I_p ratio while holding capacitances as low as possible, a figure of merit comparable with type *6442* was achieved (Table I).

Structural Features

The *Z-2664* is of a stacked ceramic and metal planer construction with electrode contacts protruding from the side of the cylindrical assembly to allow socketing, soldering, or welding to associated circuitry (Fig. 1). All contacts are spaced at multiples of 0.100 inch to conform to standard printed circuit modules. The outside diameter of 0.550 inch is determined by the minimum allowable cathode area while the longitudinal spacing between electrode contacts is set at the optimum multiple of 0.100 inch to keep capacitances low and provide ample room for welding or soldering to the terminals. For these contact spacings, the high-altitude breakdown voltage at 80,000 feet is 700 volts, giving ample safety factor over the new ASESA requirement of 500 volts for miniature tubes. The total weight of this tube is 10 grams.

The cathode is a 0.260-inch-diameter disk of a passive nickel alloy supported on a cylinder of 0.0004-inch-thick nickel-iron alloy material as shown in Fig. 2. The thin wall of the cylinder provides a rigid support for the cathode while holding heat losses by conduction to a minimum. This structure will withstand up to 7.000 *g* lateral force in a centrifuge and up to 20,000 *g* with the wall in tension. A double-coiled 13.7-milligram tungsten heater is coated by a cataphoretic process, sintered by hydrogen firing, and then vacuum-fired before assembly. This heater is enclosed in a 0.0005-inch-thick nickel heat shield which is resistance welded to the support wall and cathode disk. By holding the mass on these parts to a minimum, an operation or warm-up time of 17 seconds is achieved. This is the time required for plate current to reach 90% of its steady-state value. The current density for this 0.3-square-centimeter cathode at 15 ma (milliamperes) is only 50 ma per sq cm (milliamperes per square centimeter) which enhances its long life possibilities.

The support of the cathode assembly is spot welded to a titanium ring with the distance between the top surface of the ring and the top of the cathode held to a tolerance of 0.0005 inch. The cathode is sprayed with a carbonate coating which is shaved to give a coated height 0.003 inch higher than the metal cover.

The size of the cathode requires that the inside diameter of the grid support be 0.300 inch to give adequate clearance. Since a parallel wire frame grid would allow excessive vibration output due to individual wire resonances, a woven mesh is used (Fig. 3). A disk is cut from 0.001-inch-diameter molybdenum wire cloth, having a nominal thickness of 0.002 inch and pressed to give an over-all thickness of 0.0014 inch. This pressing serves to lock the wires in position and place all portions of the wire mesh in essentially the same plane, which is desirable for a uniform grid characteristic. The mesh, a copper brazing shim, and a tungsten support washer are placed, in that order, in a 0.001-inch-thick molybdenum support cup. This assembly is stacked between ceramic spacers and fired in a hydrogen atmosphere slightly above the melting point of copper. The support cup of the brazed assembly is then formed flush with the top of the tungsten support. It will be noted that the side of this cup is sloped to allow for the difference in thermal expansion of the tungsten washer and the titanium ring on which this cup will be supported.

The vibration output from the tube using this grid is shown in Fig. 4. The natural reasonant frequency at which peak output is obtained is 10,000 cps (cycles per second), with the smaller peak outputs occurring at subharmonics of the frequency. However, these peaks are no higher than the output from a typical receiving tube such as the *5670*, which has only one half the gain of the *Z-2664*. The integrated level of noise on the *Z-2664* would be much less than that for the *5670*.

The grid assembly is supported by a titanium ring similar to that used for the cathode and held in place by a ceramic spacer which is ground to a thickness tolerance of ±0.0005 inch (Fig. 5). This spacer, the 0.010-inch-thick tungsten grid support, and the shaved cathode height combine to give a cold grid-to-cathode spacing of 0.0035 inch. When the cathode is heated, the cathode support expands to produce a spacing of 0.003 inch. This spacing results in a transit time too large for uhf applications but one that is quite satisfactory for vhf, with particular advantages gained in low input capacitance. Greater freedom from short circuits and reduced spread of characteristics is possible with this conservative spacing.

The anode is made by welding a 0.265-inch-diameter titanium stud to the titan-

ium anode contact. This assembly is then formed to a study height tolerance of ±0.0005 inch. With a grid to anode spacing of 0.018 inch, characteristics are not appreciably affected by minor dimension changes, and a relatively low value of grid to plate capacitance is obtained.

The thin ceramic cap at the top of the anode is used primarily to add strength to the anode seal. This additional strength is needed during thermal shock caused by welding or soldering components to the anode contact or when rated dissipation is accidently exceeded by a large amount. A plate dissipation of 12 watts, which is four times the tube rating, will not damage the seal. However, this is definitely not recommended as an operating condition.

All parts of this tube are vacuum-fired prior to assembly and nickel solder shims are spot welded to the perimeter of the titanium contact parts on both top and bottom sides. The components are stacked in jigs which align the electrodes, and axial pressure is applied to each end of the tube. Loaded jigs are placed in a vacuum furnace and pumped to less than 0.1 micron of mercurial pressure. Heat is applied until the cathode has been activated, with gases escaping through the unsealed joints. The temperature is then increased to slightly above 970 C (degrees centigrade), the temperature at which titanium and nickel form a eutectic and the tube is sealed. Since this process uses a portion of the titanium metal adjacent to the nickel shim for solder, the shim is designed so that it does not cover the entire support area between the insulator and contact ring; otherwise, spacings would shift upon sealing.

Even with the high vacuum in the furnace at the time of sealing, a small amount of gas remains in the tube after sealing and some additional gas is released during initial aging. The extremely good gettering properties of titanium at elevated temperatures are utilized during aging. Heater voltage is applied to the tube in a vacuum furnace at a temperature of

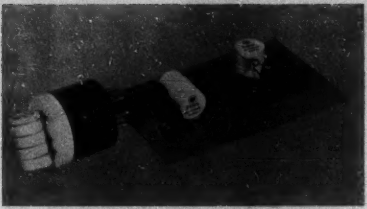

Fig. 7 (left). Low-frequency mounting methods

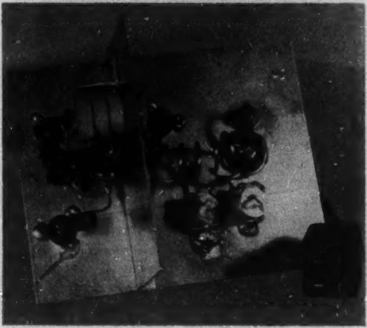

Fig. 8 (left). High-frequency mounting technique

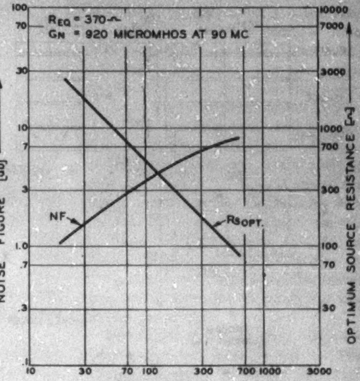

Fig. 9 (right). Predicted noise performance

approximately 750 C and the remaining gas is gettered. The relatively gas-free tube with a fully activated cathode is then stabilized at rated operating conditions for 46 hours.

Tube Mounting Techniques

The ceramic mounting base, which is sealed to the heater end of the tube, allows the tube to be fastened directly to a metal chassis or print board without the use of a socket, as shown in Fig. 6. A stainless steel screw with a rectangular head is inserted in the base slot, rotated a quarter-turn, and fastened to the chassis with a nut. Optimum strength is obtained by tightening the nut with torque of 3 inch-pounds, giving a uniform distribution of force on the ceramic base. This type of mounting withstands a 720 g shock which is equivalent to a 60-degree hammer angle on the standard Navy high-impact (flyweight) shock test machine.

For performing low-frequency tests at room temperature, an adaptor for a standard octal socket can be used. Fig. 7 shows such an adaptor and typical mounting method on a print board, which would be suitable for low-frequency operation.

To facilitate soldering seamless nickel boots are welded to the titanium electrode contacts. With circuits to be operated at room temperature, standard 40–60 lead-tin solder is satisfactory. For operation above 200 C and below 300 C, the most practical solder is a (97.5%) lead (2.5%) silver eutectic which both melts and flows at 304 C. For applications where temperatures might be a few degrees above 300 C, a resistance weld or inert arc weld would be most reliable. Essentially, any

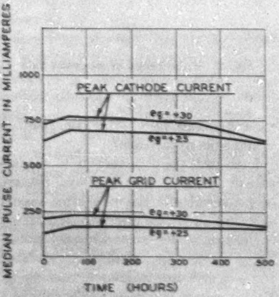

Fig. 10. Pulse life test

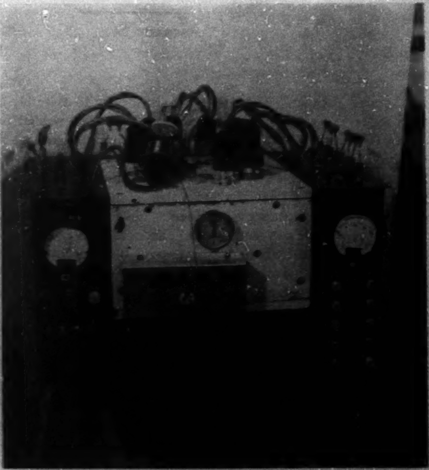

Fig. 11. High-temperature life test oven

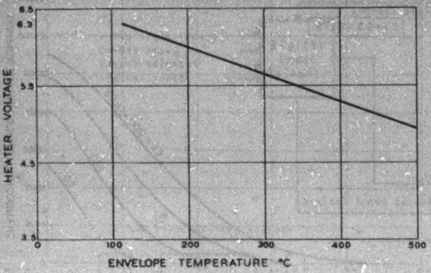

Fig. 12. **Heater derating for constant pulse emission**

method used for connecting other circuit components would be satisfactory for these contacts.

Operation as grounded grid, broadband r-f amplifier would suggest a mounting technique as shown in Fig. 8. The tube is mounted on the shield plate; the grid contact is soldered to this plate, and a bracket attached to the tube mounting base gives additional support. The lumped constant components of the input and output circuits are shielded as required.

Tube Performance

A calculated noise figure as a function of frequency, based upon transit time loading and shot noise resistance measurements at 90 mc, is plotted in Fig. 9. Because of the relatively low values of shot noise resistance, lead inductance, and capacitances, a better effective noise figure is obtained than with conventional receiving tubes.

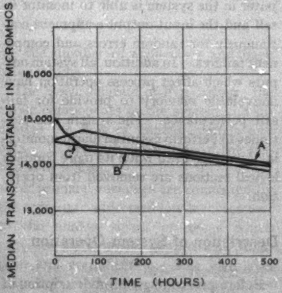

Fig. 13. **Transconductance versus life**

Test conditions:
$E_f = 6.3$
$E_p = 200$ volts
$R_k = 68$ ohms
Life test conditions:
$E_p = 250$ volts
$R_k = 130$ ohms
$W_p = 3.3$ watts
A—$E_f = 6.3$
Room ambient temperature
B—$E_f = 6.3$
300 C envelope temperature
C—$E_f = 5.65$
300 C envelope temperature

An evaluation of the stability of r-f performance in class *B* and *C* applications during life is made by pulse-life testing tubes with the standard 10-microsecond pulse at a 1,000 pulses per second rate. Fig. 10 shows the peak cathode and grid currents during life for two different grid drives.

High-temperature life tests are performed in ovens such as that shown in Fig. 11. Lead wires from the octal plug enter the oven through a ceramic shield and are resistance welded to the tube contacts. A thermocouple cemented to the center of the anode cap insulator is used to set the oven ambient temperature to give 300 C envelope temperature. There is no forced circulation in the oven so that this ambient is normally 240 C with the remaining heat created by tube dissipation. These portable ovens are rolled periodically to a test set and tube readings are made while the oven is operating at elevated temperatures to obtain a true indication of tube performance.

To secure the longest possible life from this tube when operated in a high ambient temperature, the heater voltage should be reduced by an amount necessary to prevent any rise above normal cathode operating temperature. Pulse emission is one of the most sensitive methods for measuring changes in this temperature. The heater derating curve in Fig. 12 shows the heater voltage necessary to maintain constant pulse emission for increasing envelope temperature. At the maximum rating of 300 C for this tube, the heater should be operated at 5.65 volts.

Although transformers can be purchased which will track this derating curve, there is some reluctance on the part of equipment designers to make this special provision. Therefore, this tube is now rated for 300 C envelope temperature operation at 6.3 volts without the necessity of heater derating if extremely long life is not a consideration.

Fig. 13 shows the life test performance under derated and nonderated conditions as well as room ambient operation at rated heater voltage. Although the difference at 500 hours is not extreme, a more stable value of *Gm* for the derated heater condition can be expected for longer periods of life.

Since in practice, most equipment will be adjusted at room ambient temperature and then expected to operate at elevated temperature, it is desirable to know what shift in characteristics to expect. Pulse emission, being extremely sensitive to cathode temperature, increases by approximately 50% when the tube is changed from room temperature environment to 300 C envelope temperature operation. Under the same conditions, plate current and *Gm* will increase by less than 3%.

Possible early life changes are controlled by reading *Gm* after 1 hour and after 20 hours of operation under class *A* conditions at room temperature. The distribution of *Gm* at these periods is shown in Fig. 14.

The plate current characteristic curves are shown in Fig. 15.

Transconductance transfer curves are shown in Fig. 16. Here, it can be seen

that for zero bias operation, the rated *Gm* of 15,000 can be obtained with approximately 100 volts on the plate.

Conclusions

The *Z-2664* as a vhf tube has a low cost compared with other tubes with equivalent performance. Its low power requirement and relatively small size make it especially attractive for mobile or airborne equipment use. Microphonic output is less than that normally obtained with glass receiving tubes. Elimination of socketing further reduces space requirements and eliminates oxidized contact problems at high temperatures. The maximum temperature rating of 300 C is as high as the rating on most circuit components now available. With the bulk of the tube parts composed of ceramic and titanium, deterioration due to atomic radiation is very slight. The geometry of its structure makes it more resistant to shock and vibration than any conventional assembly glass tube which might do the same job.

The LN 3000 Computer Control System

K. G. HARPLE
ASSOCIATE MEMBER AIEE

R. G. LEX, JR.
ASSOCIATE MEMBER AIEE

THE DESIGNER of a computer control system for continuous operation in an industrial process must assume two roles. One role is that of the computer expert responsible for assuring that the best computer techniques are used. The other role is that of the process application expert responsible for assuring that the system conforms to the best in process design practices.

The computer expert will use the best in components and circuit design to meet the stringent reliability and performance requirements. He will employ solid-state components, circuits will be conservatively rated, and particular attention will be given to manufacturing techniques. The computer expert feels that he now has equipment acceptable for continuous operation in an industrial process.

While the process expert may agree that the equipment will exhibit excellent reliability, he will quickly ask what error checking and fail-safe performance techniques have been used. He will point out that even the most reliable process equipment employs interlocks to provide fail-safe operation. On this basis, the process expert will insist that these features be incorporated in the computer control system before it is installed on a process.

The system described in this paper was designed using both points of view. The circuits in the system were exhaustively designed. Error detection and correction were incorporated through programming and logical design techniques. The computer in the system is able to monitor itself and the input-output equipment continuously for random errors and component failures. In addition, all system outputs which affect process operation have nonvolatile memory to provide for fail-safe performance. The system also continues to perform essential alarm monitoring functions even when its more complex logical sections are removed from operation.

Description of System Operation

Before proceeding with a description of the system operation and design features, a few brief remarks on the circuits may provide a helpful background. The logic circuits are all built around one basic diode-transistor module. The wide use of a thoroughly designed single circuit is advantageous from the reliability and maintenance standpoint. Since amplification provided by the transistor after each logical operation, a high degree of logic signal standardization is maintained throughout the equipment. Finally the design lends itself to a piggy-back module chassis card construction thereby reduc-

Fig. 1. **Block diagram of the LN series 3000 computer control system**

ing the number of connectors and back panel wiring.

The block diagram of Fig. 1 shows the major components of the system and indicates the flow of control signals and data. In brief, the operation of the system is as follows.

All primary variables are connected by the computer-addressed low-level scanner to the analog signal processor which provides input signal suppression, isolation, and amplification. The high-level output from the signal processor is sequenced to an analog to digital converter by a high-level scanner.

Digital data from the analog to digital converter and a digital address corresponding to the data are transmitted to the computer input section for entry into the computer.

All digital inputs are connected to the computer input section by a computer-addressed digital input selector. Digital time from the clock is continuously available at the computer input section.

All analog and digital data are fed into the computer as demanded by the computer program. Preprogrammed calculations are performed by the computer on all data. The results of the calculations can be stored in memory for later use or can be used to make decisions for immediate control action.

As required, the computer can initiate scheduled or on-demand printouts on any of several available printers. The computer can initiate control actions by actuating on-off outputs to start and stop equipment or by readjusting the set point of a local analog controller.

To give a better understanding of the system, each of the major components of the block diagram will be discussed in turn with respect to system function and important system design considerations.

Input Switching

All analog process variables are switched by the low-level scanner. Normally the low-level scanner samples 5 points simultaneously at a rate of approximately one group per second; this gives a basic scanning speed of 5 points per second.

If faster scanning rates are desirable, the number of points sampled simultaneously would be increased. For example, at 10 points per second, 10 points would be sampled simultaneously.

The basic system has been designed to handle a maximum of 1,275 low-level analog inputs. Each low-level input signal is switched through a separate double-pole contact of a specially designed 12-pole mercury-wetted contact relay. The relay was designed to give outstanding low-level switching characteristics. Thermal emf's generated are on the order of 1.0 microvolt and transient noise is undetectable. The scanner selection is normally controlled by the computer. In control operation this permits the computer to change the scanner sequence as changing process conditions or the mode of process operation dictates.

A digital address, corresponding to the group of input points selected, is also generated by using contacts on the mercury-wetted relay. This address is used by the computer as a check on the scanner selection circuitry and scanning relays.

Analog Signal Processor

The analog signal processor serves three systems functions; zero suppression and reference temperature compensation, input signal isolation, and input signal amplification. The input signals may have a basic maximum range of 0–100 millivolts.

Zero supression and reference temperature compensation is accomplished with bridge circuits which supply low-level voltage bias to the input signals. Reference temperature compensation is accomplished by placing temperature sensitive resistance coils in the bridge circuit. This compensation is identical to that employed with standard temperature recorders.

For a scanning rate of 5 inputs per second, 5 input amplifiers which are part of the signal processor raise the low level input signals to a 0–10-volt d-c range which is required by the analog to digital converter. The amplifiers also isolate the signal leads from the computer system to reduce errors that may be caused by potential differences between transducer grounds and the computer system ground. The amplifier is completely transistorized. The common-mode rejection is 10^6 to 1. The over-all accuracy of the amplifier is ±0.06% or better.

A filter is connected at the input of each low level amplifier to reduce errors caused by the presence of noise on the low level input signals. The filter will attenuate a 60-cycle noise signal by 300 to 1. The time for the filter to stabilize to closer than 0.1% of its final value for a step change on an analog input is less than 1 second. After simultaneous selection of the low-level inputs, a one-second delay is used before any analog signals are processed by the analog to digital converter. As previously stated, 5 input amplifiers are required to obtain a scanning rate of 5 points per second. Ten amplifiers are required to obtain a scanning rate of 10 points per second.

High-Level Scanner

A high-level scanner switches the output of the 5 input amplifiers to the analog to digital converter. High-speed mercury-wetted contact relays (2-millisecond operate time) are employed as switching devices. An address is generated by relay contacts of the high-level scanner. This address is used by the computer to check the operation of the high-level scanner control circuitry and relays.

Analog to Digital Converter

The ADC (analog to digital converter) accepts the outputs of the input amplifiers in sequence and converts this analog signal to a binary representation using the well-known weighted-count feedback technique. The binary representation is stored in a shift register to permit serial computer entry.

The ADC performs the conversion by successively comparing the analog input to a fixed progression of precision currents, each successive current being one-half the value of the preceding current. Each precision current when it is turned on is added to the sum of those currents which have been left on previously. The standard current last turned on remains on if the sum of the currents is less than the analog input, it is turned off if the sum is greater. The remaining standard currents are tried in the same way. When all of the standard currents have been tried, the arrangement of the switches which control these currents is the digital representation of the analog input. These current switches are controlled by flip-flops which comprise the shift register; therefore, the digital representation is also contained in the shift register ready for computer entry when requested by the computer. The time required for a conversion is 1.5 milliseconds.

The resolution of the ADC is 10,000 counts. The accuracy is ±0.05% of reading or 1 volt, whichever is larger, ±1/2 count.

The analog to digital converter was designed to operate as a self-contained unit. The unit is not dependent on the computer for timing signals or power. The advantages of this feature will be discussed later.

Several standard analog inputs will be connected to each system for processing by the analog input section. The computer can run preprogrammed checks on the converted digital data to check both ADC and input amplifier operation.

Digital Input Selector

The digital input selector connects all digital inputs to the input control section of the computer. Digital inputs can consist of contact closures from the process, pulse train counter inputs or manually adjusted digital inputs.

The basic system has been designed to handle a maximum of 225 counter and manually adjusted inputs or 2,040 on-off inputs. Digital inputs can be read into the computer at a maximum rate of 480 inputs per second.

Mercury-wetted contact relays are used to select all digital inputs and provide isolation from computer system voltage supplies and grounds.

A digital address corresponding to the group of selected digital input points is generated to enable the computer to check scan selection circuitry and the selection relays.

The digital input selector is controlled by the computer. In applications such as automatic start-up, the sequence of examining on-off inputs will change as emergencies arise or process conditions change.

A standard digital input will also be provided to permit the computer to check the circuitry which controls digital data entry into the computer.

Digital Clock

The digital clock is a transistorized binary counter precise to 0.1 second. The clock will supply time to the computer for logging purposes and for determining any event which will occur on a scheduled basis. The clock output can also be used as a basis for integration if desirable.

Alarm Detection

Alarm detection circuitry is offered external to the computer. Alarm settings are entered on a pinboard. As the ADC is making a data conversion, a digital alarm comparison is made. Under normal operation if an alarm, either high or low, is detected, an annunciator light is immediately actuated and a signal is transmitted to the computer. The computer can execute an off-normal printout and take whatever action is required to correct the off-normal.

Since alarm comparisons could be programmed in the computer it is desirable to discuss the advantages of external alarm detection with respect to system design. When the computer is not in service, the operator can actuate a switch on the control panel which will disconnect the computer from the input equipment, leaving all essential input equipment with power. The low-level scanner will automatically become self-sequencing and the input circuitry will continue to cycle. The ADC will operate and alarm comparisons will be made since, as previously mentioned, the ADC is a self-contained unit with its own power supply and timing circuits.

If an alarm is detected in the self-sequencing state an annunciator light will be actuated. By use of alarm memory the light will remain actuated until the point alarmed returns to normal. It is also possible to log on a printer the point number and time at which the point was alarmed.

The Computer

The operation of the entire system is controlled by the computer. One may

Vol
Pt.
196

consider the operations the computer performs as consisting of two basic parts: 1. the routine mechanics of information handling, and 2. the processing of the information in accordance with the requirements of a specific application.

In the first category, the computer performs the following functions:

1. Selects the order and timing of reading input signals.
2. Checks the address of the incoming points to verify operation of the input switching, and periodically checks the accuracy of the measurement and conversion circuits by calling for standard input signals.
3. Transmits information to the operator either periodically, on demand, or when an abnormal situation occurs in the process. Operator information is presented in both printed log form and on panel indicators.
4. Transmits information to the process, both digitally, in the case of on-off control functions, and after digital to analog conversion, in the case of resetting analog control set points.

The functions which the computer performs in processing information for specific applications may be briefly summarized as follows. They fall in three general classes:

1. Process data reduction including operating guide calculations. Such calculations typically involve complex algebraic relationships between the process variables. Statistical techniques for handling the large amount of data involved are expected to play a role of increasing importance.
2. Program controller. Process start-up and shut-down procedures typically involve a complex series of yes-no decisions. Such decisions may be made rapidly and consistently by an appropriate computer program. Either completely automatic operation may be obtained, or the results of computer decisions can be made available as instructions to the operator.
3. Process optimization. This is the most complex of the computer's functions. Today, four general approaches are in use, which will be listed in order of decreasing knowledge of process optimization conditions. First, completely determinate equations may exist, whose solution by the computer yields optimum controller settings. Second, a completely determinate mathematical model of the process may exist and be stored in the computer's memory, upon which the computer may "experiment" in either real or fast time. Third, only the form of the mathematical model may be available, in which case the computer analyzes the actual process operation in order to keep the model complete and up to date, so that it will provide a correct basis for optimization. Finally, with very little knowledge about the process, the computer may be programmed to perform carefully designed experiments upon the process itself, thus seeking out the optimum controller settings.

The digital computer which provides these various functions was designed by the computer Division of Philco Corporation to Leeds and Northrup specifications, in a jointly sponsored development. It is a general purpose, serial, internal binary, fixed-point, stored program computer having the following characteristics.

Instructions

Address Structure: Single address or 1+1 as determined by the programmer.

Order Structure: Sixteen basic orders, including square root, which may be modified to provide over 60 operations.

Computing Times: including optimum instruction and operand search,

Add, subtract, or 11 other instructions = 0.91 millisecond

Multiply, divide, or square root = 3.6 milliseconds

Shift (variable, depending on number of places) = 0.91–3.6 milliseconds

Data

Word Length: 20 bits+sign+parity.

Storage

Main Memory: Magnetic drum, 8,064 or 16,256 words.

Rapid Access: Four words standard. From a programming point of view, these appear as random access cells.

Arithmetic Registers: Three transistorized registers including the accumulator, two of which may be used as additional rapid access storage.

Miscellaneous Features

Input/Output Buffers: Complete buffering is provided for both input and output functions. All such operations can be completed by the computer in one interlace time (0.91 millisecond).

Parity Check: On all data transfers from main memory. Operator can elect to have parity error stop computation, or, in the case of instructions, to cause automatic reread.

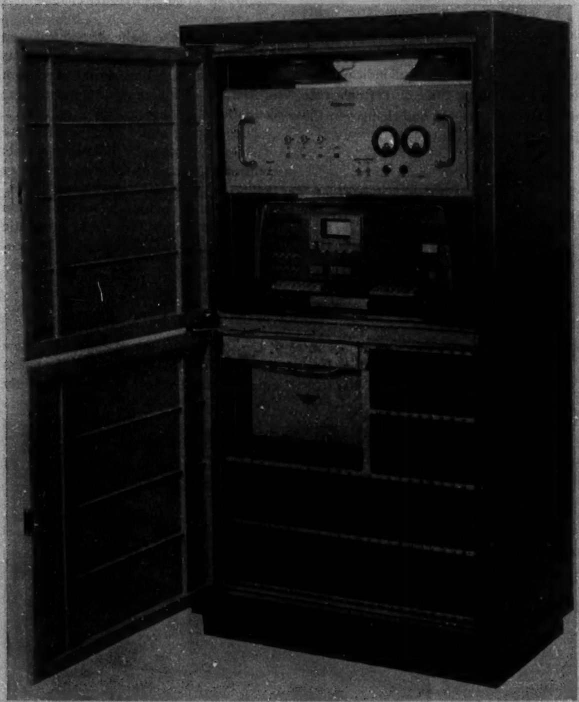

Fig. 2. LN 3000 digital computer

Protected Memory: Any multiple of 4,000 words can be protected in main memory by disabling the associated "write" amplifier. Programs stored in this section cannot be altered by random errors.

As has been mentioned previously in this paper, system reliability is obtained not only through reliable circuits, but through reliable application techniques. We have seen how the system has been designed to accommodate removal of the computer from on-line operation. Analogously, there are programming techniques available which will enhance the reliability of the computer itself. Many of these techniques have been previously reported by Ralston[1] and include such items as reasonableness and redundancy checks, detection of incorrect program jumps and endless looping, and arithmetic checks. Protected programs, written in accordance with such principles, enable an on-line control computer to compensate for most types of transient errors.

Computer Output

There are two basic digital outputs from the computer. One output is used to control and transfer data to the printers. The second output is used to control and transfer data for all control functions: addressing scanners, actuating annunciator lights, actuating on-off outputs, and adjusting analog outputs.

Printers

Each system must have a computer printer which is a standard Flexowriter with a paper tape reader and punch. This printer will be used in the preparation of computer program tapes. Programs will be entered into the computer via the paper tape reader.

The number of logging printers will vary according to system requirements. In the majority of applications, two printers will be sufficient; one printer for scheduled and on-demand printouts, and one printer for off-normal logging. Experience has indicated that the majority of maintenance problems with printers are associated with timing and adjustment of feedback contacts. In order to avoid this problem, transistorized electronic timing circuits are used for print control.

Annunciator Lights

In addition to the annunciator lights actuated by external alarm detection, 255 lights can be actuated directly from the computer. These lights will indicate such items as operating guide off-normals, rate of change off-normals, and changes in the mode of process control.

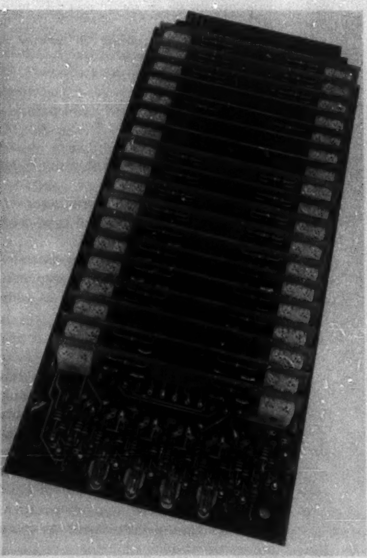

Fig. 3 (left). Logic card

Analog Outputs—Control Set Point Readjustment

Analog outputs are available to provide process control by the readjustment of local analog control loops. To obtain the maximum reliability a stepping motor is used to adjust each local analog controller. The stepping motor will normally drive a potentiometer which serves as a controller reference. The stepping motor was chosen as the reference device because of the memory inherently built in the motor. In case of power or system failures the stepping motor will remain fixed. A maximum of 255 stepping motors can be supplied with a standard system. Each motor can be addressed directly by the computer.

When a motor is selected, a pulse train is developed to rotate the motor and increase or decrease the control set point as required. The circuitry for controlling stepping motors has been designed to enforce a "reasonableness" criterion upon the change demanded by the computer. This is accomplished by limiting the magnitude of an individual change to a 1% increment.

As a further check the set point of each local controller is fed into the system as an analog input. This permits a recheck of the set point readjustment by the computer.

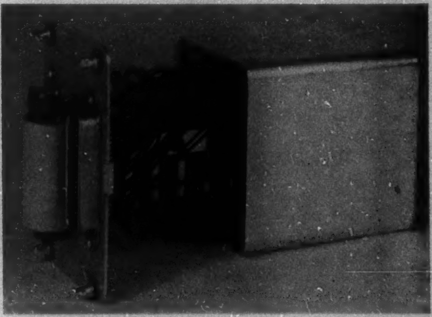
The stepping motor operates at a rate of 60 steps per second. Buffering permits continuous computer operation while set points are being adjusted.

Provision is made to allow the process operator to manually override automatic set point control. The computer is automatically informed of the manual override.

On-Off Outputs

On-off outputs are available to allow the computer to start and stop process equipment. The system will normally

Fig. 4 (below). Low-level input scanning relay



handle 255 on-off outputs, each of which can be addressed by the computer. Nonvolatile memory and manual override are also provided with each on-off output.

The circuitry for actuating on-off outputs has been designed to be fail-safe. Two computer signals are required in sequence for an on-off to be actuated. One signal is a set, the second signal is an actuate signal. The same logical circuitry is used for both the set and actuate signal. The state of logic circuitry for the set signal is inverted from the state of circuitry during the actuate signal. Unless all the logic circuitry can assume both the on and off states, no on-off output will be actuated.

System Packaging

The system is housed in cabinets 58 inches high, 37 inches wide, and 19 inches deep. The computer occupies one cabinet as shown in Fig. 2. The input-output equipment will be housed in two to five identical cabinets according to system requirements.

A maintenance and programming control panel, visible in the upper section of the computer in Fig. 2, is locked inside the computer during normal operation. The control panel may be placed on the desk next to the computer during programming and maintenance. The system control panel is similar in construction to the programming control panel and may be located at the customer's convenience.

The weight of the computer is approximately 400 pounds. Each input-output console will weigh about 250 pounds.

The equipment has been designed to operate over an ambient temperature range of 59–104 degrees Fahrenheit. Air conditioning will be incorporated for higher ambient temperatures. All components of the system are designed to be of plug-in design. A typical logic card is shown in Fig. 3. A low level input signal scanning relay is shown in Fig. 4.

Conclusions

The importance of over-all system design in the successful application of computer control systems has been emphasized. In designing such a system an appropriate balance must be achieved between the conflicting parameters of capability, reliability, and cost.

Capability specifications, such as computing speeds and the like, are relatively simply stated and compared. Reliability is more difficult to specify and compare, and in the last analysis is fully determined only after installation. For this reason restraint must be exercised by the designer in not providing an excess of capability which shows, at the expense of reliability which counts.

Attainment of satisfactory reliability has been shown to be dependent upon proper circuit design in the measurement, logic and control areas, programming techniques especially developed for online control applications, and finally a multimode system design which provides less comprehensive but adequate operation in the event that failure should occur in some of the more complex parts of the system.

Analysis and Optimization of the Bridge Magnetic Servoamplifier with True Motor Load

J. M. WALSH
ASSOCIATE MEMBER AIEE

Z. H. MEIKSIN
ASSOCIATE MEMBER AIEE

Synopsis: This paper examines the operation of a magnetic servoamplifier in which the load circuit includes the resistance and inductance of a servomotor control winding shunted by a tuning capacitor. Amplifier parameters (tuning capacitor C, limiting resistor R_s, and quiescent firing angle θ) are being optimized for best linearity and maximum motor torque. Amplifier motor transfer characteristics are established. The results are illustrated by a numerical example and verified by experiments.

A NUMBER of technical papers[1–3] have been published on the subject of the widely used Lufcy half-wave bridge magnetic servoamplifier; see Fig. 1. In none of these was a theoretical analysis performed which considered explicitly the effect of a reactive load on the operation of the amplifier. Although these papers provide valuable practical information within the limits of the approximations made, they fail to reveal characteristics of the amplifier which depend directly on the nonresistive character of the load.

Under the assumption of resistive load it may be shown that the maximum half-wave average output voltage of the amplifier cannot exceed the half-wave average supply voltage, independent of the value of R_s. This limitation results from the restricted limiter reset volt-seconds available during the reset half-cycle, equal to the supply voltage volt-seconds. A major application of the Lufcy amplifier is in conjunction with a 2-phase servomotor load. It is known from general practice that with a 2-phase servomotor load, the half-wave average output voltage of the amplifier may be made to exceed the half-wave average supply voltage, if proper adjustment of the limiting resistor is made. This is desirable in order to increase the efficiency of the amplifier, and to increase the maximum torque available from the motor amplifier set.

It is common to design and build the amplifier initially with a value of R_s approximately equal to the tuned impedance of the control phase of the servomotor, and then to decrease R_s on the breadboard gradually until no further increase in output torque of the motor for a given control signal into the amplifier is obtained. It should be noted that

Table I. Optimization Equations

Parameter	Equation	Equation No. in Test
C	$C=L/[R^2+(\omega L)^2]$	26
R_s	$\frac{1}{2}\left(2\frac{V_m}{\omega}+K_{11}\right)-K_9+K_{10}$	29
θ	θ optimum $=\cos^{-1}\left[1-\frac{\omega}{V_m}(K_9+K_{10})\right]$	32

C = tuning capacitor.
R_s = limiting resistor.
θ = quiescent firing angle.

not only is this design method inefficient, but also that it does not provide an optimum design of the amplifier, because the optimum number of the gate turns, as well as other design parameters of the amplifier, depend on the value of R_s, which was unknown at the time of the design.

One of the objectives of this paper is to present an analysis which will enable one to determine the optimum value of R_s analytically and to calculate the maximum output voltage available. With these values known, an optimum amplifier design may be carried forth.

In the course of this paper expressions for amplifier voltages and motor currents as well as motor output torque will be obtained. This will lead to the analytical establishment of the transfer curve of the amplifier with the actual tuned motor load.

It will be further shown that the best linearity of the transfer curve is obtained for quiescent firing angles, θ (i.e., the firing angle of both cores when no signal is applied), greater than 90 degrees. This in turn is favorable in the light of the heat dissipation in the amplifier, which decreases with the increase of the quiescent firing angle.

Very simple solutions for waveforms and transfer curves are obtained for magnetic amplifiers in which the output current is limited by resistance only. The analysis becomes much more elaborate if this restriction is removed. Yet the final equations are practicable and useful. The equations required for the actual design of the amplifier are summarized in Table I. The application of the results are illustrated in a numerical example.

Operation

The circuit under consideration, shown in Fig. 1, consists of load, control, and bias circuits. Common to all three circuits are two magnetic cores of senstive rectangular loop material. Each core has two gate windings, a control winding, and a bias winding.

The bias circuit is designed so that with zero control signal, both cores saturate at the same angle of the a-c supply voltage, leaving the bridge balanced, since the potentials at points *a* and *b* are equal. For a control signal with the polarity shown in Fig. 1, core *A* fires before core *B*, unbalancing the bridge with the potential at point *a* more positive than at point *b*. For a polarity reversal of the control signal core *B* fires before core *A*, causing *b* to be positive with respect to point *a*.

The load circuit consists of the a-c resistance of the motor control winding *R*, the inductance of the motor control winding *L*, and the tuning capacitor *C*.

The alternating voltage source $e_{ac}=V_m \sin \omega t$, is shown with R_s. The quantity $R_g/2$ represents the sum of the gate winding resistance and rectifier forward resistance for each leg of the bridge, assuming a constant rectifier forward resistance.

Derivation of Equations

Equations for the load voltage and current, the core winding voltage, and the output torque of the motor will be derived. For the winding polarities indicated in Fig. 1, core *A* will saturate at an angle $\omega t=\alpha_1$ and core *B* will saturate at an angle $\omega t=\alpha_2$, where $\alpha_1<\alpha_2$. Accordingly, the analysis of operation is based on four distinct time intervals or periods:

Period 1: $0\leq\omega t<\alpha_1$
Period 2: $\alpha_1\leq\omega t<\alpha_2$
Period 3: $\alpha_2\leq\omega t<\pi$
Period 4: $\pi\leq\omega t<2\pi$

The intial conditions for each interval are established by the final conditions of the previous interval.

Period 1

Period 1 follows the reset half-cycle of the amplifier, period 4. During the reset half-cycle there exist voltages across and currents in the load components. No active elements being present in the load circuit during this half-cycle, these voltages and currents must eventually reduce to zero because of the dissipation in the resistance of the circuit. It will be assumed that these voltages and currents have reduced sufficiently by the end of the reset half-cycle to permit the assumption that they are equal to zero at the beginning of period 1. This assumption is in agreement with the relative magnitudes of the resistance, inductance, and capacitance in practical servomotors.

Kirchhoff's voltage equations for the circuit are then

$$V_{ac}=(i_A+i_B)R_s+N_L\frac{d\phi A}{dt}+i_AR_g \tag{1}$$

and

$$V_{ac}=(i_A+i_B)R_s+N_L\frac{d\phi B}{dt}+i_BR_g \tag{2}$$

Assuming that the circuit parameters are such that during this nonsaturation interval

$$(i_A+i_B)R_s+i_AR_g\ll N_L\frac{d\phi A}{d}$$

and

$$(i_A+i_B)R_s+i_BR_g\ll N_L\frac{d\phi B}{dt}$$

equations 1 and 2 lead to the relation

$$N_L\frac{d\phi A}{dt}=N_L\frac{d\phi B}{dt}$$

or, upon integration between the limits ϕ_{PA} and ϕ_s and between the limits ϕ_{PB} and ϕ_B respectively,

$$(\phi_s-\phi_{PA})=(\phi_B-\phi_{PB}) \tag{3}$$

The load voltage v_L is zero during this period since the potentials at points *a* and *b* of the bridge circuit are equal, assuming that the magnetizing currents of cores *A* and *B* are the same.

PERIOD 2

At the instant $t=\alpha_1/\omega$, when core *A* saturates, the load circuit of Fig. 1 becomes as shown in Fig. 2(A).

Since, during the interval under discussion, core *B* is still unsaturated, and therefore $i_B << i_{load}$, Fig. 2(A) may be simplified as shown in Fig. 2(B). The alternating voltage source is represented by

$$V_m \sin \omega t \times U\left(t-\frac{\alpha 1}{\omega}\right)$$

The unit step function

$$U\left(t-\frac{\alpha 1}{\omega}\right)$$

enters into the expression, since the voltage is switched on at the instant

$$t=\frac{\alpha 1}{\omega}$$

by the firing of core *A*. Kirchhoff's voltage equations for the equivalent circuit are

$$V_m \sin \omega t \times U\left(t-\frac{\alpha 1}{\omega}\right) = (i_L+i_C)R_{sg}+Ri_L+L\frac{di}{dt}L \quad (4)$$

and

$$V_m \sin \omega t \times U\left(t-\frac{\alpha 1}{\omega}\right) = (i_L+i_C)R_{sg}+\frac{1}{C}\int i_C dt \quad (5)$$

Since the current through an inductance and the voltage across a capacitor cannot change instantaneously, the initial conditions for this period are

$$i_L\left(\frac{\alpha 1}{\omega}\right)=0 \quad (6)$$

$$V_c\left(\frac{\alpha 1}{\omega}\right)=0 \quad (7)$$

The solution of equations 4 and 5 together with initial conditions of equations 6 and 7 gives for the motor control winding current, for $\alpha_1 \leq \omega t < \alpha_2$

$$i_L=K\left\{f_1 \cos(\alpha_1-\omega t)-f_2 \sin(\alpha_1-\omega t)+ f_3 \exp\left[r_1\left(t-\frac{\alpha_1}{\omega}\right)\right]-f_4 \exp\left[r_2\left(t-\frac{\alpha_1}{\omega}\right)\right]\right\} \quad (8)$$

(See Appendix I.)

The motor control winding voltage V_L, for the same interval is next obtained. Referring to Fig. 2(B),

$$V_L=i_L R+L\frac{di_L}{dt} \quad (9)$$

where i_L is expressed by equation 8, the solution of which is

$$V_L=K\left\{f_5 \cos(\alpha_1-\omega t)+f_6 \sin(\alpha_1-\omega t)+ f_7 \exp\left[r_1\left(t-\frac{\alpha_1}{\omega}\right)\right]- f_8 \exp\left[r_2\left(t-\frac{\alpha_1}{\omega}\right)\right]\right\} \quad (10)$$

(See Appendix I.)

The instantaneous capacitor current is obtained from the capacitor voltage which is identical to the motor winding voltage expressed by equation 10. For the capacitor

$$i_C=C\frac{dV_L}{dt}$$

Performing this differentiation gives

$$i_C=CK\left\{\omega f_5 \sin(\alpha_1-\omega t)-\omega f_6 \cos(\alpha_1-\omega t)+ r_1 f_7 \exp\left[r_1\left(t-\frac{\alpha_1}{\omega}\right)\right]- r_2 f_8 \exp\left[r_2\left(t-\frac{\alpha_1}{\omega}\right)\right]\right\} \quad (11)$$

which expresses the instantaneous capacitor current for the period $\alpha_1 \leq \omega t < \alpha_2$.

PERIOD 3

At instant $t=\alpha_2/\omega$, when core *B* saturates, the load circuit of Fig. 2(A) becomes as shown in Fig. 2(C).

As an aid to evaluating load voltage and current for this period, Thévenin's theorem will be applied. To this end the circuit of Fig. 2(C) is opened at points 1 and 2. The Thévenin equivalent voltage of the

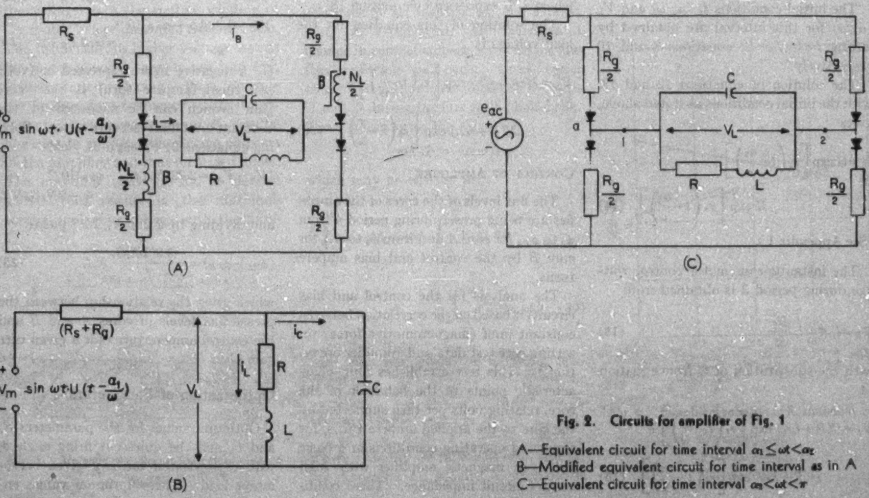

Fig. 2. Circuits for amplifier of Fig. 1

A—Equivalent circuit for time interval $\alpha_1 \leq \omega t < \alpha_2$
B—Modified equivalent circuit for time interval as in A
C—Equivalent circuit for time interval $\alpha_2 < \omega t < \pi$

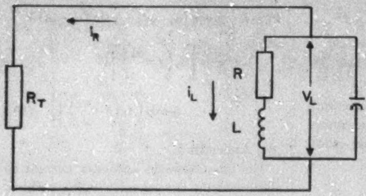

Fig. 3 (left). Thévenin's equivalent circuit for amplifier of Fig. 1 for time interval $\alpha_2 \leq \omega t < \pi$

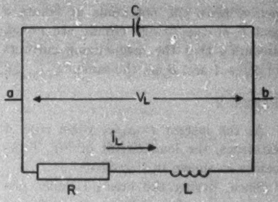

Fig. 4 (right). Load circuit for amplifier of Fig. 1 for time interval $\pi \leq \omega t < 2\pi$

circuit is equal to zero since the bridge is balanced when the load is removed. The circuit voltages during period 3 are such that all the diodes are conducting. The diodes can therefore be replaced by their forward resistances. The Thévenin equivalent resistance is thus found from Fig. 2(C) by short-circuiting the power supply e_{ac}, assuming negligible internal impedance of the power supply, by replacing the diodes by their forward resistances, and by inserting a fictitious voltage generator between points 1 and 2 after removing the load. The equivalent resistance is then found to be equal to $Rg/2$.

Thévenin's equivalent circuit of Fig. 2(C) is therefore as shown in Fig. 3.

Kirchhoff's voltage equations for the network shown in Fig. 3 are

$$\frac{1}{C}\int (i_L+i_R)dt+R_T i_R=0 \tag{12}$$

and

$$\frac{1}{C}\int (i_L+i_R)dt+Ri_L+L\frac{di_L}{dt}=0 \tag{13}$$

The initial conditions i_L (α_2/ω) and V_L (α_2/ω) for this interval are obtained by letting $t=(\alpha_2/\omega)$ in equations 8 and 10 respectively.

The solution of equations 12 and 13, with the initial conditions as stated above, gives

$$i_L=G\exp\left[r_3\left(t-\frac{\alpha_2}{\omega}\right)\right]+H\exp\left[r_4\left(t-\frac{\alpha_2}{\omega}\right)\right] \tag{14}$$

(See Appendix I.)

The instantaneous motor control voltage during period 3 is obtained from

$$V_L=i_LR+L\frac{di_L}{dt} \tag{15}$$

with the substitution of i_L from equation 14

$$V_L=G(R+Lr_3)\exp\left[r_3\left(t-\frac{\alpha_2}{\omega}\right)\right]+H(R+Lr_4)\exp\left[r_4\left(t-\frac{\alpha_2}{\omega}\right)\right] \tag{16}$$

PERIOD 4

At the instant $t=\pi/\omega$, the voltages in the circuit are such that all four diodes are blocking. The load circuit is then isolated from the rest of the amplifier components; see Fig. 4.

Kirchhoff's voltage equation for this series *R-L-C* circuit is

$$L\frac{di_L}{dt}+Ri_L+\frac{1}{C}\int i_L dt=0 \tag{17}$$

The solution of this equation with initial conditions coincident with the final conditions of period 3 is

$$i_L=M\exp\left[r_5\left(t-\frac{\pi}{\omega}\right)\right]+N\exp\left[r_6\left(t-\frac{\pi}{\omega}\right)\right] \tag{18}$$

(See Appendix I.)

Referring to Fig. 2(C), the load voltage V_L is next obtained.

$$V_L=i_LR+L\frac{di_L}{dt} \tag{19}$$

where i_L is expressed by equation 18.

The solution of this equation for the load voltage is

$$V_L=M(R+r_5L)\exp\left[r_5\left(t-\frac{\pi}{\omega}\right)\right]+N(R+r_6L)\exp\left[r_6\left(t-\frac{\pi}{\omega}\right)\right] \tag{20}$$

CONTROL OF AMPLIFIER

The flux levels of the cores of the amplifier are being preset during period 4 from ϕ_s to ϕ_{PA} for core *A* and from ϕ_s to ϕ_{PB} for core *B* by the control and bias ampere turns.

The analysis for the control and bias circuits is based on the correlation between constant mmf (magnetomotive force) resetting core test data and amplifier operation.[4] This test establishes four characteristic points of the behavior of the core, relating volts per turn supported by the core to the applied ampere turns, for simulated operating conditions of a basic half-cycle magnetic amplifier with high control circuit impedance. These conditions will be assumed to hold for the present circuit.

The voltage across the load during the gating half-cycle of the amplifier $(0<\omega t\leq\pi)$, may assume such polarity as to tend to block the rectifiers of the amplifiers. The relative magnitudes of this voltage and the supply voltage, however, are such that the rectifiers will be conducting practically until the end of the positive half-cycle of the power supply. The only period during which the amplifier is controlled is then period 4.

The totals of ampere turns applied to cores *A* and *B* during the reset half-cycle are respectively

$$AT_A=-AT_{\text{bias}}+N_cI_c \tag{21}$$

and

$$AT_B=-AT_{\text{bias}}-N_cI_c \tag{22}$$

For the linear region of the core test characteristic curve the voltages per turn supported by cores *A* and *B* are respectively

$$Vi_A=2.22f(\phi_s-\phi_{PA})10^{-8}=G_1AT_A+C \tag{23}$$

$$Vi_B=2.22f(\phi_s-\phi_{PB})10^{-8}=G_1AT_B+C \tag{24}$$

G_1, a negative figure expressed in (volts per turn)/(ampere turn) is the "core gain" which can be measured by the constant mmf flux reset core tester. Solving equations 21 through 24 yields

$$(V_B-V_A)=2.22fN_L(\phi_{PA}-\phi_{PB})10^{-8}=-2N_LG_1N_cI_c$$

and dividing by $2.22f\ N_L\ 10^{-8}$ yields

$$(\phi_{PA}-\phi_{PB})=\frac{-0.9(10^8)G_1}{f}N_cI_c \tag{25}$$

which gives the relationship between the preset flux levels of cores *A* and *B* and the control ampere turns for a given core gain G_1.

Optimization of Parameters

Optimum values for the parameters *R*, and *C*, and the quiescent firing angle θ, will be evaluated for any given servomotor load. These optimum values enable the servomotor to develop maximum torque with minimum power losses in the amplifier and also give the most linear torque-control characteristics for the amplifier-motor combination.

OPTIMIZATION OF C

The optimum value of C is that which makes the R-L-C load a maximum impedance at the fundamental frequency. This results in a high fundamental component for the motor control voltage. The optimum value of C is thus determined by the requirement for resonance of the load circuit at the fundamental frequency.

$$C=\frac{L}{R^2+(\omega L)^2} \tag{26}$$

OPTIMIZATION OF R_s

The optimum value of R_s is defined as the minimum value of R_s which does not result in the firing of core B (for control polarities as shown in Fig. 1) with maximum control signal applied to the cores as explained below. After core A fires, the supply voltage Vac is divided between R_s and the load. It is therefore clear that if R_s is increased above the certain optimum value, the voltage applied to the control winding of the motor is decreased. On the other hand, it is recognized that core B cannot support more volt-seconds during the gating half-cycle, than the amount to which it was reset during the previous half-cycle. Hence if R_s is reduced below its optimum value, core B will fire before the end of the gating half-cycle, which results in the removal of the voltage from the control winding of the motor before the end of the half-cycle. The instantaneous higher voltages across the motor winding thus do not lead to a higher torque-producing voltage, which is the fundamental frequency voltage component. A reduced value of R_s results, however, in increased circulating currents in the amplifier and thus increased losses. The optimum value of R_s, as defined above, thus results in the maximum torque-producing voltage with the minimum losses in the amplifier for a given motor.

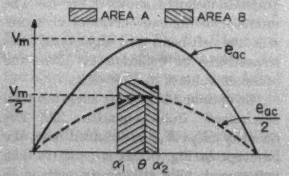

Fig. 5. Voltage waveforms for calculation of α_1, α_2, and θ

The optimum value of R_s is therefore obtained by equating the volt-seconds' change of core B during the reset half-cycle to the volt-seconds absorbed by core B during the gating half-cycle for $\alpha_1=0$ and $\alpha_2=\pi$, and solving for R_s.

Referring to Fig. 2(A),

volt-second gating_B

$$=\int_0^{\pi}\left[V_L+(i_L+i_C)\frac{Rg}{2}\right]dt \tag{27}$$

The reset volt-seconds are provided by the sum of the supply voltage and the load voltage during the reset half-cycle, as stated in equation 28:

volt-second reset_B

$$=\frac{1}{2}\int_{\frac{\pi}{\omega}}^{\frac{2\pi}{\omega}}(V_m\sin\omega t+V_L)dt \tag{28}$$

Performing the integrations indicated in equations 27 and 28 and equating the results gives

$$\frac{1}{2}\left(2\frac{V_m}{\omega}+K_{11}\right)=K_9+K_{10} \tag{29}$$

Equation 29 has R_s as the only unknown, which may be obtained graphically.

OPTIMIZATION OF θ

The maximum linearity of the amplifier is obtained for a quiescent firing angle θ, which results if $\alpha_1=0$ and $\alpha_2=\pi$ for the same control signal.[3] This value of θ is defined as the optimum value.

To determine this optimum value, a relationship between α_1, α_2, and θ must first be established. An incremental change in control ampere turns during the flux resetting half-cycle causes equal changes in volt-seconds absorbed by cores A and B during the flux gating half-cycle. Thus, referring to Fig. 5,

$$\text{area } A = \text{area } B$$

which may be written as

$$\frac{1}{2}\int_{\frac{\alpha_1}{\omega}}^{\frac{\theta}{\omega}}V_m\sin\omega t\,dt=\int_{\frac{\alpha_1}{\omega}}^{\frac{\alpha_2}{\omega}}V_B\,dt-\frac{1}{2}\int_{\frac{\alpha_1}{\omega}}^{\frac{\theta}{\omega}}V_m\sin\omega t\,dt \tag{30}$$

This equation yields the following relationship:

$$(\cos\alpha_1-\cos\theta)\frac{V_m}{\omega}=g_1+g_2 \tag{31}$$

where g_1 and g_2 are functions of α_1 and α_2; see Appendix I. Finally, θ optimum is found by letting $\alpha_1=0$ and $\alpha_2=\pi$ in equation 31

$$\theta\text{ optimum}=\cos^{-1}\left[1-\frac{\omega}{V_m}(K_9+K_{10})\right] \tag{32}$$

(See Appendix I.)

Amplifier-Motor Characteristics

The purpose of this section is to obtain a relationship between the motor torque and the amplifier control signal so that one may predict the amplifier-motor transfer characteristic curve.

The torque developed by a 2-phase servomotor, having a fixed reference voltage, is proportional to the rms value of the fundamental voltage component (of the reference voltage frequency) applied to the control phase.

$$\text{torque}=K_TV_L\text{ (fundamental)} \tag{33}$$

where K_T is the motor torque constant. The motor control voltage as a function of time V_L has been derived above for $0\leq\omega t<2\pi$, in terms of four distinct time intervals referred to as periods 1, 2, 3, and 4 respectively. This voltage during the first interval is zero, and for the remaining three intervals it is given by equations 10, 16, and 20. Let these voltages be denoted as V_{L_1}, V_{L_2}, V_{L_3}, and V_{L_4} respectively.

The motor control voltage can be expressed in terms of a Fourier series:

$$V_L=a_0+\sum_{K=1}^{K=\infty}a_k\cos K\omega t+\sum_{K=1}^{K=\infty}b_k\sin K\omega$$

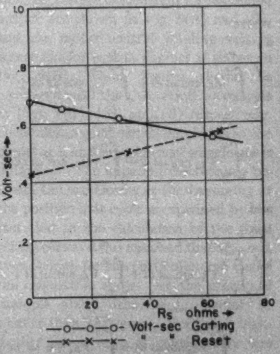

Fig. 6. Graphical solution of R_s optimum

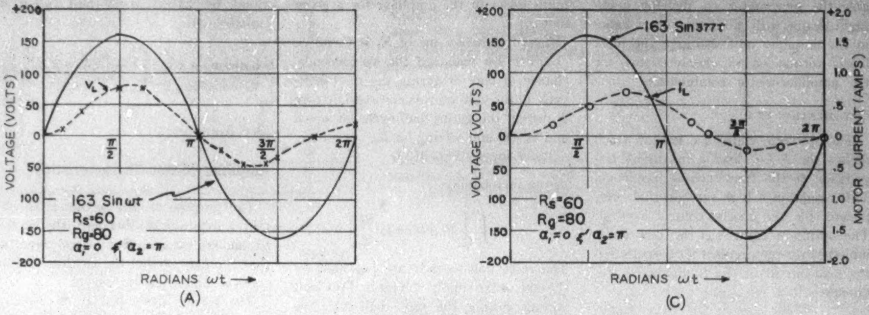
$V_m=163$ volts
$K=377$ radians
$R_g=80$ ohms



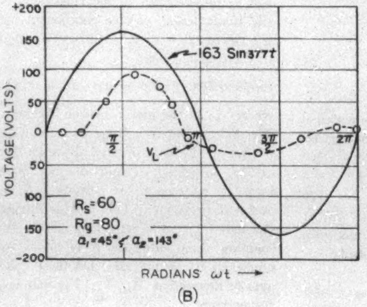


Fig. 7. Calculated load voltage waveforms

A, B—Voltage
C—Current

where the fundamental component of V_L is V_L (fundamental) $= a_1 \cos \omega t + b_1 \sin \omega t$ or

$$V_L \text{ (fundamental)} = (a_1^2+b_1^2)^{1/2} \sin\left(\omega t + \tan^{-1}\frac{a_1}{b_1}\right) \quad (34)$$

where

$a_1=$

$$\frac{\omega}{\pi}\left(\int_0^{\frac{\alpha_1}{\omega}} V_{L_1}\cos\omega t\,dt + \int_{\frac{\alpha_1}{\omega}}^{\frac{\alpha_2}{\omega}} V_{L_2}\cos\omega t\,dt + \int_{\frac{\alpha_2}{\omega}}^{\frac{\pi}{\omega}} V_{L_3}\cos\omega t\,dt + \int_{\frac{\pi}{\omega}}^{\frac{2\pi}{\omega}} V_{L_4}\cos\omega t\,dt\right)$$

and

$b_1=$

$$\frac{\omega}{\pi}\left(\int_0^{\frac{\alpha_1}{\omega}} V_{L_1}\sin\omega t\,dt + \int_{\frac{\alpha_1}{\omega}}^{\frac{\alpha_2}{\omega}} V_{L_2}\sin\omega t\,dt + \int_{\frac{\alpha_2}{\omega}}^{\frac{\pi}{\omega}} V_{L_3}\sin\omega t\,dt + \int_{\frac{\pi}{\omega}}^{\frac{2\pi}{\omega}} V_{L_4}\sin\omega t\,dt\right)$$

The evaluation of these integrals result in numerical values for a_1 and b_1. The torque of the motor is thus given by

$$\text{torque} = 0.707K_T(a_1^2+b_1^2)^{1/2} \quad (35)$$

Both a_1 and b_1 depend on the firing range α_1. To obtain the amplifier-motor transfer curve it thus remains to correlate α_1 and the control signal I_c.

Reference to equation 25 gives the correlation between the control signal I_c and the preset flux levels of the cores ϕ_{PA} and ϕ_{PB}. The correlation between the preset flux level and the firing angle α_1 is obtained as follows:

Figs. 1 and 2(A) show that for core B

$$\int_0^{\frac{\alpha_2}{\omega}} V_B dt = \int_0^{\frac{\alpha_1}{\omega}} \frac{V_{ac}}{2}dt + \int_{\frac{\alpha_1}{\omega}}^{\frac{\alpha_2}{\omega}} \left[V_L+(i_L+i_c)\frac{R_g}{2}\right]dt \quad (36)$$

but

$$V_B = \frac{N_L}{2}\frac{d\phi B}{dt}$$

whence it follows that

$$(\phi_s-\phi_{PB}) = \frac{1}{N_L}\left[\frac{V_m}{\omega}(1-\cos\alpha_1)+2(g_1+g_2)\right] \quad (37)$$

Similarly, for core A

$$\int_0^{\frac{\alpha_1}{\omega}} V_A dt = \frac{1}{2}\int_0^{\frac{\alpha_1}{\omega}} V_m \sin\omega t\,dt$$

$$V_a = \frac{NL}{2}\frac{d\phi A}{dt}$$

whence

$$(\phi_s-\phi_{PA}) = \frac{V_m}{\omega N_L}(1-\cos\alpha_1) \quad (38)$$

Subtracting equation 38 from equation 37 gives

$$\phi_{PA}-\phi_{PB} = \frac{2(g_1+g_2)}{N_L} \quad (39)$$

Combining equations 25, 31, and 39 gives

$$\alpha_1 = \cos^{-1}\left(-\frac{0.9G_1N_LN_cI_c}{V_M}+\cos\theta\right) \quad (40)$$

which yields the necessary relationship between α_1 and I_c.

Numerical Example

For the motor listed in Appendix II the measured a-c resistance of the motor control winding R was 96.5 ohms and its inductance L was 0.245 henry. The motor tuning capacitor is calculated from equation 26 and is equal to 13.7 microfarads.

The optimum value of R_s is obtained from the transcendental equation 29 by graphical means, as shown in Fig. 6. The intercept of the two curves which represent the left-hand and right-hand sides respectively of equation 29 gives the optimum value of R_s as 60 ohms.

The optimum bias firing angle θ is then determined from equation 32. The quantity (K_9+K_{10}) is obtained from the intercept in Fig. 6 and is equal to 0.55 volt-second. For the supply voltage as detailed in Appendix II, $V_m=163$ volts and $\omega=377$ radians per second. The op-

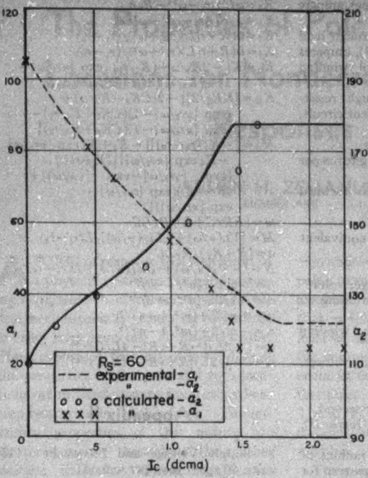

Fig. 8 (left). Calculated and experimental core firing angles versus control current

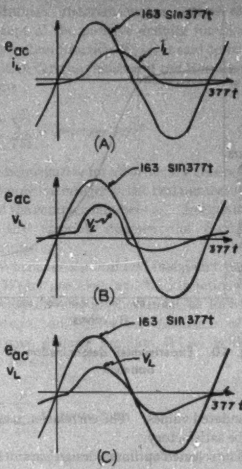

Fig. 9 (right). Experimental waveforms. (Direct tracings from oscilloscope photographs)

A—Load current at full output

B—Load voltage for $\alpha_1=45$ degrees

C—Load voltage at full output

timum value of θ is thus determined as 105 degrees.

The number of gate turns required for a selected core is then determined to permit supporting the amount of volt-seconds as obtained from equation 36 after letting $\alpha_1=0$ and $\alpha_2=\pi$. This yields 1,620 load turns.

The control and bias circuits are designed by the conventional approach based on the core test data information.

No further waveforms need be calculated for the design of the amplifier. A number will be, however, in order to compare the theoretically derived equations with experimental results.

The motor control voltage waveform at maximum output which is calculated from equations 10 and 20 is shown in Fig. 7(A). That which is calculated from equations 8 and 18 is shown in Fig. 7(C).

The motor control voltage waveform for $\alpha_1=45$ degrees is calculated from equations 10, 16, and 20, and shown in Fig. 7(B). The appropriate value of $\alpha_2=143$ degrees was obtained from equation 31.

The firing angle α_1 was calculated for various values of the control current I_c from equation 40; see Fig. 8. The corresponding values of the firing angle α_2, for the above values of α_1, were then found from equation 31 and are also shown in Fig. 8.

A word of caution is in order with regard to the application of equation 40. This equation implies that a quiescent firing angle θ is obtained with zero control ampere turns, as established by the bias ampere turns N_BI_B. The equation further implies that a value for N_cI_c can be found for which $\alpha_1=0$. This will happen when the bias ampere turns are completely counterbalanced by the control ampere turns. The net reset ampere turns for the core are then zero. Such a value of $\alpha_1=0$ would be obtained for a core with a perfect square hysteresis loop. A practical core, not having such a perfect loop, requires some volt-seconds during the gating half-cycle before saturation occurs, when zero reset ampere turns are applied to the core. Hence α_1 can never reduce to zero degrees. A minimum value for α_1 can be calculated if values of maximum flux density B_m and residual flux density B_r for the core are known. The constant mmf core tester[4] gives the necessary information of the core under the appropriate control conditions in terms of a voltage $Vi0$, which is the voltage per turn supported by the core when zero reset ampere turns are applied to it. For the particular core of the present numerical example the value was $Vi0=1.2\times10^{-3}$ volts per turn.

The minimum firing angle is obtained from the following relationship for the average voltage:

$$V_{A0}=\frac{1}{2\pi}\int_0^{\alpha_1}\frac{Vm}{2}\sin\omega t\,d\omega t$$

$$=0.45\frac{Ng}{2}Vio \quad (41)$$

For the numerical values given in Appendix III this yields the value $\alpha_{1\min}$(=21 degrees.

Experimental Investigation

A half-wave push-pull bridge magnetic amplifier, as shown in Fig. 1, was designed and constructed to allow:

1. Investigation of motor current and voltage waveforms.
2. Measurement of the amplifier-motor transfer characteristics.
3. Examination of the selected optimum design parameters.

The details of experimental hardware and data are described in Appendix II.

Actual waveforms of the motor control winding voltage and current for maximum output are shown in Fig. 9(A) and (C), and the motor control winding voltage waveform for $\alpha_1=45$ degrees is shown in Fig. 9(B). These figures should be compared with the theoretical waveforms in Figs. 7(C), (A), and (B) respectively. Generally, a good correlation between the theoretical and experimental waveforms is obtained. The apparent discrepancy between the waveforms at the beginning of the positive half-cycle is explained by the fact that in the calculation of the theoretical curves it was assumed that $\alpha_{1\min}=0$, even though for the particular core tested the calculation shows (see the numerical example above) that $\alpha_{1\min}$ cannot be smaller than 21 degrees. For many high-quality cores $\alpha_{1\min}$ is considerably less than 21. Setting $\alpha_{1\min}=0$ simplifies the calculations considerably.

Core "firing" angles α_1 and α_2 were measured for various control currents and are shown in Fig. 8, together with the

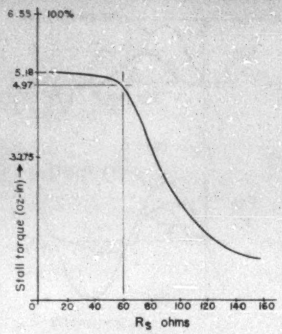

Fig. 10. Experimental determination of R_s optimum

calculated values. The correlation seems to be satisfactory.

The selected optimum design parameter R_s was examined experimentally by observing the indication of the maximum motor torque, while varying the value of R_s, as shown in Fig. 10. The maximum motor torque was observed to rise sharply as the value of R_s was decreased from a value of 150 ohms to the calculated optimum value of 60 ohms, giving 76% rated motor torque output for the latter. For further decrease in R_s, the maximum motor torque increased only very slightly, giving 79% rated motor torque output for values of R_s less than 20 ohms.

Motor output torque versus amplifier input characteristics for the various values of θ were obtained. The calculated optimum angle $\theta=105$ degrees gave the widest linear range.

Summary

The half-wave push-pull bridge magnetic amplifier with a tuned motor load has been investigated. The special behavior of the amplifier under nonresistive load lead to the optimization of amplifier design parameters. The optimization equations are summarized in Table I.

Nomenclature

$AT_A(AT_B)$ = total reset mmf for core A (core B), ampere turns
AT_{bias} = bias mmf, ampere turns
B_m = maximum or saturation magnetic flux density, gausses
B_r = residual magnetic flux
C = capacitance, farads
e_{ac} = instantaneous supply voltage
G_i = "core gain," volts per turn per ampere turn
$i_A(i_B)$ = instantaneous current through load winding of core A (core B), amperes
i_L = instantaneous motor control winding current, amperes
i_R = instantaneous current through resistance of Thévinin's equivalent circuit, amperes
N_cI_c = control mmf, ampere turns
N_L = number of total load winding turns per core
R_g = load winding resistance plus forward resistance of diode, ohms
R_s = limiting resistor, ohms
R_T = resistance of Thévinin's equivalent circuit, ohms
t = time, seconds
Vac = instantaneous supply voltage, volts
$ViA(V_{iB})$ = voltage per turn of winding on core A (core B), rms volts
$V_L(t)$ = instantaneous motor control winding voltage, volts
V_L = average motor control winding voltage, volts
V_m = peak supply voltage, volts
ω = angular frequency, radians per second
$\alpha_1(\alpha_2)$ = firing angle of core A (core B), degrees
γ = a value of $\omega t>\pi$, degrees or radians at which load voltage becomes zero for $\alpha_1=0$ and $\alpha_2=\pi$
θ = quiescent firing angle, degrees or radians
$\phi_A(\phi_B)$ = flux level of core A (core B), webers
$\phi_{PA}(\phi_{PB})$ = preset flux level of core A (core B), webers
ϕ_S = saturation flux, webers

Appendix II

1. Supply Voltage and Frequency: 115 volts, 60 cps (cycles per second)

2. Magnetic Cores
   Size: 1.5-inch inside diameter, 2.5-inch outside diameter, 0.5-inch height
   Material: Hipernik V (50% nickel, 50% iron alloy, grain-oriented)
   Construction: Toroidal cores, wound from 2-mil thick strip
   Core Gain: $G_i=-0.0325$ volt per turn per ampere turn, measured at 60-cps excitation
   Windings:
      Load windings (total per core), 1,620 turns no. 29 AWG (American Wire Gage), 40 ohms
      Control winding, 500 turns no. 38 AWG
      Bias winding, 300 turns no. 38 AWG

3. Servomotor
   Diehl type *FPE 25*
   Voltage rating, 115 volts for reference phase, 57.5 volts for control phase
   Frequency, 60 cps
   Torque at stall, 6.55 inch-ounces
   No-load speed, 3,600 rpm

The Properties of Pole and Zero Locations for Nondecreasing Step Responses

ARMEN H. ZEMANIAN
MEMBER AIEE

A FORM of response to a step input in a physical system is the nondecreasing type, which is of interest to the circuit designer, especially when an overshoot in the step response is objectionable. The purpose of this paper is to discuss the properties of the pole and zero locations of rational system functions whose step responses are of this form. The few known properties of this nature are scattered mainly throughout the mathematical literature. These results are gathered here and presented in a unified manner. Secondly, several other results are developed that are believed to be new. In some cases, the proofs of the following theorems are merely sketched or omitted entirely when they are available in the referenced literature.

This paper is arranged into three parts. In the first part, two well-known theorems from the theory of Laplace transforms are stated, each of which gives a necessary and sufficient condition on the system function that insures a nondecreasing step response. These conditions apply whether or not the system function is rational. In the second part, necessary conditions that the pole and zero locations must satisfy for a nondecreasing step response are given. The third part is concerned with sufficient, but not necessary, conditions on the pole and zero locations that insure a nondecreasing step response. This part constitutes the major portion of this paper and is especially of interest in the design of systems.

Only those rational system functions, whose corresponding responses to input step functions are bounded, will be considered. In particular, the discussion will be restricted to system functions $W(s)$ having the form,

$$W(s)=K\frac{\prod_{i=1}^{h}(s+\eta_i)\prod_{i=1}^{2g}(s+\nu_i)}{\prod_{i=1}^{m}(s+\rho_i)\prod_{i=1}^{2q}(s+\xi_i)} \qquad (1)$$

where $s=\sigma+j\omega$ denotes the complex frequency variable; $-\eta_i$ and $-\nu_i$ denote the real and complex zeros, respectively; $-\rho_i$ and $-\xi_i$ denote the real and complex poles, respectively; and K is a positive constant. It will be assumed throughout that $m+2q>h+2g$ so that there are at least as many poles as zeros. Moreover, the complex poles and zeros of $W(s)$ will occur in complex conjugate pairs and all the poles will have negative real parts. The η_i, ν_i, ρ_i, and ξ_i need not be distinct so that multiple poles and zeros are possible.

The response $a(t)$ to a unit step input function is related to the system function $W(s)$ through the following Laplace-Stieltjes transform.

$$W(s)=\int_0^\infty e^{-st}\,da(t) \qquad (2)$$

As a result of the aforementioned restrictions on $W(s)$, $a(t)$ will be a sum of terms having the form

$$Ct^{\mu-1}e^{-\alpha t}\cos(\beta t+\psi) \qquad (3)$$

where C, α, β, and ψ are real constants with $\alpha>0$ and where μ is a positive integer. In addition, $a(t)$ may also have a constant term. Thus, $a(t)$ is a differentiable function for $t>0$. The condition that $a(t)$ is nondecreasing for $t>0$ is entirely equivalent to the statement that the unit impulse response $w(t)$, which is the derivative of $a(t)$, is nonnegative for $t>0$ and has possibly a positive impulse at $t=0$.

Part I. Necessary and Sufficient Conditions

In a previous paper[1] two realizability theorems were given which insured that an impulse response matrix was obtainable from a linear, fixed, passive n-terminal network. These results were based upon two theorems from Laplace transform theory, Mathias' theorem[2] and Bernstein's theorem; see also theorem 12a, page 160 of Widder.[3] Because of the similarity between the direct and inverse Fourier transforms, these same two theorems may also be applied to determine system functions corresponding to nondecreasing step responses.

Mathias' theorem makes use of the concept of the positive definite function. The system function $W(j\omega)$ is said to be a positive definite function if the Hermitian forms

$$\sum_{i=1}^{p}\sum_{k=1}^{p}W(j\omega_i-j\omega_k)y_iy_k^* \qquad (4)$$

are nonnegative for all arbitrary choices of the positive integer p, the real numbers ω_i, and the complex numbers y_i. In equation 4, the asterisk denotes the complex conjugate.

Whenever the real and imaginary parts of $W(j\omega)$ are even and odd functions of ω, respectively, as they must be for real systems, an equivalent definition of a positive definite function $W(j\omega)$ is that the forms,

$$\sum_{i=1}^{p}\sum_{k=1}^{p}R(\omega_i-\omega_k)x_ix_k,$$

are nonnegative for all arbitrary choices of the positive integer p and the real numbers ω_i and x_i where $R(\omega)$ denotes the real part of $W(j\omega)$.

Under the aforementioned restrictions on $W(j\omega)$, a generalization of Mathias' theorem, which is due to Bochner,[4] may be stated as follows:

Bochner's Theorem: A necessary and sufficient condition for $a(t)$ to be nondecreasing is that $W(j\omega)$ be a positive definite function of ω.

Another such condition is given by the theorem due to Bernstein concerning completely monotonic functions. The real function $W(\sigma)$ of the real variable σ is said to be completely monotonic for $\sigma>0$ if $W(0)=W(0+)$ and if

$$(-1)^kW^{(k)}(\sigma)\geq 0 \qquad (5)$$

for $\sigma>0$ and for all nonnegative integers k. In equation 5, $W^{(k)}(\sigma)$ denotes the kth derivative of $W(\sigma)$. With this notation Bernstein's theorem is the following:

Bernstein's Theorem: A necessary and sufficient condition for $a(t)$ to be nondecreasing is that $W(\sigma)$ be a completely monotonic function for $\sigma>0$.

That Bernstein's theorem may be applied to system functions having nondecreasing step responses has previously been pointed out by Choudhury and

ARMEN H. ZEMANIAN is with New York University, New York, N. Y.

The author wishes to acknowledge the advice of Prof. C. F. Rehberg.

Chakrabarti[5] and by Aaron and Segers.[6] As mentioned previously, these theorems hold for nonrational system functions as well as rational ones. There are several other necessary and sufficient conditions of this type. In particular, the results of Cramér[7] and Khintchine[8] should be noted.

The rest of this paper will be concerned with the pole and zero locations of rational system functions. Necessary and sufficient conditions on these locations for a nondecreasing $a(t)$ have been derived by Macdiarmid[9] and Cutteridge[10] in the special cases where the system function has two or three poles and at most two or three zeros, respectively. The present investigation will consider sufficient conditions on the poles and zeros of $W(s)$, which insure that $a(t)$ is nondecreasing, in the general case where the number of poles and zeros of $W(s)$ is unrestricted. First, however, some necessary conditions for a nondecreasing $a(t)$ will be discussed.

Part II. Necessary Conditions on the Pole and Zero Locations

A set of necessary conditions that was first obtained by Mulligan[11] and subsequently by Lukacs and Szasz[12] and by Takano[13] is given by the following statement:

Mulligan's Theorem: The following conditions on $W(s)$ must hold if $a(t)$ is a nondecreasing function.

1. If $W(s)$ has a complex pole at $-\alpha+j\beta$ where $\alpha>0$, then $W(s)$ has at least one real pole at $-\rho$ such that $\alpha>\rho\geq 0$.
2. If the real pole closest to the imaginary axis occurs at $-\rho$ and if there are complex poles at $-\rho\pm j\beta_i$ $(i=1, 2, \ldots, N)$, then no such complex pole can have a multiplicity greater than the multiplicity of the real pole at $-\rho$.
3. If the poles closest to the imaginary axis occur only at the three points $-\rho\pm j\beta$ and $-\rho$ (so that $N=1$), and if these poles have the same multiplicity μ, then $A\geq 2|B|$ where A is the coefficient of $(s+\rho)^{-\mu}$ and B is the coefficient of $(s+\rho+j\beta)^{-\mu}$ in the partial fraction expansion of $W(s)$.

These necessary conditions may be established by expanding $W(s)$ into partial fractions and then taking the inverse Laplace transformation to get the unit impulse response $w(t)$. If the poles closest to the imaginary axis are all complex, so that condition 1 is not fulfilled, then the asymptotic behavior of $w(t)$ as t increases indefinitely is given by a sum of terms of the form 3 with no constant term. It follows that $w(t)$ must take on negative values so that $a(t)$ cannot be nondecreasing. Similarly, to establish condition 2, consider the case where there are complex poles whose real parts are equal to the real pole closest to the imaginary axis. For each pair of complex conjugate poles in this set of poles, the corresponding terms in $w(t)$ will again be of the form 3, where μ represents the multiplicity of any such pole pair. Hence, the terms in $w(t)$ that dominate as t approaches infinity will be those due to the poles of highest multiplicity in this set of poles. If the real pole is of lower multiplicity than any such complex pole pair, then the asymptotic behavior of $w(t)$ will again be given by terms of the form 3 without any constant term. This again implies that $a(t)$ cannot be nondecreasing. Finally, condition 3 is the special case of condition 2, where $N=1$. In this case the asymptotic behavior of $w(t)$ as t approaches infinity is given by

$$t^{\mu-1}e^{-\rho t}[A+2|B|\cos(\beta t+\psi)]$$

where A and B are defined in condition 3. For this expression to be nonnegative it is necessary that $A>2|B|$.

If we restrict ourselves only to those rational system functions that have no zeros in the finite s plane, then Mulligan's conditions are also sufficient for a nondecreasing step response when the number of poles is no greater than four. This will be demonstrated later. However, his conditions are not sufficient when the number of poles equals five. Takano[13] gives a counterexample.

Other necessary conditions may be derived using the approach given on page 167 of Widder.[3] Let $a(t)$ be nondecreasing and not a constant for $0<t<\infty$. Since

$$(-1)^k W^{(k)}(\sigma)=\int_0^\infty t^k e^{-\sigma t}da(t)$$

$(-1)^k W^{(k)}(\sigma)$ is positive along the entire real axis within the region of convergence for this integral. In other words, if the largest real part of all the poles of $W(s)$ is denoted by $-\delta$, then

$$(-1)^k W^{(k)}(\sigma)>0 \tag{6}$$

for $-\delta<\sigma<\infty$.

Now consider

$$-\frac{d}{d\sigma}\log W(\sigma)=-\frac{W^{(1)}(\sigma)}{W(\sigma)} \tag{7}$$

and

$$\frac{d^2}{d\sigma^2}\log W(\sigma)=\frac{W(\sigma)W^{(2)}(\sigma)-[W^{(1)}(\sigma)]^2}{[W(\sigma)]^2} \tag{8}$$

Because of equation 6, equation 7 is positive for $\sigma>-\delta$. Furthermore, for x_1 and x_2 real and for $\sigma>-\delta$,

$$x_1^2W(\sigma)-2x_1x_2W^{(1)}(\sigma)+x_2^2W^{(2)}(\sigma)=\int_0^\infty (x_1+x_2t)^2e^{-\sigma t}da(t)\geq 0$$

Equality holds only if $x_1=x_2=0$. The fact that this quadratic form is positive definitely implies that, for $\sigma>-\delta$, the numerator of the right hand side of equation 8 is positive so that equation 8 itself is positive. Substituting equation 1 into equations 7 and 8, one obtains:

Widder's Theorem: If $a(t)$ is nondecreasing, then the poles and zeros of $W(s)$ must satisfy the following conditions:

$$\sum_{i=1}^{h}\frac{1}{(\sigma+\eta_i)^k}+\sum_{i=1}^{2g}\frac{1}{(\sigma+\nu_i)^k}<\sum_{i=1}^{m}\frac{1}{(\sigma+\rho_i)^k}+\sum_{i=1}^{2q}\frac{1}{(\sigma+\xi_i)^k} \tag{9}$$

for $k=1$ and 2 and for $\sigma>-\delta$.

As an immediate consequence of this theorem, we have:

Widder's Corollary: If $a(t)$ is nondecreasing, all the real zeros of $W(s)$ must lie to the left of the largest real pole of $W(s)$.

This fact may also be developed from Bochner's theorem as follows. The Laplace-Stieltjes transform, equation 2, may be written as

$$W(\sigma+j\omega)=a(0+)+\int_0^\infty e^{-j\omega t}e^{-\sigma t}w(t)dt \tag{10}$$

where $a(0+)\geq 0$. Now, $e^{-\sigma t}w(t)$ is nonnegative and hence its Fourier transform is a positive definite function by Bochner's theorem. Moreover, the addition of a positive constant will not destroy the positive definite character. Hence, $W(\sigma+j\omega)$ is a positive definite function of ω. A property of such functions is that they are positive at $\omega=0$, except in the trivial case where the function is identically zero, as can be seen by setting $p=1$ in equation 3. Thus, $W(\sigma)>0$ for $\sigma>-\delta$ so that $W(\sigma)$ has no zeros for $\sigma>-\delta$.

Actually, Widder's corollary is a special case of a result due to Laguerre and extended by Widder,[14] which states that the number of changes of sign of $w(t)$ cannot be less than the number of real zeros of $W(s)$ within the region of convergence of the Laplace transformation. This was pointed out to the author by Professor C. F. Rehberg.

Finally, in the case where the number of poles of $W(s)$ equals the number of its zeros $(h+2g=m+2q)$, an application of the initial and final value theorems to equation 1 yields still another necessary condition for a nondecreasing step response. Namely,

$$\prod_{i=1}^{h} \eta_i \prod_{i=1}^{2g} \nu_i > \prod_{i=1}^{m} \rho_i \prod_{i=1}^{2q} \xi_i$$

Part III. Sufficient Conditions on the Pole and Zero Locations

Sufficient Conditions That Are Obtainable from Elementary Rational Functions. In this and the following sections, various sets of sufficient conditions on rational system functions that insure nondecreasing step responses will be presented. The convolution theorem, theorem 11.7b, page 91 of Widder,[3] may then be used to apply these results to a much wider class of system functions. For instance, taking the product of two system functions, $W_1(s)$ and $W_2(s)$, corresponds to taking the convolution of their two step responses, $a_1(t)$ and $a_2(t)$. That is,

$$\mathfrak{L}^{-1}[W_1(s)W_2(s)] = a_1(t)a_2(0+) + \int_0^t + a_1(t-x)da_2(x) \qquad (11)$$

Hence, if $a_1(t)$ and $a_2(t)$ are both nondecreasing, the step response corresponding to the product of $W_1(s)$ and $W_2(s)$ is also nondecreasing. The same result holds for a product of any number of such system functions.

As an example, consider the elementary rational functions given by equations 12 through 16. The step response of equation 12 is nondecreasing and those of equations 13 through 16 will also be nondecreasing if the corresponding inequalities on the pole and zero locations are satisfied.[10]

$$\frac{1}{s+\rho} \qquad (12)$$

$$\frac{s+\eta}{s+\rho}, \quad \eta > \rho \qquad (13)$$

$$\frac{1}{(s+\rho)(s+\xi)(s+\xi^*)}, \; Re\xi \geq \rho \qquad (14)$$

$$\frac{(s+\eta_1)(s+\eta_2)}{(s+\rho_1)(s+\rho_2)},$$

$$\eta_1+\eta_2 \geq \rho_1+\rho_2 \text{ and } \min(\eta_1, \eta_2) \geq \min(\rho_1, \rho_2) \qquad (15)$$

$$\frac{(s+\nu)(s+\nu^*)}{(s+\rho_1)(s+\rho_2)}, \; 2Re\nu \geq \rho_1+\rho_2 \qquad (16)$$

Hence, if a system function is a product of such elementary functions, its step response must also be nondecreasing. It is also possible to establish results of this nature by use of Bernstein's theorem rather than by the convolution integral.[6,15] It should be noted that combining equation 12 with equation 14 shows that Mulligan's conditions are sufficient as well as necessary for a nondecreasing $a(t)$ if the system function has no zeros and no more than four poles.

As was mentioned previously, Macdiarmid[9] and Cutteridge[10] have developed a fairly complete set of necessary and sufficient conditions on the pole and zero locations for rational functions having no more than three poles and three zeros. Of course, any one of these elementary functions may be used as factors for system functions as was done in the previous paragraph. The rest of this paper will consider transfer functions where the number of poles is not in general restricted and, furthermore, it will derive sufficient conditions that do not appear to be obtainable by the use of the convolution integral from conditions on elementary functions.

Sufficient Conditions for a General System Function. The next theorem[16] makes use of the following notation and numbering system for the poles and zeros. The real poles will be numbered according to their increasing magnitudes; that is, $0 < \rho_1 \leq \rho_2 \leq \ldots \leq \rho_m$. All the zeros and complex poles will be denoted by $-\gamma_i$ and numbered according to their increasing real parts; that is, denoting the real and imaginary parts of γ_i by α_i and β_i, respectively, the γ_i are numbered according to $\alpha_1 \leq \alpha_2 \leq \ldots \leq \alpha_n$ where $n = h+2g+2q$. Those γ_i that have the same real part will be numbered in any sequence subject to this restriction. If a ρ_i or a γ_i has a multiplicity of $\mu > 1$, it will be counted μ times.

Two lemmas will be needed. Let $-G(\sigma)$ be the logarithmic derivative of $W(\sigma)$,

$$G(\sigma) = -\frac{d}{d\sigma}\log W(\sigma) = -\frac{W^{(1)}(\sigma)}{W(\sigma)} \qquad (17)$$

$$G(\sigma) = \sum_{i=1}^{m}\frac{1}{\sigma+\rho_i} + \sum_{i=1}^{2q}\frac{1}{\sigma+\xi_i} - \sum_{i=1}^{h}\frac{1}{\sigma+\eta_i} - \sum_{i=1}^{2g}\frac{1}{\sigma+\nu_i} \qquad (18)$$

$$G(\sigma) = \sum_{i=1}^{m}\frac{1}{\sigma+\rho_i} + \sum_{i=1}^{n}\frac{\pm 1}{\sigma+\gamma_i} \qquad (19)$$

In the last expression, the plus sign is used if γ_i is a pole and a minus sign is used if γ_i is a zero.

Lemma 1: If $W(s)$ has no zeros on the positive real axis or at the origin and if the $G(\sigma)$ is completely monotonic in the same interval, then $W(\sigma)$ is also completely monotonic in this interval.

Under the assumed restrictions on $W(s)$, $W(\sigma)$ is nonnegative for $\sigma \geq 0$. With this fact, the work of Aaron and Segers[6] establishes lemma 1.

Lemma 2:

If $x \geq 0$, $y_i \geq 0$, and

$$x \geq \sum_{i=1}^{n} y_i,$$

then, for $k = 1, 2, 3, \ldots,$

$$(x+1)^k + n - 1 \geq \sum_{i=1}^{n}(y_i+1)^k$$

Proof: It is evident that

$$x^k \geq \left[\sum_{i=1}^{n} y_i\right]^k \geq \sum_{i=1}^{n} y_i^k$$

Therefore

$$\sum_{i=1}^{n}(y_i+1)^k = \sum_{i=1}^{n}\left[y_i^k + \binom{k}{1}y_i^{k-1} + \binom{k}{2}y_i^{k-2} + \ldots + 1\right] \geq x^k + \binom{k}{1}x^{k-1} + \ldots + \binom{k}{k-1}x + n = (x+1)^k + n - 1$$

Theorem 1: Let $W(s)$ be a system function of the form 1 and let $m \geq n = h+2g+2q$. If $\rho_n \geq \alpha_n$ and if

$$\sum_{i=1}^{n}\alpha_i \geq \rho_1 + (n-1)\rho_n \qquad (20)$$

then the unit step response $a(t)$ is nondecreasing.

Proof: From equation 20 and the fact that the $\rho_n \geq \alpha_n$, it follows that $\alpha_1 \geq \rho_1$ so that this necessary condition is fulfilled. The inequality 20 may be rewritten as

$$\rho_n - \rho_1 \geq \sum_{i=1}^{n}(\rho_n - \alpha_i).$$

The quantities $\rho_n - \alpha_i$ are nonnegative. Thus, for $\sigma \geq 0$,

$$\frac{\rho_n-\rho_1}{\sigma+\rho_1} \geq \sum_{i=1}^{n}\frac{\rho_n-\alpha_i}{\sigma+\rho_1} \geq \sum_{i=1}^{n}\frac{\rho_n-\alpha_i}{\sigma+\alpha_i}$$

Invoking lemma 2,

$$\left(\frac{\rho_n-\rho_1}{\sigma+\rho_1}+1\right)^k + n - 1 \geq \sum_{i=1}^{n}\left(\frac{\rho_n-\alpha_i}{\sigma+\alpha_i}+1\right)^k$$

Hence,

$$\frac{1}{(\sigma+\rho_1)^k} + \frac{n-1}{(\sigma+\rho_n)^k} \geq \sum_{i=1}^{n}\frac{1}{(\sigma+\alpha_i)^k}$$

Now $\rho_n \geq \rho_i$ for $i = 1, 2, \ldots, n$, so that the last inequality is replaced by

$$\sum_{i=1}^{n}\frac{1}{(\sigma+\rho_i)^k}\geq\sum_{i=1}^{n}\frac{1}{(\sigma+\alpha_i)^k} \tag{21}$$

Moreover, for a pair of complex conjugate poles or zeros,

$$\frac{2}{(\sigma+\alpha_i)^k}>\left|\frac{1}{(\sigma+\gamma_i)^k}+\frac{1}{(\sigma+\gamma_i^*)^k}\right| \tag{22}$$

Finally, differentiating equation 18 k times, one obtains

$$(-1)^k G^{(k)}(\sigma)=k!\left[\sum_{i=1}^{m}\frac{1}{(\sigma+\rho_i)^{k+1}}+\sum_{i=1}^{2q}\frac{1}{(\sigma+\xi_i)^{k+1}}-\sum_{i=1}^{h}\frac{1}{(\sigma+\eta_i)^{k+1}}-\sum_{i=1}^{2g}\frac{1}{(\sigma+\nu_i)^{k+1}}\right] \tag{23}$$

Inserting inequalities 21 and 22 into 18 and 23, it is readily seen that $(-1)^k G^{(k)}(\sigma)$ is nonnegative for $\sigma\geq 0$ and $k=0, 1, 2, \ldots$. Thus, $G(\sigma)$ is completely monotonic in the same interval. Lemma 1 completes the proof.

As an example, consider the system function

$$\frac{(s+2.4)(s+2.4-j)(s+2.4+j)}{(s+1)(s+3)^2}$$

It satisfies the hypothesis of theorem 1 so that the corresponding step response is nondecreasing.

Sufficient Conditions When All the Poles and Zeros Have the Same Real Part. Lukacs and Szasz[17,18] have developed several sets of sufficient conditions for nondecreasing step responses for the special case where all the poles and zeros have the same real part and the imaginary parts of all the poles are integral multiples of the smallest such imaginary part. Their two simplest and, hence, most useful results will be proved in this section. The proofs given here are essentially those of Lukacs and Szasz. However, they are somewhat more elementary in that no use is made of the Vandermonde determinants.

Consider a system function having only simple poles, all of whose real parts are the same. In this section the poles will be numbered by assigning the same subscript to pairs of poles that are complex conjugates of each other. The numbering will increase in accordance with the distance of the poles from the real axis. Thus, the system function may be written as

$$W(s)=\frac{K}{(s+\alpha)\prod_{i=1}^{q}[(s+\alpha)^2+\beta_i^2]} \tag{24}$$

where $\alpha>0$ and $0<\beta_1<\beta_2<\ldots<\beta_q$. The unit impulse response $w(t)$ corresponding to this $W(s)$ is for $t>0$

$$w(t)=e^{-\alpha t}\left[K_0+\sum_{i=1}^{q}K_i\cos\beta_i t\right] \tag{25}$$

where

$$K_0=\frac{K}{\prod_{k=1}^{q}\beta_k^2}$$

$$K_i=\frac{(-1)^q K}{\beta_i^2\prod_{\substack{k=1\\k\neq i}}^{q}(\beta_i^2-\beta_k^2)}$$

From equation 25 it is seen that the unit step response $a(t)$ corresponding to this $W(s)$ will be nondecreasing if and only if the quantity

$$K_0+\sum_{i=1}^{q}K_i\cos\beta_i t$$

is nonnegative. This will be the case under the following conditions.

Lukacs-Szasz Theorem 1: If $W(s)$ is given by equation 24 with $\alpha>0$ and if $\beta_i=i\beta_1$ for $i=1, 2, \ldots, q$ (that is, if the β_i are the first q consecutive, positive, whole multiples of β_1), then $a(t)$ is nondecreasing.

Proof: It is clearly sufficient to establish the result in the case where $K=\beta_1=1$. Expanding the function $(1-\cos t)^q$ into a Fourier series, one obtains

$$(1-\cos t)^q=\sum_{i=0}^{q}c_i\cos it \tag{26}$$

where

$$c_0=\frac{2^q\Gamma\left(q+\frac{1}{2}\right)}{\sqrt{\pi}(q+1)}$$

$$c_i=2(-1)^i\frac{q(q-1)\ldots(q-i+1)}{(q+1)(q+2)\ldots(q+i)}c_0$$

Furthermore, substituting $\beta_i=i$ for $i=1, 2, \ldots, q$ into equation 25, $w(t)$ becomes

$$w(t)=e^{-\alpha t}\sum_{i=0}^{q}K_i\cos it \tag{27}$$

where

$$K_0=\frac{1}{(q!)^2}$$

$$K_i=\frac{2(-1)^i}{(q-i)!(q+i)!}$$

The theorem is proved upon comparing equations 26 and 27, and noting that $w(t)$ is the obviously nonnegative function,

$$w(t)=\frac{\sqrt{\pi}}{2^q(q!)\Gamma\left(q+\frac{1}{2}\right)}e^{-\alpha t}(1-\cos t)^q$$

Lukacs-Szasz Theorem 2: If $W(s)$ is given by equation 24 with $\alpha>0$ and if $\beta_i=(2i-1)\beta_1$ for $i=1, 2, \ldots, q$ (that is, if the β_i are the first q consecutive, odd, whole, positive multiples of β_1), then $a(t)$ is nondecreasing.

Proof: Once again, we need prove the result only for $K=\beta_1=1$. The function $(\sin t)^{2q-1}$ may be expanded into:

$$(\sin t)^{2q-1}=\sum_{i=1}^{q}b_i\sin(2i-1)t \tag{28}$$

where

$$b_i=\frac{(-1)^{i-1}(2q-1)!}{2^{2q-2}(q-i)!(q+i-1)!}$$

Now let $f(t)$ equal $w(t)/\exp(-\alpha t)$. Substituting $\beta_i=2i-1$ for $i=1, 2, \ldots, q$ into equation 25 and differentiating the resulting $f(t)$, one obtains

$$f^{(1)}(t)=\sum_{i=1}^{q}\frac{(-1)^{i-1}K}{2^{2q-2}(q-i)!(q+i-1)!}\sin(2i-1)t \tag{29}$$

Comparing equations 28 and 29, it is seen that

$$f^{(1)}(t)=\frac{K}{(2q-1)!}(\sin t)^{2q-1}$$

However, by the initial value theorem, $f(0+)=0$ for $q\geq 1$. Thus,

$$w(t)=\frac{Ke^{-\alpha t}}{(2q-1)!}\int_0^t(\sin x)^{2q-1}dx$$

This is a nonnegative function.

Using a more general approach, Lukacs and Szasz have proved other results of this nature even in the case where $W(s)$ has zeros having the same real part as that of the poles. The next theorem is an example of this. Unfortunately, most of their other results are quite involved and hence not particularly useful.

Lukacs-Szasz Theorem 3: Let $W(s)$ be of the form,

$$W(s)=K\frac{(s+\alpha)^2+\delta^2}{(s+\alpha)\prod_{i=1}^{q}[(s+\alpha)^2+\beta_i^2]}$$

where $\alpha>0$ and where $\beta_i=i\beta_1$ for $i=1, 2, 3, \ldots, q$. Then $a(t)$ is nondecreasing if and only if $2\delta^2\geq q\beta_1^2$.

Before leaving this section another technique for determining a nondecreasing step response will be noted. For this approach the zeros need not have the same real part but may lie anywhere in the s plane and be of any multiplicity. However, if all the poles are simple, have the same real part, and outnumber the zeros and if the imaginary parts of all the poles are whole multiples of the smallest, positive, imaginary part of the poles, then the unit impulse response is of the form

$$w(t)=e^{-\alpha t}\, g(t)$$

where $g(t)$ is a cosine polynomial. To determine whether $a(t)$ is nondecreasing, one need only establish the nonnegativity of $g(t)$. J. F. Schultze[19] has given a variety of criteria on the coefficients of $g(t)$ which insure that $g(t)$ is nonnegative. However, in order to use these criteria one must first determine the coefficients of $g(t)$. Hence, this approach is not as useful as the criteria on the pole and zero locations if it is these locations that are known beforehand.

The Case Where All the Poles Are Real and There Is at Least One Pair of Complex Conjugate Zeros. According to Mulligan's theorem and Widder's corollary, the real zeros and complex poles must not lie to the right of all the real poles if the step response is to be nondecreasing. However, this is not the case for the complex zeros. As a simple example, consider the system function having a pair of simple zeros at $s=\pm j\beta$ $(\beta>0)$ and a triple pole at $s=-\rho$ $(\rho>0)$.

$$W(s)=\frac{s^2+\beta^2}{(s+\rho)^3} \tag{30}$$

The corresponding unit impulse response for $t\geq 0$ is

$$w(t)=e^{-\rho t}\left[\frac{\rho^2+\beta^2}{2}\, t^2-2\rho t+1\right] \tag{31}$$

This expression is nonnegative if and only if $\beta\geq\rho$. Hence, by choosing β large enough, the impulse/response can be made nonnegative.

Brule[20] has developed a precise result of this nature in the case where all the poles are real, the pole furthest to the right being simple, and where there are no zeros other than one pair of complex conjugate zeros. He shows that, if the magnitude of the imaginary part of the zeros is larger than a certain quantity, the corresponding impulse response will be nonnegative.

The possibility of generating a nondecreasing step response by choosing the imaginary part of the complex conjugate zeros large enough exists for more general system functions. For instance, given any system function having only real poles and only complex zeros, the step response can always be made nondecreasing without changing the real parts of the zeros simply by placing the zeros far enough away from the real axis. The same statement can be made even when there are real zeros so long as the step response corresponding to the real poles and real zeros alone is nondecreasing. Such behavior can be expected since indefinitely increasing the imaginary parts of the zeros moves them out toward infinity resulting in a system function whose step response is nondecreasing. This result may be established as follows:

Theorem 2: Let

$$W(s)=[(s+\alpha)^2+\beta^2]F(s) \tag{32}$$

where $\beta>0$, α has any real value, and the poles of the rational function $F(s)$ are all real. Also, let the poles of $F(s)$ outnumber its zeros by at least three. If the step response corresponding to $F(s)$ is nondecreasing, then the step response corresponding to $W(s)$ will be nondecreasing for β sufficiently large.

Proof: Replacing $s+\alpha$ by s corresponds to multiplying the impulse response by exp (αt). This will not change the sign of the impulse response at any point. Hence, it is sufficient to establish that the impulse response is nonnegative in the case where α equals zero. Such a shift in the pole and zero pattern may place real poles on the positive real axis but this is of no consequence in the following argument.

Denote the unit impulse response of $W(s)$ and $F(s)$ by $w(t)$ and $f(t)$, respectively. Since the poles of $F(s)$ outnumber its zeros by at least three, $f(0+)$ and $f^{(1)}(0+)$ are both zero. Hence, by equation 32, wherein $\alpha=0$,

$$w(t)=f^{(2)}(t)+\beta^2 f(t) \tag{33}$$

Now, $f(t)$ is a finite sum of terms of the form,

$$A_i t^{\mu_i-1}\, e^{-\rho_i t} \tag{34}$$

where A_i and ρ_i are real and μ_i is a positive integer. Since $f(t)$ is nonnegative, there is a value of time T beyond which $f^{(2)}(t)$ is positive, except possibly in the case where the real pole of $F(s)$ furthest to the right is at $s=0$ and is of single or double multiplicity. Hence, by equation 33, $w(t)$ is positive for $T\leq t<\infty$ and for all $\beta>0$. In the exceptional case the same conclusion follows since $f^{(2)}(t)$ becomes arbitrarily small with respect to $f(t)$ as t approaches infinity.

Furthermore, $f^{(1)}(t)$ is again a finite sum of terms of the form 34. This function is analytic for all finite t, considering t to be a complex variable. But the zeros of any analytic function are isolated[21] and hence $f^{(1)}(t)$ can have only a finite number of zeros on the real interval $0\leq t\leq T$. Therefore, $f(t)$ has only a finite number of maxima and minima for $t\geq 0$ and there are only a finite number of points at which $f(t)$ is zero.

In the neighborhood of each minimum of $f(t)$, $f^{(2)}(t)$ is nonnegative. Since $f(t)$ is also nonnegative, a positive number A, sufficiently small, can be found such that, for all intervals within which $0\leq f(t)<A$, $f^{(2)}(t)$ will be nonnegative. Denote this finite set of intervals by I. By equation 33, $w(t)\geq 0$ for t in I.

Moreover, $f^{(2)}(t)$ is a bounded function in $0\geq t\geq T$. Let $-B$ $(B>0)$ be a lower bound on $f^{(2)}(t)$. In the complement of I with respect to $0\leq t\leq T$, $f(t)\geq A>0$ and $f^{(2)}(t)>-B$. So by equation 33, $w(t)\geq -B+\beta^2 A$. Thus, for $\beta^2>B/A$, $w(t)$ will be nonnegative in the complement of I and hence for all t. This completes the proof.

An immediate consequence of theorem 2 is that, starting with a nondecreasing step response, we may generate another nondecreasing step response by adding any number of pairs of complex zeros so long as the resulting system function has more poles than zeros and the imaginary parts of the added zeros are large enough.

It should be noted that the result given by theorem 2 can be stated in the case where $F(s)$ is allowed to have complex poles if one is not interested in the behavior of the step response after it remains within some given deviation ϵ from its final value. This is the situation in any practical instance. In this case a time T can be found beyond which $|a(t)-a(\infty)|<\epsilon$. In the time interval, $0\leq t\leq T$, $f(t)$ will have only a finite number of points where it is zero and the preceding proof for the interval, $0\leq t\leq T$, applies in exactly the same way. This may be stated as follows:

Corollary 2a: Let

$$W(s)=[(s+\alpha)^2+\beta^2]F(s)$$

where $\beta>0$, α has any real value, and the poles of the rational function $F(s)$ outnumber its zeros by at least three. Also, let the step response corresponding to $F(s)$ be nondecreasing in the interval $0\leq t\leq T$. Then, the step response corresponding to $W(s)$ can be made nondecreasing in the same interval by choosing β sufficiently large.

The Lukacs-Szasz theorem 3 serves as an example of this corollary. In this case T may assume any finite value.

Appendix

Elgerd and Stephens[22] have computed a large number of transient responses corresponding to a variety of pole and zero patterns. Some of these serve as examples for the foregoing results.

Static Control for a Mechanically Regulated D-C Supply

H. J. ABRAMS
NONMEMBER AIEE

J. F. BRUBAKER
MEMBER AIEE

A NEW APPROACH to automatic voltage control of a regulating transformer was sought in conjunction with a rectifier transformer and semiconductor rectifying elements connected in a 6-phase double-way circuit. Conventional control for a load tap changer is not designed to detect and correct for fluctuations directly in a d-c line, yet close control of the voltage across the 40-kv rectifier output was required for a radar pulsing station. The alternative of a-c sensing at a point just ahead of the rectifier transformer was considered but this was abandoned due to the problems of reactive drop compensation.

This paper is intended to lay the background for and to describe the method by which the problem was solved with the design of a new d-c sensing control, using two high-gain transistor-magnetic bistable amplifiers and a varistor-detector. Power gains of 10^8 with 20-millisecond response time and a drift level of 10^{-8} watts in the bistable amplifier reduced the system accuracy to that of the varistor-detector. Nevertheless, over an ambient temperature range of 25 to 55 degrees centigrade the trip-point accuracy of the system can be held to better than 0.1%. The success of the control may set the trend for other applications where the output to be controlled is direct current. The low-voltage tap on a bleeder resistance bank across the 40-kv line is the link that made the application of this control possible. There is no foreseeable difficulty in controlling voltages up to 300 kv by the same technique.

Over-all System Operation

Function of Regulating Transformer

To describe clearly the nature of the over-all problem it would be well first to review the function of regulating transformers as a class. In power apparatus a regulating transformer (synonomous with power regulator) is distinguished from the familiar step-up or step-down power transformer in that its ratio is not fixed but rather is variable within certain limits, usually ±10%. Its kilovolt-ampere parts are determined in general by its range of regulation relative to the kilovolt-amperes of the system. Regulation is made possible by one or more automatically controlled 32-step load tap changers interconnected with the windings of the regulating transformer.

In the case under discussion the range of regulation is extremely high by normal standards, inasmuch as the output voltage must be variable within limits of zero and 100% of the 4,160-volt 3-phase sup-

ply system voltage, with an additional extension to take care of a possible ±5.0% variation in the supply. In Fig. 1, a simplified block diagram of the basic system components, the regulating transformer may be thought of as representing three separate cores housed within a single oil-filled case. These cores and associated windings are identified by function as: 1. the exciting autotransformer, 2. the series transformer for the coarse tap changer (so named because of the relatively large 2.5% voltage changes per step), and 3. the series transformer for the vernier tap changer (so named because of the relatively small 1.0% voltage changes per step). The output of the regulating transformer is applied to a step-up rectifier transformer capable of maintaining a maximum of 40,000 volts at 840 kw on the d-c side of a rectifier.

FUNCTION OF AUTOMATIC CONTROL EQUIPMENT

It is the function of the automatic control equipment to provide intelligence for correct operation of the load tap changers in accordance with a predetermined operational sequence, and subject to load demands. The special nature of this particular system's operation requires that there be three stages of automatic control, each initiated directly or indirectly by external events.

1. *Start-Up Stage.* Load voltage is raised from a predetermined minimum to the approximate operating level in about 25 seconds of elapsed time after closing of the load breaker. The coarse tap changer automatically stops when the preset manually selected tap has been reached.

2. *Operating Stage.* The control transfers to an automatic voltage-regulating unit which employs the vernier tap changer to maintain finer control of output voltage and to compensate for fluctuations in the supply. The voltage level to be maintained is preselected manually for the control unit.

3. *Shut-Down Stage.* Upon tripping of the load breaker, control shifts once more to the coarse tap changer and lowers the voltage to the predetermined minimum value. It is then ready for possible recycling.

VOLTAGE CONTROL DURING OPERATING STAGE

This paper concerns itself primarily with the operating stage as described in item 2, during which the control must continually measure changes in load voltage, and correct for them automatically within the range of the vernier tap changer. In power regulator applications voltage is seldom detected at the true load center. An accurate image of the load-center voltage is available at the output of the regulator through the use of a compensator to simulate line drop at any given load. Thus, if voltage must be maintained at point *B* but detected at point *A* in Fig. 1, a compensator is required with values of resistance and reactance chosen so as to represent the resistance and commutating reactance associated with the d-c load and the rectifier transformer. This is the conventional solution to the problem and, for the ideal case of a given number of rectifiers fed from a common supply system, it would fall within the capabilities of conventional a-c voltage-regulating relays and compensators.[1]

Choosing Voltage-Sensing Method

Consider two alternatives facing the designer at an early point in the planning of the voltage control:

1. Employment of conventional a-c sensing at point *A* in Fig. 1 with a compensating device to provide an a-c image of the d-c output at point *B*.

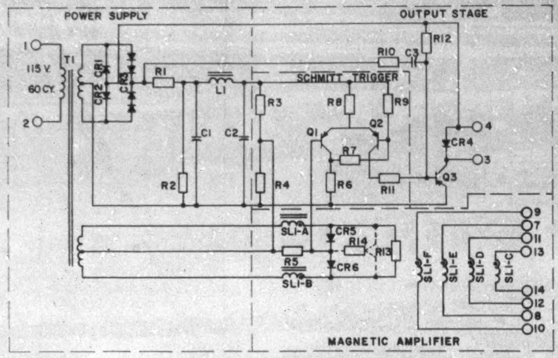

Fig. 5. Schematic diagram of bistable amplifier

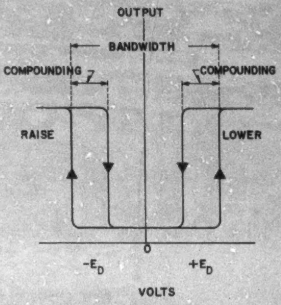

Fig. 7. Bandwidth and compounding characteristics of control system

2. Design of a new control for sensing the d-c output at point *B* through a bleeder tap.

Indirect Sensing of D-C Output

Two advantages stand out immediately in favor of alternative 1. The a-c control is standard and available. Furthermore, complete isolation from the line voltage is afforded by the connection of a potential transformer at point *A*. An obstacle looms, however, in the choosing of compensation constants to simulate the reactive drop of the circuit. This arises from the certainty that in system operation a varying number of in-phase rectifiers will be fed from the common a-c source. Thus the effective commutating reactance[2] to be considered is not a predictable constant but is instead dependent on the number of rectifiers being supplied simultaneously through the common source reactance. With alternative 1 it is therefore not possible to produce an accurate image of the d-c output for an individual rectifier at all possible values of the total system load.

Direct Sensing of D-C Output

The choice of alternative 2 eliminates the need for compensation, thus focusing attention entirely on the development of a control sensitive to average voltage deviations in the 40-kv d-c output.

Fig. 2 illustrates in block form the arrangement of components used to provide this type of control. Advantage is taken of the availability of a bleeder-resistance bank *R* in shunt with the 40-kv line and having a 1.0% tap for metering purposes. An arrester is connected between this 400-volt tap and ground to protect the sensing circuit from accidental overvoltages. Remote switchboard mounted voltmeter *V* and potentiometer *R2* facilitate the selection of the desired output voltage within a specified range. Resistor *R1* limits the voltage obtainable across *R2* to a value well within the limitations of the sensing unit.

There is no output from the voltage-sensing unit when the input is exactly 200 volts. A signal is delivered to the motor-control relays of the vernier tap changer only when the deviation is greater than the bias setting of either the raise or the lower bistable amplifier. The effect of tapping in more resistance at *R2* is to maintain a lower voltage level on the main rectifier output. Conversely, tapping out more resistance at *R2* has the effect of maintaining a higher output level.

The D-C Sensing Control

The d-c sensing control system is similar to the well-known balanced beam type of relay control, except that all static components are used. Attempts to use as many standard components as possible were very successful. The detector and bistable amplifiers are off-the-shelf items, but coupling networks had to be designed and a few adjustment potentiometers included for the compounding and bandwidth adjustments. The basic system, Fig. 3, consists of a varistor-detector circuit which has a null output at 200 volts; see Fig. 4. When the d-c input exceeds 200 volts, the output of the

* See Fig. 3.

detector will be a positive voltage. Two bistable amplifiers are biased so that an adjustable dead zone is located around the zero axis. The bistables offer a 20,000-ohm load to the detector. With this load the gain of the detector is about 0.4 volt per volt. Thus, if the input voltage should increase 4 volts, a 1.6-volt signal will be fed into the bistable. This is more than sufficient to actuate the lower bistable, which switches from the off to the on state. This in turn causes the vernier tap changer to function and to lower the voltage as many steps as necessary to return the high voltage to the desired output value. If the input voltage is lower than 200 volts, the raise bistable will be actuated in a similar manner.

A varistor-detector with a relatively high operating voltage for null output was chosen. Its null point is temperature-compensated.

The bistable amplifiers, Fig. 5, in this control combine the advantages of both magnetic amplifier and transistor circuitry.[3] The input stage of the bistable amplifier is a half-wave push-pull magnetic amplifier. This, in turn, drives a transistor Schmitt trigger.[4] A Schmitt trigger is a flip-flop circuit which has two stable states, either on or off. The trigger may be adjusted so that with zero control it may be either at full output or zero output. An output transistor power stage, which is switched by the Schmitt trigger, delivers 24 volts at 210 milliamperes full-wave rectified direct current. Since the first stage is a half-wave push-pull magnetic amplifier, low drift and fast responses are assured. The output of the magnetic amplifier stage around null is a spike of positive or negative voltage. This voltage spike is used to trigger the transistor circuit into the on or off steady-state condition. A very small amount of power is necessary to change the spike from positive to negative, since the change in the average power output of the magnetic amplifier is extremely small. At a maximum of $1^1/_2$ cycles' delay, power gains as high as 10^3 may be obtained with this device; see Fig. 6.

A zener-diode reference circuit is used to supply the bias to the bistable amplifiers so that they can be biased away from the null point of the detector to any degree of bandwidth desired.

CONTROL ADJUSTMENTS

Sensitivity adjustments are made by changing the regulated bias signal to each bistable. This control is accessible from the front of the d-c sensing panel and it permits adjustment of the regulator bandwidth. The regulator bandwidth, as shown in Fig. 7, is the change in voltage between the pickup voltages, of the raise and lower bistables. The range of adjustment is from ±0.2% to ±5.0% of the input voltage. Controls for changing the feedback to each bistable amplifier are also available at the panel. This allows the compounding to be changed from 0.1% to 5.0% of the operating voltage. Compounding is defined here as the change in voltage E_d necessary to move from the on to the off state of either bistable amplifier.

PERFORMANCE

The performance just described can be realized with a ±5.0% change in the voltage and a ±3-cycle change in the frequency of the station control supply. Since the control will be located in a temperature-controlled environment, the ambient temperature will be held between 20 and 55 degrees centigrade. There is

Fig. 8. Front view of d-c sensing control panel, showing sensitivity control centrally located between controls for compounding adjustments

Fig. 9. Rear view of d-c sensing control panel, showing zener-diode reference, varistor-detector, and output relay cases mounted between the bistable amplifiers

essentially no change in performance over this temperature range. The complete control was not tested over a wide ambient temperature range, but the detector and the bistable amplifiers have been shown capable of operating over a much wider temperature range with very low drift levels.

A sample design will show that the null drift of the detector circuit and the percent voltage change per tap change are the limiting factors of the system accuracy. With a 200-volt E_{in} input to the detector, the detector's output voltage E_d will be zero. From Fig. 4 it may be seen that with a 20,000-ohm load, the detector's gain will be 0.4 volt per volt. If a 0.1% system were desired, it would be necessary to actuate the raise or lower voltage bistable with a ±0.2-volt change in E_{in}. With a detector gain of 0.4 volt per volt, the change in E_d for a 0.2-volt change in E_{in} is 0.08 volt.

From Fig. 6(B) it may be seen that, with a 400-turn control winding and a 20,000-ohm input impedance, it is possible to have compounding equal to 30 millivolts. The compounding power P_c, or the power necessary to move from the on to the off state is

$$P_c=\frac{(0.03)^2}{20{,}000}=4.5\times10^{-8}\text{ watts}$$

If the on point of each bistable is biased so that it takes a 0.08-volt change in E_d to turn it on, it would be possible to achieve a system with ±0.1% bandwidth and 0.038% compounding.

The foregoing analysis, of course, does not take into account the drift in the detector or that the value of the voltage change per tap is 1.0%. The use of such a low trip-point accuracy in conjunction with a tap changer having 1.0% steps would result only in unnecessary operations, known as tap-changer hunting. Consequently, the bandwidth setting recommended for this application is ±1.5 volts E_{in}, giving a system accuracy of 0.75%. Table I shows actual data on this system, tested with various line voltages and frequencies. The null characteristic of this particular varistor-detector varies somewhat from that shown in the typical curve data of Fig. 4.

The simplicity and compactness of the control is evident from an examination of Figs. 8 and 9. The panel assembly measures 10$^1/_2$ inches high, 11 inches wide, and 7 inches deep, thus comparing favorably in size with corresponding a-c sensing controls.

Conclusions

From standard static components a workable d-c sensing control has been developed that shows good promise. Its basic element is the bistable amplifier, acting as a sensitive relay in an on-off system for raise and lower voltage control. A varistor-detector, operated from a bleeder-resistance bank, senses changes in the output of a d-c power supply to trigger the amplifier. Fast response, widely adjustable bandwidth and compounding, and a low drift level in respect to varying ambient temperature and supply voltage and frequency, make it particularly suitable when it is used in conjunction with a regulating transformer feeding the rectifier-filter supply system for a radar pulsing station.

In addition to radar, this control is suitable to a wide field of other rectifier applications, including sonar, as well as equipment for proton acceleration. Rectifier systems presently deal in d-c outputs from 10 to 300 kv and in power levels as high as 3,000 kw. The control is not limited to regulators of the step type but may be used in a wide variety of applications where the output to be controlled is direct current.

Data Processing as a Tool for Generalizing Communications Systems

WILLIAM F. LUEBBERT
NONMEMBER AIEE

AUTOMATIC data processing is a tool for transforming, processing, and calculating information. If one accepts this fact, one should be prepared to describe the fundamental capabilities of automatic data processing. Since communications is itself a tool, it is instructive to attempt to describe its fundamental nature in a similar frame of reference and compare the two. The results of such a simple analysis lead to a viewpoint which has important implications on system and equipment design.

The fundamental capability of data-processing equipment can be described as the ability to transform information into more desirable or useful forms. From the same viewpoint, the fundamental capability of conventional communications equipment can be described as the ability to transfer information to a more desirable or useful location. Of course, from an abstract-logical viewpoint a transfer is merely one special kind of transformation, one in which only physical location is changed. Combining these descriptions, one is led to the concept of a generalized data-handling system capable of performing generalized transformations, of which conventional one-location data processing would be one special case and conventional no-processing data transmission would be another special case. In such a system there would be no fundamental distinctions between data processing and data transmission, but only distinctions of convenience based upon application, use, and design emphasis.

An examination of the information flow and manipulation in typical data-processing and communication equipments shows almost immediately that there is a very considerable mixture of functions going on in both types of equipment. A considerable amount of the activity going on inside any computer or data processor consists of simple transfers of information from one part of the processor to another.

At the same time within communications equipment a major part of the activity concerns generation, manipulation, and other processing of information used for control, supervisory, and error reduction purposes. In many cases nearly identical operations go on in both data-processing and communications equipments, with the differences, if any, being matters of design emphasis based upon application and use.

Is such a concept a reasonable one, and does it have any practical utility? The answer to the first part of this question will be examined in detail in this paper. Whether this concept has practical utility will be determined by the success in actual use of the equipment and system concepts it generates, which are receiving initial implementation in the FIELDATA family of equipments. These concepts are explained in this paper.

It is conventional to consider communications systems as consisting of three types of subsystems: subscriber, central-office, and transmission subsystems. The impact of automatic data-processing equipment, techniques, and concepts upon each of these three kind of subsystems will be illustrated by discussions of three topics:

1. The impact of data processors at subscriber locations, with particular emphasis upon the effects of processors upon the amount of communications required to meet user demands.
2. The impact of data processors on central office activities such as circuit of message switching.
3. The impact of data processing upon the design of data terminals which include transmission capabilities.

Impact of Data Processors at Subscribers' Locations

Experience to date shows that the introduction of data-processing equipment is often accompanied by an explosive increase in communications requirements. In part, this is due to the voracious appetite of data processors for current, up-to-date information in applications which take advantage of their abilities to process vast amounts of information economically. In part, it is because their tremendous speed of processing compared to the speed of human processors dramatically changes time factors in an over-all data-handling cycle.

For example, if a given report prepared by nonautomated techniques requires 45 days for its preparation, a delay of 3 or 4 days consumed in sending the raw data by mail is hardly noticed. However, if a data processor requires only one day to prepare the report from the raw data, this same 3- or 4-day delay in the mail becomes the overwhelming factor determining over-all report preparation time, and an obvious bottleneck. Clearly if the report is an important one, badly needed for effective planning, there is a strong tendency to demand better communications service to eliminate the bottleneck. Hence, considerable amounts of data once transferred by mail are frequency added to the electrical communications requirements.

This mushrooming of communications requirements is not, of course, an inevitable result of the adoption of data processing. On the contrary, one of the most attractive features of data processors to the communicator is their ability to process and reduce raw data to a more concentrated form, boiling out those portions which are irrelevant, redundant, or insignificant, so that the communications system and its human users need not be burdened. If a data processor is used to reduce data to one tenth of its raw form, it may then be used to reduce communications required to transmit that data by the same factor. Thus, data processors acting as data reduction devices located at an entry point of data into a communications system may be a particularly valuable tool for preventing large sources of raw data from overloading a communications system with excessive demands for service.

Of course, the same increased speed of processing by machines which disrupts the balance of many processing communications cycles, thus increasing the demand for electrical communications, may under other conditions have the opposite effect. If the key factor in a situation is the achievement of a fixed delivery deadline and the processing time is reduced, then the processing time saved becomes

---

Paper 59-1093, recommended by the AIEE Data Communication Committee and approved by the AIEE Technical Operations Department for presentation at the AIEE Fall General Meeting, Chicago, Ill., October 11–16, 1959. Manuscript submitted May 11, 1959; made available for printing June 26, 1959.

WILLIAM F. LUEBBERT, formerly with the U.S. Army Signal Research and Development Laboratory, Fort Monmouth, N. J., is with the United States Military Academy, West Point, N. Y.

available for communications. For example, if a 15-day deadline exists and 14 of those days are required for manual processing of data, then only one day is available for transmittal of the information, and electrical transmission may be necessary to meet the deadline. However, if an automatic data processor can prepare the information in 2 days, the remaining 13 days allow ample time for transmittal of the information in more routine fashion by mail or messenger, thus reducing the demand for electrical communications.

Whether the factors tending to increase communications requirements or those tending to decrease them are dominant in a particular case when automatic data-processing is introduced is, of course, not so much a function of the data-processing equipment as it is of the situation, and the concepts and techniques of employment of the equipment.

Which of these factors become dominant in a particular case when data-processing equipment is introduced is not so much a function of the equipment used as it is of the concepts and techniques of employment used. The equipment will have an impact upon communications requirements, but it is only a tool, and the user and his method of employment of this new and powerful tool will, in the final analysis, determine what its impact will be.

Data Terminals

Many practical cases of the close interrelation of transmission and processing functions are immediately obvious in the area of devices used for data entry and output. For example, computers frequently use paper tape readers similar to those used in teletypewriter transmitter distributors, and paper tape punches that could easily be used in teletypewriter reperforators. Similarly, the idea that various kinds of input-output devices such as card readers and punches and magnetic tape transports, widely used for data processing, can effectively be adapted for the use of communications lines is also being exploited in equipments such as the IBM (International Business Machines Corporation) Transceiver, the Collins Kinetape, etc.

FIELDATA emphasizes this kind of exploitation to the extreme, particularly encouraging it by assuring that interconnection of semiautonomous equipment modules be made in accordance with common standards, regardless of whether these equipments are conceived primarily for computer-associated or transmission-associated functions. This makes it possible for the same data terminals to operate with not only the data-processing type of inputs and outputs (such as computers, paper tape, magnetic tape, and IBM cards) but also with real time weapons system data, and with telegraphic data.

Control circuitry is so devised that pure binary as well as alphanumeric (alphabetic-numeric) data may be handled. Since any digital code, be it Baudot (teletypewriter), Holerith (IBM card), or any of a wide variety of computer codes, may be represented in binary bit-by-bit form, the FIELDATA devices have the potential of transmitting or handling any type of digital data. Thus they could be used with digitized voice, digitized facsimile, or other types of digitized analog signals.

The use of common standards, codes, and standard data rates makes possible the kind of data transmission equipment concept which leads naturally to a division of the subassemblies of data transmission equipment into three kinds:

1. *Input-Output Transducers.* These are devices for converting information from some human- or machine-usable form such as paper tape, magnetic tape, punched cards, analog electrical voltages, strokes on a keyboard, etc., into digital form.

2. *Transmission Transducers.* These are devices for converting data in digital form into appropriate signals for transmission over radio, wire, or other kinds of propagation media.

3. *Embolic* Equipment.* This is equipment which is normally inserted between input-output transducers and transmission transducers; it is used primarily to perform control and supervisory functions, error detection and/or correction, buffering and/or speed conversion, code conversion, or encryption necessary for proper system operation of the data transmission equipment. The functions of embolic equipment are information-processing functions. Inputs and outputs will both be digital in form although supplementary analog information may also be available particularly in some kinds of error control schemes. A general purpose computer is potentially a very powerful and flexible type of embolic equipment, but the necessary functions can often be performed much more economically by specialized equipment.

This division of subassemblies may be a physical division into separate items of equipment, or into semiautonomous parts of a single equipment (either in separate boxes or in a single box), or it may be merely conceptual with no physical implementation.

Obviously, maximum flexibility and adaptability can be achieved if any input-output transducer can operate with any transmission transducer. This permits one to tailor an equipment to meet the requirements of a particular situation. It permits one to choose the in-out device suitable for the user's most convenient data form (paper tape, magnetic tape, IBM cards, etc.) independently of the nature of the transmission facility available. One can then choose the transmission transducer on the basis of the transmission medium used (very-high-frequency radio relay, high-frequency radio, loaded cable, carrier transmission on wire, etc.) independently of the user's data form. Then the two are joined together to advantage of common standards of interconnection or intercommunication between modules and to create a well-tailored combination.

The question then arises, "Why embolic equipment?" Certainly, by proper choice of common interconnection or intercommunications characteristics, one can minimize requirements for code conversion, buffering, speed conversion, etc. Ideally, one should be able to join the input-output transducer to the transmission transducer without embolic equipment, so why have it? The answer is that there are three important functions in a data terminal which seem convenient, to separate from both in-out transducers and transmission transducers: communications supervision, error control, and cryptographic security.

Supervisory functions are conveniently separated from the input-output transducers and the transmission transducers because supervisory requirements may be strongly influenced by both. Error control requirements may also be strongly influenced by both the in-out data and the transmission situation, and may even in some cases not be desired at all. Thus, it is best treated as a module which can be tailored to the paired requirements of in-out and transmission or completely omitted. Cryptographic security is conveniently a separate module so that it may be omitted in those cases where security is not required or desired.

Primary and Secondary Information

To discuss supervisory activities conveniently it is desirable to make a distinction between two kinds of information which flow through a communications system primary and secondary information.

---

* A coined term from the Greek *embolisimos*, to put between or insert. The word is also used in medical, astronomic, and ecclesiastic literature to describe other specific kinds of intercalations.

Primary information is that information which a user wishes transferred to another location, i.e., the information to be communicated.

Secondary information is that information added to the primary information either by the originator or by equipment of the communications system which is used to perform functions of supervision, routing, error control, and related activities necessary or desirable to permit the primary data to be effectively communicated. This information is used by communications equipment and personnel and is normally of no use or interest to the ultimate recipient of the primary information.

A basic requirement for maximum flexibility and adaptability is that the user, who enters data at an input device and receives data at an output device, need not be required to exercise judgment or knowledge, to perform special activities, or to use or interpret secondary information. This, in turn, makes it desirable to isolate secondary information from the input-output devices, which are the users' point of contact with the communications system. A convenient way of establishing and enforcing this isolation is the creation of a distinct embolic module which generates, receives, interprets, and/or acts upon secondary information and passes on action requirements derived from this secondary information over local control lines to its associated input-output transducer and transmission transducer. It is important to note that such an equipment need not have any ability to interpret or act upon primary data, and thus its operation can be made completely independent of the coding used for primary data so long as there is a unique method of distinguishing primary from secondary data.

In the FIELDATA family of equipments the segregation of primary and secondary data is accomplished in a particularly simple way by providing separate transmission symbol "alphabets" for primary and secondary data. The basic unit of data in FIELDATA codes is a 6-bit character. For primary data this may be merely a 6-bit block with no specific meaning assigned to specific bits within it, and no restrictions on the permissible code combinations which may be transmitted. If this information is alphanumeric in form so that specific bit meanings must be assigned for electric typewriters, printers, and similar input-output transducers to operate, then the FIELDATA alphanumeric code given in Appendix I is used. A similar but distinctly different 6-bit FIELDATA supervisory data code has also been created; see Appendix II. In situations where both FIELDATA primary data and FIELDATA supervisory code data might appear on the same six lines, the same six channels of tape, etc., a seventh bit is added to provide unique distinction. This seventh bit is normally a binary ONE for primary data and a binary ZERO for supervisory data. If, on a particular recording medium such as paper tape or on a particular kind of transmission channel, adequate reasons exist for tagging the difference between these two symbol alphabets in some other way, then other methods could be used. All secondary information except error control redundancy is handled by the FIELDATA supervisory data code in FIELDATA equipments.

The number, variability, and difficulty of measurement and analysis of the various factors which contribute to the frequency and interrelationships of transmission errors or particular circuits is staggering. At present, the state of the art is such that only crude estimates of frequency of error can be made for typical equipments when they are exposed to disturbances other than gaussian noise, and that practically nothing can be estimated in advance about the interrelationships of error under practical conditions of impulse noise, crosstalk, propagation variations, etc.

This is particularly unfortunate because the effectiveness of the various digital error control schemes available is strongly dependent upon the interrelationships of errors. For example, a simple parity check is capable of detecting single errors but not double errors. If errors occur randomly, double errors will seldom occur and this very simple check will be quite powerful. Thus, if the bit error rate is 10^{-4}, a simple parity check will reduce the undetected error rate to 10^{-8}. On the other hand, if errors tend to be clustered, a parity check will be rather ineffective. Thus, if the conditional probability of a second error immediately following the first is 0.5 and the bit error rate is 10^{-4}, then a parity check will reduce the undetected error rate to only 0.5×10^{-4}. Given knowledge of the interrelations, checks can be designed which give high protection with a minimum amount of checking equipment. Unfortunately this knowledge is usually unavailable.

If the most important sources of errors occur in a data communications link, is it proper to incorporate the major error control features of the link into the transmission transducers? The FIELDATA concepts answer this question with a very definite "No." The key reason for this is that while the *occurrence* of errors and the raw error rate and characteristics are determined primarily by transmission factors, the error *requirements* are determined by the use of the data. The means and techniques of error control appropriate to a particular situation obviously depend upon the interaction of these factors. However, it is a fundamental modularity principle of FIELDATA that the characteristics of transmission transducers should as nearly as possible be independent of the details of user input-output characteristics and data employment.

If one were to incorporate the error control features into the transmission transducers and one desired to provide p classes of controlled error service to users with q modulator-demodulator assemblies, then one would require p times q types of complete transmission transducers. The obvious answer is to separate modularly, making the error control module an item of embolic equipment. This allows one advantage of similarities in requirements and raw error characteristics among the different situations to reduce the variety of equipments to be constructed.

In view of the present difficulties in predetermining the specific error characteristics of transmission transducers prior to construction and test, it also permits construction of new transmission transducers and their use with existing error control embolic equipments until the specific error characteristics of the transducer can be measured, and new error control embolic equipment designed if necessary to meet user requirements with the measured transmission error characteristics.

In addition to these practical advantages of placing error control responsibilities in embolic equipment modules rather than in transmission transducer modules, there are conceptual advantages associated with maintaining the simplest possible information flow patterns and a division of activities among the three basic kinds of assemblies.

In general, transmission transducers pay no attention to the information content of the digital information they convert to modulated transmission form, neither knowing nor caring whether the data is primary or secondary data, whether it is redundant or irredundant, or what code or codes it uses. In contrast to this, embolic equipments normally act as information-processing devices. Thus, in supervising a transmission link, embolic supervisory equipments act on sensory information received from transmission transducers and in-out transducers. They generate, process, and interpret secondary supervisory information to control the over-all operation of the communications link.

The error control problem is exactly parallel. Acting on information about user requirements (from the in-out transducer side) and on information and sensory information about transmission errors from the transmission transducer side, error control equipment is required to generate, process, and interpret error control information, using it to control (often via supervisory operations) the over-all operation of the communications link in such a way as to control its errors. Thus it is obvious that from the information processing viewpoint the performance of error control as an embolic function has a close parallel to other embolic functions and is distinctly different from the functions otherwise performed by transmission transducers.

Among the Fieldata equipments being developed in implementation of these concepts are the following:

Transmission transducers

- *AN/TSQ-32;* 600–1,200 bps (bits per second); Stelma Corporation.
- *AN/TSQ-33;* 600–2,400 bps; Collins Radio Company.
- *AN/TSQ-35;* 19,200 bps; Bendix Aviation Corporation. Bendix Pacific Division, Bendix Aviation Corporation.

General-purpose computers

- Mobidic; Sylvania Electric Products, Inc.
- Basicpac-Logipac; Philco Corporation.
- Informer-Data Coordinator; International Business Machines Corporation

In-out transducers:

- Electric typewriter; Smith-Corona, Inc.
- Paper tape reader; Smith-Corona, Inc.
- Paper tape punch; Smith-Corona, Inc.
- High-speed printer; Anderson-Nichols and Company.
- Paper tape transport; Ampex Corporation.
- Magnetic tape transport; Ampex Corporation.
- Tacden; Aeronutronics, Division of Ford Motor Company

Special embolic equipment

- *CV-689;* cryptosecurity adaptor; Collins Radio Company.
- *CV-690;* control equipment; Collins Radio Company.
- *CV-691;* data concentrator; Collins Radio Company.

The transmission transducers of the Fieldata family are limited in number. However, the choice of the 75×2^x pattern of data rates permits widespread augmentation by minor modification of existing or developmental teletypewriter multiplexed transmission equipments. In addition, future expansion is simplified by the fact that future equipments will be able to utilize the same embolic and input-output equipments, and will thus be cheaper to develop than data transmission equipments which require development of embolic and/or input-output equipment as part of the same package. Expected future expansion will place greater emphasis on transducers for radio circuits.

The *AN/TSQ-32* is a transmission transducer capable of accepting data from a standard Fieldata connection and of transmitting it serially as frequency shift modulation of a single subcarrier over a standard voice channel. Transmission rates are 1,200 bps or 1,500 wpm (words per minute) over good quality circuits, and 600 bps over poorer circuits.

The *AN/TSQ-33* is a transmission transducer capable of accepting data from a standard Fieldata connection and of transmitting it as eight channels, as synchronous phase quadrature modulation of four subcarriers over a standard voice channel. Transmission rates are 2,400 bps (3,000 wpm) over good quality circuits, with 1,200 and 600 bps available for use over poorer circuits. This equipment is essentially a militarized, miniature compatible Fieldata version of the Kineplex *TE-206*.

The *AN/TSQ-35* is a transmission transducer capable of accepting data from a standard Fieldata connection and of transmitting it by amplitude modulation of eight subcarriers orthogonally spaced in frequency and time. The transmission base band is the 48-kc band between 12 and 60 kc used for military and commercial cable and carrier circuits. Representative circuits are the Army spiral-4 and associated *AN/TCC-7*,- 8, and -11 equipments; and commercial types *N* and *K* carrier equipments. In addition to point-to-point full duplex operation this equipment has special features for the multiple-station "common net" round-robin type of operation.

In addition to these transmission transducers specifically designed for Fieldata a wide variety of existing military and commercial teletypewriter transmission equipments can be used for Fieldata transmission with only minor modification. Examples of such equipment are the *AN/FGC-54* capable of transmission and diversity reception of Fieldata information at 2,400 bps over long-haul 3-kc radio circuits using 32 channels, which operate at 75 bps. Another example is the *AN/FGC-29*, potentially capable of transmission and diversity reception Fieldata information at 1,200 bps using 16 channels which operate at 75 bps. Yet another example is the *AN/TCC-30* potentially capable of transmitting 1,200 bps using 16 channels which operate at 75 bps.

The Fieldata computers form the most complete and well-balanced portion of the Fieldata family. They may act as either input-output transducers or as embolic equipments for data transmission purposes, having the ability to accept, process, and emit either primary or secondary data. All are designed for direct operation with data transmission equipment. In their employment the Mobidic, which was the first machine to have its characteristics "frozen," is the least capable machine with regard to data transmission having serious restrictions on its use of the supervisory code functions. The most flexible in its employment of data transmission will be the data co-ordinator, a newer equipment which will be capable of terminating a large number of data transmission circuits simultaneously, and which will have a number of special capabilities and console positions to facilitate its use as a facilities co-ordination processor for an integrated communications data-processing system.

All the Fieldata computers are general purpose processors of modular design and great flexibility. All of these computers are designed for field use with operation and maintenance simple enough for field personnel. The largest, Mobidic mounts in a semitrailer van, while the others mount in shelters which can be carried on a truck.

The input-output transducers of the Fieldata family serve double duty as computer input-output devices and as data transmission input-output devices. The group under current development constitutes a minimum group of general usage items, a number of which are in only partially militarized form. This minimum group will be augmented by future field teletypewriter equipments which will utilize Fieldata code, and by advanced equipments now under study to provide specialized input-output capabilities. The items are mostly quite conventional, and detailed descriptions are omitted here.

The specialized embolic equipments in Fieldata provide cryptographic security, interconnection of input-output and transmission transducers, and tie-in of Fieldata circuits to existing teletypewriter circuits.

Three major items of special embolic equipment are being developed for FIELDATA. The *CV-689* is a special cryptosecurity adaptor which permits an existing type of security equipment to be inserted just before the transmission transducer in any FIELDATA data transmission assembly, thus providing cryptographic security.

The *CV-690* is a device which provides supervisory control, error control, and synchronizing buffer facilities for connecting paper tape or magnetic tape units to the *AN/TSQ-32* or *-33*. Although future plans call for similar special militarized embolic equipments for other kinds of input-output equipment such as card equipment, none is now under development. However, rather minor modifications of commercial Collins Kinecard equipment will permit nontactical employment of *AN/TSQ-33* equipment for card transmission, and at least some versions of the MOBIDIC will include card equipment which, through the computer, can reach transmission facilities.

Although FIELDATA concepts make provision for a wide variety of error control and supervisory control systems, only the particular system used in the *CV-690* will actually be used initially, except for computer-to-computer transmission, since other embolic devices using different error control or supervisory control schemes are now under development. When experiments do determine the actual frequency and interrelationship of errors for particular transmission transducers, it is expected that more effective schemes will be devised. However, the very simple 2-dimensional (interlaced) parity error detection scheme followed by the request-back or rerun type of error correction used in the *CV-690* is particularly easy to implement, and is expected to suffice for initial testing.

The *CV-691* data concentrator is a device designed to bridge the gap between existing large-scale 60- and 100-wpm teletypewriter facilities and FIELDATA equipment. Although all FIELDATA processors have normal provision for a paper tape reader which accepts teletypewriter tape, as well as one for FIELDATA tape, there exists a significant need, especially at locations where FIELDATA processors might not be available, to accept multiple channels of teletypewriter information and convert this into FIELDATA form to take advantage of FIELDATA transmission transducers and error control, permit recording on FIELDATA magnetic or paper tape, permit printing on FIELDATA high-speed printers, simplify entry into FIELDATA computers, etc. The *CV-691* accepts up to 25 (or 50) teletypewriter inputs, stores the information in a buffer core memory (made up of the same memory planes as used in MOBIDIC), assembles it into message blocks, converts it into FIELDATA form, applies the same error and supervisory control as the *CV-690*, and emits the data in FIELDATA form at rates up to 2,400 bps (3,000 wpm). The receive side performs the inverse functions.

As more and more of the voice and other analog communications systems convert to pulse code modulation and other digital forms, it is expected that additional types of FIELDATA embolic equipment will be required to perform the error control, supervisory functions, and buffering synchronization necessary to tie input-output transducers to their digital bit streams.

The FIELDATA family is an attempt to create an integrated family of data transmission equipments to meet Army needs. Though it lacks many of the features and equipments of an ideal family of data transmission equipments, it will make available in experimental quantities by the end of 1960 the first integrated family of equipments for experimental establishment of a truly integrated communications data-processing system. It is the first system in which both data-processing and communications equipment utilize the same input-output and storage devices, the same voltages, impedance levels codes, and other common interconnection characteristics; it is the first in which the equipments are so designed that in many cases the only way to determine whether a device is used for communications or data processing is to look at its specific application in the system.

Appendix I. Fieldata Alphanumeric Code

The following table represents the alphanumeric code for alphanumeric information in specific form.

	000	001	010	011	100	101	110	111
000	MSP	SET	RESET	LF	CR	SP	A	B
001	C	D	E	F	G	H	I	J
010	K	L	M	N	⊙	P	Q	R
011	S	T	U	V	W	X	Y	Z
100	)	–	+	<	=	>	–	$
101	*	(	"	:	?	!		⊕
110	0	1	2	3	4	5	6	7
111	8	9	'	;	/	.	SPEC	IDLE

MSP: Called "Master Space"; printed symbol ≷

SET: Causes a change of machine state or switch position. When translating to or from teletypewriters, this is interpreted as "Figures Shift"; printed symbol ζ

RESET: Causes the opposite change of machine state or switch position. When translating to or from teletypewriters, this is interpreted as "Letters Shift"; printed symbol ⁒.

CR: Carriage return; printed symbol <

LF: Line feed; printed symbol ←.

SPEC: Called "Special." Used as an escapement or alphabet expander. SPEC followed by another symbol forms a symbol pair with a new meaning which can be arbitrarily defined in any particular system. For example, SPEC A might be defined as α, SPEC B as β, etc. Extent of influence is only one symbol. However, the combination SPEC SPEC may be used to indicate that the characters following are to be interpreted by reference to a table of symbol assignments; printed symbol □.

IDLE: No information content; a deletable character.

Appendix II. Fieldata Control and Supervisory Code

Another 6-bit FIELDATA supervisory data code is described below. Though similar to that of Appendix I it has distinct differences.

Most Significant Bits	Least Significant Bits 000	001	010	011	100	101	110	111
000	←——Format effectors					——→	a	b
001	c	d	e	f	g	h	i	j
010	k	l	m	n	o	p	q	r
011	s	t	u	v	w	x	y	z
100 101 110 111	Various system supervisory and control symbols such as "start of block," "end of block," "end of file," "are you ready?," "I am ready," "please retransmit last block," etc.							

In FIELDATA standard form, items, in the alphanumeric code, or other user (primary) data, are designated with a control bit in the ONE condition. If the communicator desires to restrict himself to the bottom half of the control code, eschewing the alphabet made available in the top half, then the resultant code is self-clocking because an OR of the control bit and of the most significant bit of the code will always contain a ONE.

If in a particular system it is desired to provide 2-case alphabetic operation, i.e., *a* or *A*, *b* or *B*, etc., for the easy-read or business correspondence type of format, one may absorb the alphabetic portion of the control code into the user (primary) information code. This gives a user alphabet of 96 symbols and a control and supervisory alphabet of only 32. In such a case a 2-bit test is necessary to separate control functions: i.e., both the control bit and the most significant information bit must be tested. Treating the control bit as the least significant bit for sorting a binary sort will result in sorting in the order *a, A, b, B, c, C*, etc. By treating it as the most significant bit the two cases will be alphabetized separately, i.e., *a, b, c, d*, etc.; then *A, B, C, D*, etc.

Moon Reflection Studies with Bistatic Radar at 3,000 Mc

A. W. STRAITON
NONMEMBER AIEE

C. W. TOLBERT
NONMEMBER AIEE

MEASUREMENTS have been made of moon-reflected radar signals transmitted by the Royal Radar Establishment from Malvern, England, and received by the Electrical Engineering Research Laboratory of The University of Texas at Austin, Texas. These supplement monostatic radar measurements made by a number of organizations and a few bistatic measurements which have been noted in news articles and mentioned at technical symposia. Reports have been made of monostatic measurements in the very-high-frequency (vhf) band by Trexler and Evans and in the 3,000-mc (megacycle) region by Yaplee and Hughes.[1–4]

The measurements reported in this paper were made to demonstrate the feasibility of receiving moon-bounce signals approximately one fourth of the distance around the earth and to obtain information on the character of the signals received over this path. The signal study should shed light on the surface of the moon, distance to the moon, the Faraday rotation in the ionosphere, and the motion of the moon.

Theoretical Considerations

It is obvious that signal detection is made easier by an increase in transmitted power and in the gain of the transmitting and of the receiving antennas. For the higher frequencies, the gain for a given size antenna is increased but so also is the cost of construction.

Bandwidth

The signal-to-noise ratio may be increased by decreasing the bandwidth. This bandwidth must, however, be wide enough to accept any changes in frequency due to Doppler effects associated with the earth's rotation, the moon's libration, and changes in distance between the earth and the moon. The bandwidth must also be wide enough to avoid pulse distortion. For this latter reason, it is possible to make measurements with comparably low-power continuous wave operation, while higher peak power is needed for pulse operation.

Scattering Cross Section of the Moon

The only uncertain factor in the radar equation, as applied to the moon returns, is the back-scattering cross section of the moon. This reflection is dependent on the smoothness of the moon surface relative to the wavelength used. For wavelengths of several meters, the moon's surface has been described by Siegel as quasi-smooth, implying that large areas of the moon are relatively smooth for this wavelength.[5] It would be expected, however, that for centimeter wavelengths, the moon's surface would appear rougher and have more areas which would serve as effective reflecting regions.

In addition to the roughness, the reflections from the moon will be influenced by the nature of the surface. A thick layer of low density dust might serve to reflect only a small amount of energy from the surface with additional reflections taking place from a solid layer beneath the dust.

Polarization Effect

For a linearly polarized transmitting antenna, the polarization at another location may be determined for two earth stations in the Northern Hemisphere north of the sublunar geographical position (GP), the first location observing after lunar transit and the second location observing before transit, by the following equation:

$$p = \arctan\left[\cot\frac{A}{2}\left(\frac{\cos\frac{L_x-L_m}{2}}{\sin\frac{L_x+L_m}{2}}\right)\right] - \arctan\left[\cot\frac{A}{2}\left(\frac{\sin\frac{L_x-L_m}{2}}{\cos\frac{L_x+L_m}{2}}\right)\right] + \arctan\left[\cot\frac{B}{2}\left(\frac{\cos\frac{L_y-L_m}{2}}{\sin\frac{L_y+L_m}{2}}\right)\right] - \arctan\left[\cot\frac{B}{2}\left(\frac{\sin\frac{L_y-L_m}{2}}{\cos\frac{L_y+L_m}{2}}\right)\right] \quad (1)$$

where

p = polarization
L_m = sublunar latitude
L_x = latitude of the first station
A = difference in longitude between the lunar ground position and the station
L_y = latitude of the second station
B = difference in longitude between the lunar ground position and the station

If the linearly polarized receiving antenna is rotated with respect to the polarization of the incoming wave, the signal strength will be reduced by the cosine of the angle between the polarization of the antenna and that of the incoming wave. Thus a change in signal level caused by polarization effects will be encountered during a measurement period as the sublunar latitude and longitude vary as a function of time.

Faraday Rotation

The polarization of the radio wave going through the ionosphere will be

Paper 60-518, recommended by the AIEE Radio Communication Systems Committee and approved by the AIEE Technical Operations Department for presentation at the AIEE Southwest District Meeting, Houston, Tex., April 4–6, 1960. Manuscript submitted December 28, 1959; made available for printing February 10, 1960.

A. W. STRAITON and C. W. TOLBERT are with The University of Texas, Austin, Tex.

This work was possible only because of the excellent co-operation of the Radio Astronomy Group at the Royal Radar Establishment in England, who provided the essential transmission as well as many valuable suggestions concerning the reception technique.

The work conducted by the Electrical Engineering Research Laboratory of The University of Texas described in this paper was sponsored by the Wright Air Development Center under Air Force Contract *33(616)-6257*.

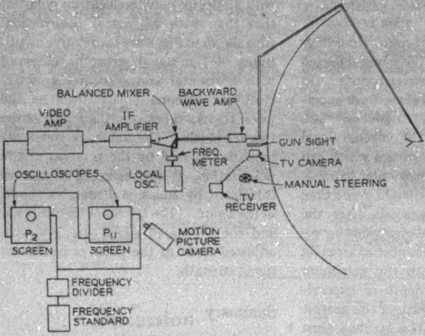

Fig. 1 (left). Receiver block diagram

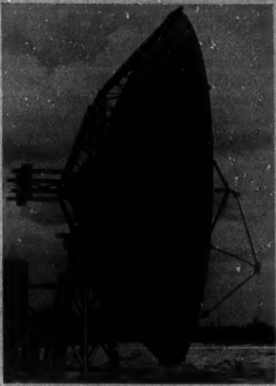

Fig. 2 (right). Receiving system

rotated through an angle α due to the movement of the charges by the wave in the earth's magnetic field. The direction of rotation will be additive for the return trip. The amount of this rotation is given for radar frequencies greater than 100 mc per second by

$$\alpha = \frac{e^3}{2\pi m^2 c^2 f^2} \int_{\ell}^{0} N(s) H(s) \cdot ds \qquad (2)$$

where e and m are the charge and mass of the electron, c is the velocity of light, and f is the radar frequency. $N(s)$ and $H(s)$ are the electron density and magnetic field, respectively, along the transmission path ℓ over which the integral is taken.

It is noted that this effect varies inversely as the square of the frequency. Extrapolating the results of vhf measurements indicates that this effect would be very small at 3,000 mc per second.

Transmitted Data

The transmitting station was located at Malvern, England, at a latitude of 52.1°N and a longitude of 2.3°W. The transmitting antenna was a 45-foot parabola which transmitted 5-microsecond pulses at a repetition rate of 250 per second. The transmitted frequency was very nearly 3,000 mc, with a power of 2 megawatts. By prearranged agreement, the repetition rate was maintained at 250 per second with a deviation of less than one part in 10^8.

Previous monostatic measurements at Malvern had shown a reflected signal strength at the receiver of 10^{-13} watts.

Receiver Data

The receiver for the studies was located at the Balcones Research Center of The University of Texas, at a latitude of 30.4° N and a longitude of 97.7° W. This is equivalent to an hour-angle separation of 6 hours and 22 minutes from Malvern and a great circle distance of 4,780 statute miles.

The receiving system, shown in block diagram in Fig. 1, was designed and assembled primarily to detect and identify the moon-reflected signal as transmitted from Malvern. The antenna and the r-f (radio-frequency) amplifier are the "heart" of the system, the other components being designed to be complementary and to display the received signal. The skin of the 28-foot antenna, a parabola formed by eight sections of Fiberglas-reinforced copper foil, was supplied by Wright Air Development Center. A framework of aluminum and steel trusses was fabricated that allowed the skin to be attached to an *F/SCR-268* radar mount. The resulting altazimuth mount was optically pointed with a telescope gunsight. Tracking of the moon was manual and was facilitated through the use of a television camera and receiver aligned with the gunsight. The parabolic reflector was horn-illuminated with a 10-db (decibel) taper and the waveguide feed from the horn terminated at the r-f amplifier. The resulting gain and beamwidth were calculated to be 46 db and 0.8 degree, respectively. A Hughes Products *PAS-2* backward-wave amplifier (bwa) was attached to the antenna mount as shown in Fig. 2, and the coaxial cables to its input were utilized to form the vertical rotary joint. The output from the bwa, operated with a gain of 20 db and a noise figure of 5 db, was waveguide-coupled to a balanced mixer and thence to an i-f amplifier with a bandwidth of 400 kc. The local oscillator, a *6BL6* klystron, was used to heterodyne to the i-f frequency of 44.5 mc, with no frequency stabilization being employed other than that inherent in the system.

The output of the second detector, after passing through a video amplifier, was applied to two cathode-ray oscilloscopes, one with a P_{11} screen for photographic purposes and the other with a P_2 screen for eye observations. Synchronizing pulses with a repetition rate of 250 ± 10^{-6} sec^{-1} were derived from a Hewlett-Packard frequency standard. Interval markers at 20 seconds were also derived for timing purposes. Provision was made for recording with a 16-mm motion picture camera, a Type A signal display, and a display similar to that used at Malvern, where the signal is applied to the z axis of an oscilloscope whose x and y coordinates are 80 seconds and 1,000 microseconds. The 1,000-microsecond sweep was synchronized with the pulse repetition rate.

The beamwidth and the pointing of the antenna were measured by means of a signal generator on top of a 270-foot tower at a distance of 2,500 feet. Observations were also made using the sun as a signal source. Prior to the measurements, the Royal Radar Establishment provided the transmitter frequency within ±0.1 mc and the periods during which the transmitter would be operated.

Measurements

The first attempt to receive the signal, made on August 22, 1959, with vertical antenna polarization, was unsuccessful. Failure was due, in part, to the antenna polarization and to a difference in indicated transmitter frequency as measured at Malvern and at Austin. The second attempt was made on the following night with horizontal polarization. Approximately 2 hours after moonrise, the signal was tuned in. The adjustable parameters of the receiver were optimized and eye observations and photographs of the intensity modulation display were made. Stratus clouds prevented optical sighting of the moon on the following night, thereby prohibiting the pointing of the antenna. The fourth night of the prescheduled measurements was canceled by mutual agreement, primarily due to the poor weather conditions at Austin but also to allow antenna repairs to be made at Malvern.

A second set of measurements was scheduled for the period between September 21 and September 24. Because of the narrow latitude permitted in adjusting the parameters of the intensity modulation scheme with the low signal-to-noise ratio experienced during the previous measurements, motion picture recordings of the Type A presentation were made during this period. No difficulty was experienced in tuning in the signal during this period. On September 21, photographic recordings and eye observations of the signal were made for approximately 5 hours with 45-degree counterclockwise antenna polarization. Low stratus clouds prevented antenna pointing on September 22. Measurements were made for approximately 5 hours with horizontal polarization on September 23. The measurements scheduled on September 24 with vertical polarization could not be made because of cloud cover.

Results

Shown in Fig. 3 are typical recordings of Type A displays of the moon-reflected signal at four different sweep speeds. On each frame of the film there were superimposed approximately 10 sweeps. The observed upper 6 db of the reflected signal has cumulative characteristics which can best be described as being similar to noise. Signal returns were distributed over a time interval of 350 microseconds after the earliest return. This corresponds to receiving signals from a number of areas on the moon's surface with the maximum signal coming from a depth of approximately 7.5 kilometers back of the nearest point on the moon. The greatest time delay corresponded to a depth of approximately 50 kilometers, which would occur at about one third of the distance from the center of the edge of the optical disk. The interval time during which the upper 6 db of a single discrete return could be observed averaged approximately one-quarter second. The mean distribution of signal amplitudes versus time are shown in Fig. 4.

The spectra which were enhanced by frequency modulating the sweep repetition rate about 20 microseconds at 2 cycles per second were primarily determined by eye observations of the P_2 screen. A more extended period of returns was observed with 45-degree counterclockwise polarization than with horizontal polarization. Also shown in Fig. 4 are the relative amplitudes of the signal strengths observed with horizontal and 45-degree counterclockwise antenna polarizations as the moon traversed between the zenith at the two terminals. The values of signal attenuation caused by the rotation of the polarization of the reflected signal as calculated by equation 1 are also shown in the figure. The curves of the observed and the calculated signal strength were adjusted to fit at the point of maximum signal strength.

Summary

The moon-reflected signal as transmitted from Malvern, England, was easily received in Austin, Texas, with a 28-foot antenna and a receiver with a noise figure of approximately 6 db. The upper 6 db of the spectra of the reflected signals were made up of a large number of pulses of varying amplitudes and positions along a time base of approximately 350 microseconds. The maximum returns occurred approximately 50 microseconds after the first return. The average polarization of the reflected signal was essentially linear and has a value which correlates reasonably well with that calculated for a plane reflecting surface. The complex nature of the reflection prevented any conclusions other than the those relating to the effective reflecting areas of the moon and to the average polarization.

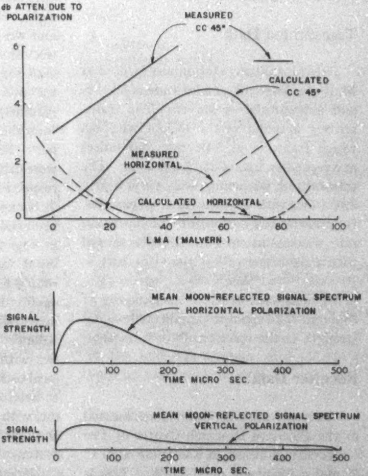

Fig. 4 (right). Spectra and polarization of reflected signals

Appendix. Signal-to-Noise Ratio

The signal-to-noise ratio for echoes from the moon is given by

$$\frac{Ps}{Pn}=\frac{P_T A_R G_T \sigma}{16\pi^2 R_T^2 R_R^2\ FKTb}$$

where

Ps = signal power at receiver
Pn = noise power
P_T = transmitter power
A_R = effective area of receiving antenna
G_T = gain of transmitting antenna
σ = scattering cross section of target
F = receiver noise
K = Boltzmann's constant
T = receiver ambient temperature
b = receiver bandwidth
R_T = distance from transmitter to moon reflecting region
R_R = distance from receiver to moon reflecting region

Discussion

V. A. Hughes (Royal Radar Establishment, Malvern, Worcestershire, England): Since the first radar reflections were obtained from the moon by the United States Signal Corps and independently by Bay in Hungary in 1946, measurements have been considerably extended. The early measurements were made with comparatively low power transmitters and, in order to obtain the required signal-to-noise ratio, long pulse lengths and CW were used, producing a signal scattered back to the receiver which consisted of contributions from the whole of the lunar surface. At the meter wavelengths used, apart from a long period of fading due to Faraday rotation in the ionosphere, lunar libration produced a short period amplitude fluctuation by introducing Doppler shifts in the scattered signal from different elements on the surface. It was thought that the lunar surface would scatter isotropically, but by carrying out an analysis of the fluctuations, Evans, as pointed out in reference 2 of the paper, showed that most of the radiation was returned from a central region of the disk that had a radius only one-third of the lunar radius.

With the more recent use of radars with high peak power and microsecond pulse length it has been possible to confirm that at least from wavelengths of 1.5 meters to 10 cm this very directional type scattering exists. This has been discussed in references 1, 3, and 4 of the paper.

Measurements at Malvern at the wavelength of 10 cm using the 45-foot-diameter radio telescope with a 2-megawatt radar with 5-microsecond pulse length have shown in fact that for unit area of the lunar surface the ratio of scattered power to incident power flux, defined as the scattering cross section per unit area, is given by[1]

$$\sigma'=\sigma_0'\ exp\,\{-10\theta\}$$

where σ_0' is about 0.7, for angles of incidence θ between about 3 degrees and at least 14 degrees.

Such highly directional scattering led Senior and Siegel[2] to suggest that the echo was caused by specular reflection from three or four areas on the surface that were smooth in comparison with the wavelength; the moon has been described as quasi-smooth. The theory required that the leading edge of the echo was due to reflection from one of the regions and hence must remain nearly constant in amplitude. However the short pulse length measurements at Malvern show a leading edge which fluctuates in a random fashion; comparison with results obtained by Yaplee using a 2-microsecond pulse length shows that the mean amplitude of the leading edge is proportional to pulse length and hence to the area illuminated on the lunar surface. Moreover, a surface with irregularities much greater than a wavelength, such as the surface of the sea, also scatters in a highly directional way[3] with a law comparable to that for the moon but dependent on the state of the sea.

To decide further if the lunar scattering is from a few specular areas or from a rough surface this joint experiment was arranged between Malvern and Texas. Signals transmitted from Malvern were received both back in Malvern and also in Texas, and in the latter case were received at an angle of about $1^1/_2$ degrees to the incident angle, this being the angle subtended by the base line Malvern–Texas at the moon. If the echo were due to a few specular reflections from smooth surfaces on the moon then a correlation might be expected between the spikes in the signals received at both sites. In fact no correlation was observed; whereas the signal received at Malvern shows a steep rise at the leading edge, that received in Texas shows a gradual increase as would be expected if the scattering was from a rough surface.

The model that is suggested for the lunar surface, based on the scattering law, is one with vertical irregularities which have an rms value greater than a wavelength and a horizontal scale which is about 20 times greater. The surface would appear to be undulating and over representative annular areas of 8,000 km², corresponding to the area of the lunar surface from which signals are received with a 5-microsecond pulse, have a mean gradient of about 1 in 20. If this had been steeper, then we would have expected a more isotropic scattering, while a smaller gradient would have shown more directional reflecting properties.

This bistatic experiment has also shown the feasibility of transmitting signals for long distances over the surface of the earth, and has demonstrated the limitations that would be imposed on the use of the moon as a radio relay. Due to the type of scattering from the moon, the frequency bandwidth for a normal communication system would probably be limited to about 3 kc but a much smaller bandwidth may be necessary if good signal-to-noise ratio is required due to the "persistence" of the returned signals. Hence, to estimate the total scattering cross section of the moon for communication purposes we can integrate σ over the whole of the surface

$$\sigma=2\pi a^2\sigma_0'\int_0^{\pi/2}\sin\theta\ exp\{-10\theta\}\,.d\theta$$

$$=2\times10^{-2}\pi a^2\sigma_0$$

where a is the lunar radius, 1,738 km. For the wavelength of 10 cm, this becomes

$$\sigma=1.4\times10^{-2}\pi a^2$$

$$=1.3\times10^4\ \text{km}^2$$

However, some more recent measurements with higher performance radars and long pulse lengths at a wavelength of about 0.75 meter have shown that for larger values of θ the scattering from the lunar surface becomes isotropic with a derived scattering cross section per unit area σ_i of about 6.10^{-3}. Though there appears to be a slight wavelength dependence on the scattering, to a first approximation we shall assume that the isotropic term has the same value at the wavelength of 10 cm. The value of the scattering cross section may then have to be increased by a further factor σ_I which for the case of CW or pulse lengths greater than about 11 ms is

$$\sigma_I=2\pi a^2\sigma_i$$

$$=1.2\times10^{-2}\pi a^2$$

$$=1.1\times10^5\ \text{km}^2$$

The total scattering cross section of the moon at the wavelength of 10 cm would then be 2.4×10^5 km². The scattering cross section of the moon for pulse lengths less than 11 ms may be obtained by integrating σ and σ_i over the appropriate areas of the lunar surface.

A. W. Straiton and **C. W. Tolbert.** Cross-correlations of the reflected signal as received in Austin and in Malvern were made subsequent to the writing of the paper. The correlation coefficient was found to be extremely low for the single pulse spectra. Low correlation coefficients have been reported by R. B. Dyce and R. A. Hill for diversity reception of moon reflected signals at a frequency of 106.1 mc.[1]

T. B. A. Senior and K. M. Seigel[2] find that the moon reflected signal can be explained by specular reflection from 20 or 30 major areas on the moon's surface. Those areas nearest the center of the moon producing the first of the spectrum of returns are thought to be spherical portions of the surface. Areas further back are thought to be craterlike. The individual returns constituting the reflected signal spectra per pulse of the quasi-smooth model, are each produced by a single scattering area. Rough scattering of much smaller amplitude is permitted for the total lunar hemisphere illuminated.

V. A. Hughes, as explained in his discussion, finds that the reflected signal can best be explained by a lunar model of many reflecting areas. These reflecting areas result from an undulating lunar surface. The individual pulses of the reflected signal spectrum are produced by interference between the signal reflected from these many areas.

These theoretical models are the two most commonly expounded. Either can be used to explain the low correlation of bistatic reception. The reflecting areas of the quasi-smooth model need only to be large with respect to the wavelength ($>$100 meters^2 at 3 kmcs) in order that the reflected flux per reflecting area be confined to a beam width narrow with respect to the angle subtending the receiver separation. The "undulating" model would inherently produce low correlation for bistatic reception because of the interference of the reflected signals from the many reflecting areas postulated. The gradual increase in the amplitude of the mean reflected signal spectrum received at Austin as opposed to the steep rise of the leading edge of the signal received at Malvern, along with the 3 to 6 db lower signal strength experienced at Austin relative to that received at Malvern, are more easily explained by the undulating model than by the quasi-smooth model.

Of the four parameters of the moon-reflected signal obtained from the measurements at Austin: spectrum amplitude distribution; absolute signal strength; relative amplitude versus antenna polarization; and cross correlation coefficients of the Malvern and Austin signal spectra, the absolute signal stength was subject to error of the order of the discrepancy measured and was therefore not included in the paper. The authors are however sufficiently confident of the measurement and the reference absolute level is, therefore, included.

The REA-1 Transposition System

A. G. CHAPMAN

J. V. BUSCEMI
MEMBER AIEE

J. M. FLANIGAN
ASSOCIATE MEMBER AIEE

THE *R1* transposition system (sometimes coded *R1-5*) has been employed in many cases for transposing rural open-wire telephone lines. These have been both subscriber lines and trunk lines, voice and carrier. The *R1* system has the attractiveness of:

1. Patterns lending themselves to simplicity in engineering and construction.
2. No transposition "sections" or "*S*" poles.
3. No quantitative limits on sag or span length deviations.
4. Up to 5 pairs per crossarm and up to 4 crossarms.

The *R1* transposition system was designed primarily for use in the voice-frequency range and the available data indicate it is not too suitable for open-wire lines over which a number of multichannel carrier current systems are operated. Crosstalk considerations limit the maximum permissible carrier frequency and the number of pairs of wire suitable for carrier operation.[1,2] Unpublished data on measurements taken by Rural Electrification Administration (REA) engineers over a frequency range of 40–495 kc have since further confirmed the limitations of the *R1* transposition system for multisystem carrier application. Some representative data on the *R1* transposition system are presented later in this paper.

In looking over available transposition systems during 1954 and later, not only was the *R1* system unsuited to broader carrier application, but none were known to REA which retained much of the simplicity and economy of the *R1* system and which were designed for low-cost carrier systems having frequencies well above about 150 kc.[3–5] It was thought that open-wire carrier would become increasingly attractive economically in bringing modern telephone service to farm and other rural people as a greater variety of economical types of carrier equipment became available. What was needed was a transposition system designed to furnish a suitable transmission medium, from a noise, crosstalk, and absorption loss point of view for these new carriers. These systems have achieved their lower cost by using several times the minimum spacing of 4 kc between adjacent carrier frequencies. Through 1958, the number of carrier channels used in REA borrowers' systems were about 1,000 for trunks and 900 for subscriber lines. There is a trend toward increased use of subscriber carrier channels.

Objectives of the New System

Considering that the average REA borrower's central office has in the order of 130 lines and the average number of subscribers per borrower is around 1,200, a new transposition system did not have to provide for many crossarms and wire pairs. Nor do REA borrowers, by and large, operate long intertoll lines. Homes or central offices in rural areas may fall anywhere along a pole line route, and if such a system were to be suitable for subscriber or for trunk carrier, transposition sections with *S* poles would sharply limit its application. Borrowers in the High Plains area of the United States, and elsewhere, were finding that tandem transposition brackets had to be superseded by point brackets because the former tended to make bare-line wires subject to open-wire contacting during exceptionally windy periods. Therefore, the use of either tandem or point transposition had to be provided for.

Paper 60-43, recommended by the AIEE Wire Communication Systems Committee and approved by the AIEE Technical Operations Department for presentation at the AIEE Winter General Meeting, New York, N. Y., January 31–February 5, 1960. Manuscript submitted November 2, 1959; made available for printing March 7, 1960.

A. G. CHAPMAN and J. M. FLANIGAN are with the Rural Electrification Administration, the former at South Orange, N. J., and the latter at Washington, D. C.; J. V. BUSCEMI is with the Anaconda Wire & Cable Company, Hastings-on-Hudson, N. Y.

The authors wish to acknowledge that they were greatly helped by reference 3 by W. C. Babcock, E. Rentrop, and C. S. Thaeler. The design and field trial of the REA-1 transposition system necessitated the co-operation of a number of REA engineers and REA borrowers' representatives. The authors are particularly indebted to REA engineer Paul G. Lambidakis, for his diligent and skillful work in making extensive calculations and field measurements.

A—Type 10A crossarms
B—Type 10B crossarms

Of the entire material cost of an open-wire line, pole costs have proved to be the single biggest portion, so it was important to have a transposition system permitting average pole spacing, which would take advantage of the strength properties of bimetallic conductors possessing low carrier attenuation properties. Furthermore, a stringent tolerance on pole spacing deviations would lead to too many "set-in" poles, and therefore a greater number of average poles per mile; or tight deviation requirements would lead to midspan brackets, which may flop over or cause excessive sag deviations on longer spans. With these considerations in mind, the following objectives were established for the new transposition system:

1. A maximum of 2 crossarms and 4 pairs on each.
2. For 2 or more top crossarm pairs, a line length up to 30 miles; for second-arm pairs, about half this length.
3. The system to be "splittable," i.e., pairs could enter or leave the line (assuming proper carrier level co-ordination) at any pole.
4. Ability to use standard 10-ft (foot) *A*-type crossarms—12-in. (inch) spacing.
5. Average span lengths up to 310 ft.
6. Liberal transposition pole spacing deviations as per the rule that: the sum of all values of U^2 is not greater than $6L$, where U is the deviation, in feet, of a transposition inteval from the average length of all intervals; L is the length of the line in feet. For existing lines, the limiting value of $6L$ may be necessary to avoid excessive pole setting. For new lines a value of $3L$ or less is often readily obtained and this is highly desirable to improve crosstalk and noise.
7. Loss as a result of absorption of energy by nearby pairs not to become excessive below about 350 kc when the average transposition interval is 300 ft. For other interval lengths the top frequency is in inverse proportion to 300 ft.
8. Bare-line output-to-output far-end pair-to-pair crosstalk loss of 50 db (decibels) or more at as high a carrier frequency as possible. (This would be the minimum far-end crosstalk loss between the voice-frequency drops of like zero loss carrier channels.) It was realized that a bare-line far-end loss of 50 db or more could not be realized above about 200 kc and that in the range of about 200–350 kc, it would be necessary to depend on the crosstalk advantages inherent in the design of various carrier systems. These advantages are attributable to compandors, staggered carrier frequencies, frequency inversion, FM (frequency-modulated) capture, etc.
9. Bare-line input-to-output near-end pair-to-pair crosstalk loss of not less than about 40 db. The crosstalk currents involved in such a loss are reflected at points of impedance mismatch and appear as far-end crosstalk currents. As in item 8, crosstalk advantages are needed to meet the near-end loss requirements at the higher frequencies.

Thus, the *REA-1* transposition system was developed with the intent of retaining much of the simplicity and economy of the *R1* system. At the same time steps were taken to provide marked improvement in carrier frequency crosstalk losses and noise and consequent simplification in engineering a number of carrier systems on the same open-wire line. Because low-cost carrier systems have carrier frequencies up to about 350 kc,[6–9] the frequency range up to 500 kc was considered in design and in field measurement of crosstalk losses between pairs and insertion losses between the two ends of each pair.

The physical nature and engineering of the *REA-1* transposition system are discussed in detail in the REA Telephone Engineering and Construction Manual—463.[10] A brief discussion of the transposition system performance and some of the data obtained in a field trial will be given in this paper. For background information, general design considerations involved in the development of the *REA-1* system will be touched on.

Special Features of REA-1 Transposition System

Unlike the *R1* system, the pole pairs are omitted. This was done to im-

Fig. 3. Schematic of REA-1 transposition system

prove the crosstalk coupling per-unit length between different pairs and to reduce carrier frequency noise and absorption losses. In the *R1* system, half the pairs are usually transposed at the odd-numbered poles, and the other half are transposed at the even numbered poles. Occasionally, to improve crosstalk, the simple transposition patterns are broken by omitting transpositions at poles numbered 25, 50, 75, etc. The *REA-1* system follows the same general plan except that transpositions are occasionally omitted or added at transposition poles 16, 32, 48, etc. Altering the simple patterns at such poles is highly expedient since this permits the use of published charts and tables in computing the crosstalk losses between pairs over a wide frequency range.[3] If the patterns are altered at poles 25, 50, 75, etc., the computations are simple at voice frequencies but very involved at carrier frequencies.

Unlike the *R1* system, the rules for the *REA-1* system require control of the differences in sag of the two wires of a pair (±2 in., initially) and control of the differences in transposition pole spacing. As a result of the required transposition pole spacing control, every pole may not be a transposition pole (i.e., a pole at which some pair is transposed).

Transposition Brackets

Fig. 1 indicates schematically the wire configuration when tandem transposition brackets are used with the *REA-1* system. The figure shows the first four transposition intervals. The wires of a pair taper from 14 to 2.5 in. in each transposition interval or vice versa (3 in. at the dead-end pole). If there is an intermediate pole in a transposition interval, its pinholes are specially bored to place the insulators in position to maintain about the normal taper in a transposition interval.

Tandem transposition brackets are used in moderately windy areas for economy. In exceptionally windy areas 12-in. point-type transpositions may be used as indicated in Fig. 2(A). Limited REA field trials suggest that someday it may be economical to use plastic insulated wires to prevent wire hits and to use tandem transposition brackets. Plastic insulation has been found useful in preventing wire corrosion and wire-to-wire leaks caused by Spanish moss, etc.

The wire spacings of Fig. 1 are suitable for joint use since there is ample climbing space between wires 4 and 7, etc. For bare wires and joint use in exceptionally windy areas, the wire spacings of Fig. 2(B) are recommended.

Diagram of the REA-1 Transposition System

Fig. 3 gives the transposition patterns in schematic form for 256 transposition intervals. It may be seen that for pairs 1–2, 7–8, 13–14, and 19–20 the basic pattern is that of transposing at the even-numbered transposition poles. The omission of transpositions at certain points is indicated by circles. For pairs 3–4, 9–10, 11–12, and 17–18, the basic pattern is that of transposing at the odd-numbered transposition poles. Additional transpositions are indicated by a cross inside a circle. The "letter designations" for the patterns in 256 transposition intervals are shown to the left of Fig. 3.[3]

Fig. 4 gives a diagram which is useful for engineering *REA-1* transposition systems. For simplicity only the notes applicable to the use of tandem transposition are given.

Design Considerations

The wire spacings of Fig. 1 result in a tapered transmission line for which, in theory, the nature of the propagation is different than if the wires are parallel. However, the slightly tapered transmission line of Fig. 1 behaves about like one in which the wires are parallel and about 8 in. apart. For 300-ft transposition pole intervals and about 405 kc, the phase change per transposition interval is about 45 degrees and there is a large attenuation-frequency "absorption peak."

Referring to Fig. 3, in 256 transposition intervals there are two basic patterns a_3 (transpositions at even-numbered poles), and P_4 (transpositions at odd-numbered poles). If there were no circles or circle crosses, half the pairs would be transposed a_3 and the other half P_4.

⊗ Point-type transposition

✕ Tandem transposition

** Transpose from pole 257 to 512 like 1 to 256 etc. At transposition poles with boxed numbers, 16, 32, etc., special transposition patterns are used. For last pole substitute ○ for ✕ and omit ⊗

To implement the objectives for the new system, the following design considerations were kept in mind:

1. Pairs transposed alike for a considerable distance may have objectionable near-end crosstalk at voice frequencies and objectionable far-end crosstalk at the high carrier frequencies.

2. Pairs transposed to patterns a_4 and P_4 for a considerable distance have objectionable far-end crosstalk at the higher carrier frequencies.[19]

3. If 256 transposition intervals actually existed, the fewer the interruptions of the basic patterns the higher (better) the crosstalk losses would be. For example, with 256 intervals, a circle in pair 7–8 at pole 128 and no circle crosses in pair 9–10 would give desirable crosstalk characteristics to pair combination 7–8 to 9–10.

4. If there were only a few pattern interruptions, the design could not be split. For example, if the line length has 127 transposition intervals, an interruption in basic pattern at only transposition pole 128 does not break up the basic patterns in 127 intervals.

5. Too many circle crosses are undesirable since, when tandem transpositions are used as much as possible, the circle crosses represent relatively expensive point-type transpositions. From Fig. 3 and about 310-ft transposition pole spacing it may be calculated that the transpositions per pair mile are:

Crossarm	Tandem Transpositions	Point Transpositions
Top	8.5	0.15
Second	8.2	0.40

Fig. 6. (A) Far-end and (B) near-end crosstalk coefficients in crosstalk units/mile/kc

Case A—Measured[3]
Case B—Computed per REA
Case C—Computed[3]

For comparison, a long (7.5-mile) 0–1 transposition section has about 12.4 point transposition per carrier pair per mile. The difficulty in choosing the circles and circle crosses depends on the number of pair combinations. Because it was felt that the top crossarm would usually be ample to give the desired number of voice and carrier channels it was decided first to design the top arm as simply and economically as possible and let the second arm be more complicated. The second arm is used for voice channels and for a relatively few carrier channels for short distances.

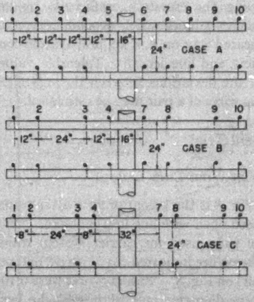

Fig. 5. Configuration of open-wire pairs on two 10-ft crossarms, wire diameter 0.104 in.

Case A—Eight 12-in. pairs and two 18-in. pole pairs
Case B—Eight 12-12-in. pairs
Case C—Eight 8-in. pairs
All wires tied out

Crosstalk Coefficients

As explained in reference 3 near-end or far-end crosstalk current ratios (times 10^6) between open-wire pairs are calculated by multiplying a "crosstalk coefficient" by an "unbalance factor." The crosstalk coefficients are expressed in crosstalk units per mile per kilocycle. The crosstalk coefficients are preferably measured but may be calculated with reasonable accuracy.[3]

For parallel wires those coefficients can be computed from the geometry of the wire configuration.

Fig. 5 indicates three wire configurations for two 10-ft crossarms 24 in. apart. Line wires of 0.104-in. diameter were assumed in computing coefficients.

(A)—Four 12-in. pairs and one 18-in. pole pair per crossarm.

(B)—Four 12-in. pairs per crossarm.

(C)—Four 8-in. pairs per crossarm.

The coefficients for case *A* were measured.[3] The coefficients for case *C* were computed.[3] The coefficients for case *B* were computed by REA engineers by the method of reference 3. As a check an alternative method of estimating coefficients was also used. This involved calculations of mutual inductance between pairs, direct capacitance unbalances between pairs and carrier frequency characteristic impedances of pairs. The direct capacitance unbalances were estimated from published measured direct capacitances for 4 to 30 parallel telephone wires.[10]

Case *A* indicates the normal wire arrangement with a type *10A* crossarm. Case *B* indicates the wire configuration used with *REA-1* transpositions in especially windy areas; see Fig. 2(A). Fig. 1 shows the wire configuration used with *REA-1* transpositions in moderately windy areas where tandem transpositions are used. The mean wire spacings, in inches, of Fig. 1, in any span are about:

8 22 8 38 8 22 8

The wire spacings of case *C* of Fig. 6 are, in inches:

8 24 8 34 8 24 8

It was hoped that the crosstalk coefficients for the wire configuration of Fig. 1 would resemble those for the wire configuration of case *C* of Fig. 5 because of the rough similarity in the previous two sets of wire spacings. The far-end and near-end crosstalk coefficients for cases *A*, *B*, and *C* of Fig. 5 are given on Figs. 6(A) and (B).

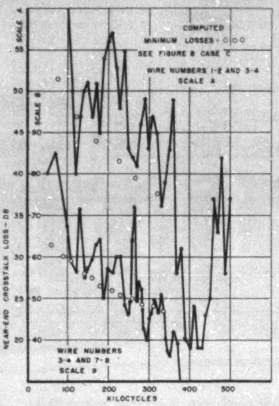

Fig. 7 (left). REA-1 transpositions. Near-end input-to-output crosstalk losses measured and computed

Computed losses due to transposition patterns: 0.104-in. 40% copperweld, 70 F

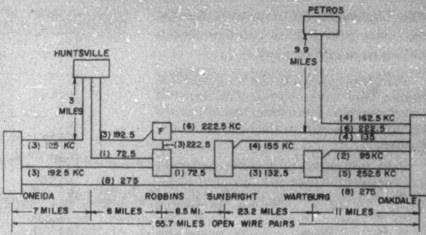

Fig. 8 (above). Open-wire carrier systems in Tennessee

Channels per pair = average 5, maximum 8
Greatest length of channel = 55.7 miles

(8) 275 = 8 channels, top frequency of 275 kc
F = pole-mounted carrier-separation filter.
Open-wire carrier pairs on top arm except two are on second arm Wartburg-Oakdale

It must be seen from Fig. 6(A) that the case *B* configuration usually results in a considerable reduction in far-end coefficients from those for case *A*. Open-wire carrier channels use different frequencies for opposite directional transmission and far-end crosstalk is controlling. The lower far-end coefficients shown for case *B* than for case *A* were the justification for omitting the pole pairs. On Fig. 6(A), case *C* coefficients are considerably lower than case *B* coefficients and as noted above, it was hoped that the case *C* coefficients would apply for the tapered wire configuration of Fig. 1.

However, crosstalk data from a field trial of a two crossarm line having 128 accurately spaced 300-ft transposition intervals indicated that the far-end crosstalk coefficients for the tapered pairs lay between the case *B* and *C* values of Fig. 6(A) and usually nearer the case *B* values. This is not surprising since, strictly speaking, the crosstalk coefficients for tapered pairs vary from point-to-point in a span.

Fig. 6(A) shows the pair-to-self far-end crosstalk coefficients (1–2 to 1–2, etc.). Such coefficients control the magnitude of absorption peaks and the coupling between output and input of amplifiers via interaction crosstalk.[3] The pair-to-self coefficients are improved by a factor of about 0.5 by the use of 4 rather than 5 pairs per crossarm; case *B* versus case *A*.

Fig. 6(B) shows near-end crosstalk coefficients for cases *A*, *B*, and *C*. While the case *B* coefficients are lower than the case *A* coefficients for the larger values such as those for 1–2 to 3–4, case *B* has higher coefficients for such pair combinations as 3–4 to 7–8, 1–2 to 11–12, etc. It was hoped that the coefficients of case *C* rather than those of case *B* would apply to the tapering spans of Fig. 1. Fortunately the 128 transposition interval field trial indicated that the larger near-end coefficients were nearer those of case *C* than those of case *B*. This is indicated on Fig. 7 by a comparison of measured near-end crosstalk losses and the minimum losses computed as a result of the transposition patterns.

Unbalance Factors Due to Transposition Patterns

As noted in the foregoing, the total crosstalk in a given length is calculated, in crosstalk units (CU), by multiplying a crosstalk coefficient by an unbalance factor. The crosstalk loss in decibels = $120-20\log_{10}$ (CU).

Charts and tables are given in reference 3 for computing "type unbalance factors," that is, the unbalance factors depending on the transposition patterns. These are tabulated or plotted as kilocycle miles versus *BD* where *B* is the phase change in degrees per mile for some particular frequency in kilocycles. The length in miles for some particular transposition pattern is indicated by *D*. If *V* is the velocity in miles per second at some particular frequency in kilocycles,

$$BD = 2\,(\text{kc})(D)\,\frac{180{,}000}{V} = 2\,(\text{kc})\,D$$

approximately

The type unbalance factors are given in reference 3 for symmetrical transposition patterns called "fundamental transposition types" which may have "extra transpositions" in each 32nd of a length *D*. Type unbalance factors rise and fall with *BD* but the highest (worst) values increase rapidly with *BD*.

Unsymmetrical patterns such as those used with the *R1-5* transposition system require special calculations. Because the *REA-1* transposition system is a "split-table" design, a length of line actually used may not contain a symmetrical transposition pattern but only a part of such a pattern. Care was taken in choosing the patterns to avoid excessive crosstalk currents due to partial patterns.

Unbalance Factors Due to Wire and Pole Spacing Irregularities

Even if the unbalance factors due to transposition patterns are made very small there still may be serious crosstalk due to irregularities in wire spacing and in transposition pole spacing. As discussed in reference 3 if there are *n* transposition intervals in a transposed line and if the rms deviation from the average interval is *r* feet, it is possible to estimate the rms crosstalk due to these transposition interval deviations. This is done by multiplying the crosstalk coefficients by unbalance factors which depend in a complicated way on *n*, *r*, kc, propagation constant, and line length. Tolerable values for the deviations between the sags of the two wires of a pair may be estimated.

Field Trial

OPEN-WIRE LINE LAYOUT

Fig. 8 is the layout of an *REA-1* transposed open-wire line in Tennessee. Only the pairs used for carrier system transmission are indicated (by a single line per pair) on Fig. 8. The line wires were 0.104 in. in diameter and were 40% d-c conductivity copperweld. In all parts of the main line and its branches, there existed at least the four pairs on the top arm. The second crossarm with one to four pairs existed in short stretches. Pairs not presently used for carrier frequency trunks as shown in Fig. 8 are used for voice-frequency loops or trunks. Between Oakdale and Wartburg (11 miles) there were four carrier pairs on the top arm and two carrier pairs at the ends of the second arm. One or two other pairs existed on the second arm in short stretches.

Fig. 8 does not show the short 22-gauge nonloaded entrance cable which brought the carrier pairs into the offices. These cables were usually not longer than 0.3 kilofoot. Exceptions were a cable of 2.3 kilofeet at Wartburg and one of 3.0 kilofeet at Oneida. Pair 9–10 carries 8 carrier channels with a top carrier frequency of 275 kc from Oakdale to Oneida, a distance of about 58 miles. To avoid a loss of about 10 db in the Oneida cable at a possible channel 10 carrier frequency of 335 kc, pair 9–10 was bypassed around the cable over an insulated open-wire pair. This pair was transposed at every other pole. Each span tapered from 4-in. wires spacing to one-inch spacing. The plastic insulated wires were placed in special fittings which were mounted on small angle irons which were bolted to the cable poles a little above the cable. The measured loss of pair 9–10 at 335 kc between the Oakdale and Oneida offices was 34 db. This loss is low enough to ensure an excellent speech to noise ratio.

As may be calculated from data on Fig. 8, there are about 1,183 channel-miles used over 238 pair-miles or an average of about 5 channels per pair. These data are as of June 15, 1959. At that time the highest carrier frequency for like channels on different pairs was 222.5 kc. This was for pairs 1–2 and 7–8 in the 11-mile stretch from Oakdale to Wartburg. In June 1959, measurements of noise and crosstalk volume were made at the carrier line side of all carrier receiving terminals indicated on Fig. 8, with the test pair de-energized. These volumes were measured in decibels relative to one milliwatt (dbm) in 6-kc bands centered at the various carrier frequencies. The measured volumes were corrected for receiving gain or loss and indicated that noise or crosstalk volumes arising in the outside plant were low enough that modern telephone system objectives would be met at the voice drop terminals. This was confirmed by listening tests at the voice-frequency carrier channel drops. All channels were found to have very little noise or crosstalk volume.

Although all parts of the open-wire line indicated on Fig. 8 had not been completed in Sept. 1957 because of the right-of-way difficulties, it was decided to make carrier frequency insertion loss and crosstalk loss measurements on completed sections of line at that time. As this was the first installation of the *REA-1* transposition system, it was thought important to get an experimental check on the theoretical performance of the REA-1 system as soon as possible.

It was hoped to measure insertion and crosstalk losses for a distance of 42 miles between Oakdale and Huntsville and for various fractions of this distance. To avoid delay however the following three lengths were measured (TP indicating transposition pole),

From	To	Approximate Length, Miles	Number of Pairs Tested
Oakdale	*TP 128*	7.3	6
Robbins	Huntsville	9.2	4
Oakdale	Petros	22.0	4

In order to obtain the maximum possible number of pairs for test in these lengths, it was necessary to make low capacitance crossconnections at the Petros junction pole (TP201) and at the Huntsville junction pole (TP512 plus 194).

In the branch line from Petros junction pole to Petros, the transposition poles were numbered (and transposed) from 1 to 182. After the tests it was concluded that somewhat higher crosstalk losses would have been obtained for some pair combinations by numbering (and transposing) the transposition poles continuously from Oakdale to Petros. This would have numbered the transposition poles on the branch line from TP201 to TP382. This numbering method for branch lines was later specified in REA Manual 463. Likewise, while the Robbins to Huntsville junction pole was numbered with the appropriate main-line numbers TP512 plus 84 to TP512 plus 194, the branch line to Huntsville was numbered TP zero to TP49 instead of TP512 plus 194 to TP512 plus 243.

The average length of transposition interval (usually one span) and the deviations in these intervals for the three test lengths are as follows:

Test Section	*L*, Ft	Average Transposition Interval, Ft	Sum of U^2, Ft
Oakdale–TP128	38,534	300	0.88 *L*
Robbins–Huntsville	48,579	306	5.7 *L*
Oakdale–Petros	116,160	300 (about)	1.0 *L* (about)

In the Oakdale-TP128 section there were only 7 transposition intervals with *U* deviations which varied appreciably from the average value of 300 ft. These *U* values varied from 22 feet to 118 ft. In the Robbins-Huntsville section, because

Alternate pairs on same crossarm; 70 F

of the rugged terrain, there were 35 U values of appreciable amount. These values varied from 11–200 ft. There were 5 transposition intervals over 400 ft long (410–464 ft). These were used to span ravines and streams. The shortest transposition interval was 100 ft.

Of the three test sections, the Oakdale TP128 section was the most useful for comparison of theory with measurements because the crosstalk losses for 128 uniformly spaced transposition intervals may be computed in a reasonable time and since all combinations of 6 pairs could be measured.

INSERTION LOSSES BETWEEN 600-OHM RESISTORS

Insertion losses (in decibels) were measured for all the pairs in all three test sections. Representative insertion loss frequency curves are shown on Fig. 9 for 7.3 miles and for 22 miles. The computed loss for a single uniformly spaced 8-in. pair is shown for comparison (up to 350 kc).

Inside pair 7–8 is transposed at all even-numbered transposition poles. As predicted by theory,[3] there is a large sharp absorption loss peak at around 400–410 kc. The engineering rule is that

$$\text{kc} = \frac{240{,}000}{2d}$$

where $2d$ is the distance between transpositions in feet (in this case about 600 ft)

At the peak frequency, the absorption loss varies rapidly with length as may be seen from Fig. 9. At a somewhat lower frequency, 350 kc, the increase in loss per mile with length is not rapid. It may be seen from Fig. 9 that the loss is increasingly greater than the computed value from about 150 kc upward. This may be explained on the basis of an extra out-of phase arriving current which may be computed from pair-to-self far-end crosstalk theory.[3]

Outside pair 1–2 is transposed like inside pair 7–8 except that transpositions are omitted at transposition poles 32, 96, 160, 192, etc. As will be seen from Fig. 9, these omitted transpositions level the very high peak at 400–410 kc but they splash the debris over the kilocycle landscape and do not help in making frequencies usable above about 350 kc.

Since the top usable frequency is in inverse proportion to the transposition pole spacing, shortening the spacing increases the top frequency and vice versa. This is illustrated by Fig. 10 which shows insertion loss-frequency curves for pairs 1–2 and 7–8 of an *R1-5* transposed line and for a line length of 14.1 miles. Here the critical frequency is 320–330 kc instead of 400–410 kc because the usual spacing between transpositions in any one pair is about 734 ft instead of 600 ft. With pair 5–6 an absorption peak of 55 db at 330 kc was measured for the 14.1-mile length. This pair is transposed at each odd-numbered transposition pole. This tends to build up a large single peak which is probably somewhat reduced because the transposition interval deviations are quite large (summed $U^2 = 9L$). The other pairs

196

have transpositions omitted at some of the transposition poles numbered 25, 50, 75, etc. These omitted transpositions tend to splash the big peak about but the usable top frequency appears to be 290–300 kc.

CROSSTALK LOSSES

In each of the test sections, all combinations of the through pairs were measured for input-to-output near-end crosstalk loss in db and output-to-output far-end crosstalk losses. Fig. 7 showed measured and computed near-end crosstalk losses (Oakdale to TP128) for combination 1–2 and 3–4 and combination 3–4 and 7–8.

Figs. 11, 12, and 13 show representative measured far-end crosstalk losses for horizontally adjacent pairs, horizontally alternate pairs, and vertically adjacent pairs. Losses when sending on the lower-numbered pair (of a pair combination) are indicated by solid lines and losses when sending on the higher numbered pair are indicated by dashed lines. The solid and dashed lines differ somewhat and this is theoretically a result of irregularities in construction.

On Figs. 11, 12, and 13, a comparison is made between *REA-1* transposed pairs and *R1-5* transposed pairs. The comparison is not an exact one since *REA-1* pairs were 7.3 miles long and had 0.104-inch 40% conductivity copperweld conductors while the *R1-5* pairs were 10.9 miles long and had 0.080-inch 30% copperweld wires. The average transposition pole spacing was 300 ft for the *REA-1* pairs and 367 ft for the *R1-5* pairs.

If the *R1-5* transposition pole spacing were reduced to 300 ft and the line length reduced from 10.9 to (300/367) 10.9, or 8.9 miles, the *R1-5* transposed pairs would be expected to have 5 to 10 db higher far-end crosstalk losses over the frequency range of 50–350 kv. Even with such an adjustment, the *REA-1* far-end crosstalk losses run about 15 db higher than those for *R1-5* transpositions. This may be deduced from Figs. 11, 12, and 13. This improvement is probably a result of selection of transposition patterns suitable for the higher carrier frequencies[8] and better control of irregularities in construction.

A comparison of measured near-end crosstalk losses for *REA-1* and *R1-5* transpositions indicates an advantage for the former of about 15–20 db.

Fig. 14 shows measured values of far-end crosstalk loss for the line lengths of 7.3, 9.2, and 22.0 miles. The pair combination is 1–2 and 3–4. At each frequency there is given the average of two values of crosstalk loss, one for sending on 1–2 and the other for sending on 3–4. As

First figures give output-to-output far-end losses; second figures give input-to-output near-end losses. 300-foot transposition intervals. A pair is indicated by its lowest numbered wire.

* Measured in 7.3-mile stretch. Other crosstalk losses are computed using case B coefficients of Figs. 6(A) and (B) and assuming sum of $U^2 = 6L$ in feet.

shown by Fig. 14, the effect of line length in decreasing the crosstalk loss is not marked even though the transposition patterns for the 9.2- and 22.0-mile lengths were not completely symmetrical ones. Also, as previously discussed, the transposition pole spacing deviations were much greater in the 9.2-mile length than in the other two lengths.

Thus, theory and experiment indicate that with *REA-1* transpositions and for combinations of pairs on the top crossarm, the crosstalk losses do not decrease with length to any marked extent. However, the rate of decrease of crosstalk losses with increase in transposition pole spacing is quite rapid. Contrariwise, the rate of increase of crosstalk losses with decrease of pole spacing is quite rapid. This effect may be deduced from Figs. 7, 11, 12, 13, and 14, by multiplying the frequency scales by $300/d$ where d is the transposition pole spacing in feet.

Crosstalk Loss Data for Engineering Purposes

For engineering purposes Table I has been prepared. This gives crosstalk loss data for pair combinations on the top crossarm and for 7.3-, 14.5-, and 29.1-mile lengths. The crosstalk losses were measured for the 7.3-mile lengths. The tables also give data for 7.3- and 14.5-mile lengths, for combinations of pairs on different crossarms and for combinations of pairs on the second crossarm. As indicated on the table, some of the latter two types of pair-combinations were measured. A brief summary of conclusions to be drawn from these tables is given in the following.

Conclusions

1. The field trial indicates that the *REA-1* transposition system meets the objective that it retain much of the simplicity and economy of the *R1-5* transposition system and at the same time provides marked improvement in carrier frequency crosstalk losses.

2. From the standpoint of tolerable absorption loss and tolerable crosstalk losses, the maximum usable frequency is about 350 kc for a transposition pole spacing of 300 ft. The maximum usable frequency is inversely proportional to the transposition pole spacing.

3. Combinations of pairs on the top crossarm are in sufficient agreement with the crosstalk loss objectives up to 200 kc and for at least 29–30 miles. From 200–350 kc a crosstalk advantage (due to compandors, "FM capture," etc.) of 5–20 db is required depending on the top frequency. The crosstalk objectives were 50 db or more for far-end crosstalk loss and 40 db or more for near-end crosstalk loss.

4. Combinations of pairs involving one or more second crossarm pairs are in sufficient agreement with the crosstalk loss objectives up to 200 kc and for a length of 7–10 miles (assuming 300-ft transposition pole spacing). As expected, from 200 to a maximum of 300 kc, a crosstalk advantage of 5 to 20 db is required.

5. Further field tests of crosstalk losses up to 350 kc and for lengths of 30 miles or more might give additional data very useful for engineering purposes.

6. Crosstalk losses have not been carefully investigated for lengths longer than those given in Table I. A brief study indicates that doubling the maximum length given for any pair combination on this table would not usually cause any serious decrease in these losses insofar as they are controlled by the transposition patterns. Exceptional combinations are pair 9–10 to pair 13–14 and pair 3–4 to pair 11–12. For these combinations the far-end crosstalk losses are estimated to decrease about 6 db if the 14.5-mile length is doubled. The crosstalk losses, however, are determined not only by the transposition patterns but also by irregularities in construction. If it is desired to exceed the line lengths of Table I by an appreciable amount it is suggested that the rule for controlling transposition pole spacing irregularities shall be that the summed values of U^2 do not exceed $3L$ instead of $6L$.

It is hoped that, with the development of the *REA-1* transposition system, the authors and their associates have written a footnote to the history of better communications at a reasonable cost.

Analysis of Transcendental Nonlinear Systems

ALFRED A. WOLF
MEMBER AIEE

IN THE RECENT literature[1–6] certain aspects of a nonlinear theory were introduced which enable the solving of a class of nonlinear systems whose general dynamic equation is given by one like the following:

$$Z(D)x(t)+F\{x,\dot x,\ldots\}=g(t) \tag{1}$$

where the linear part $Z(D)x(t)$, the nonlinear part $F\{x,\dot x,\ldots\}$, and the driving function $g(t)$ are required to satisfy certain conditions given in references 1 and 2, and x is the response function. The dotted letters are time derivatives, so that $\dot x = d/dt$. The linear integro-differential operator has the form

$$Z(D)=\sum_{n=-N_1}^{N_2} f_n D^n$$

The coefficients f_n are constants for each value of n and the bounds N_1 and N_2 are positive, negative, or either one is zero, depending on $Z(D)$. Time-varying linear terms are easily added in a similar manner and offer no difficulty either of a theoretical or computational nature. The forcing function $g(t)$, although assumed here to be a deterministic process, may be relaxed to a random process with the aid of the transform ensemble theorem, as explained in reference 6.

In the papers cited,[1–6] the partition method was introduced based on the abovementioned restrictions. The method was applied to nonlinearities of the polynomial type. (The polynomials may include the function x and its derivatives in any complicated manner.) This paper shows how to apply the partition method to transcendental nonlinearities and illustrates the method with a simple example.

Solution of Differential Equations Containing Transcendental Nonlinearities

Many nonlinear problems in physics give rise to nonlinearities which may be represented as transcendents. For example, in solid-state physics, electronics, and transistor circuitry, equation 2 might be a representative equation describing the particular phenomena.[7]

$$Z(D)x(t)+be^x=g(t) \tag{2}$$

where $x=x(t)$ is the normalized solution. Another source of transcendence occurs in saturating systems.[8] Such systems as vacuum-tube circuitry, servomechanisms, etc., may be represented as

$$Z(D)x(t)+c\tanh x=g(t) \tag{3}$$

In synchronous machines[9] the stability of the machine, its pullout torque, etc., is usually studied by means of an equation of the following type:

$$J\ddot\theta+r\dot\theta+a\sin\theta=T \tag{4}$$

where

θ = angular displacement of the rotor
J = moment of inertia of the rotor
r = a resistive damping torque coefficient
$a\sin\theta$ = control torque
T = load torque

Under certain conditions it is possible to transform equations such as those given above into corresponding nonlinear differential equations of the polynomial type.[2] Then, when the resulting nonlinear differential equation is solved with algebraic types of nonlinearities, the solution for the differential equation with the transcendental nonlinearity is easily solved by reversing the transformation.

Solution Procedure

Given: A nonlinear differential equation such as

$$Z(D)x(t)+F(x)=g(t) \tag{5}$$

in which $F(x)$ is a transcendent. If the inverse function $F^{-1}(w)$ has an algebraic derivative, then equation 5 can be converted to a nonlinear differential equation with algebraic nonlinearities.

If the resulting algebraic nonlinearities satisfy the conditions previously imposed,[1,2] then a unique solution exists in the sense previously given. With this principle it is now possible to convert equations 2, 3, and 4 to the algebraic type of nonlinearity.

Consider, first, equation 2. Let

$$w=e^x \tag{6}$$

or its inverse

$$x=\log w \tag{7}$$

Then, on substituting equation 7 into equation 2 and differentiating w with respect to t in

$$Z(D)\log w+bw=g(t) \tag{8}$$

equation 8 becomes

$$Z(D)\frac{\dot w}{w}+bw=\dot g(t) \tag{9}$$

Let

$$Y(D)=\frac{1}{Z(D)} \tag{10}$$

and preoperate on each factor of equation 17 by $Y(D)$; simplifying yields

$$\dot w-bwY(D)\dot w-wY(D)\dot g=0 \tag{11}$$

In a similar manner equation 11 is converted to

$$\dot w+c(1-w^2)Y(D)\dot w=(1-w^2)Y(D)\dot g(t) \tag{12}$$

under the transformation

$$w=\tanh x \tag{13}$$

and equation 12 becomes

$$J\dot w+r\sqrt{1-w^2}\,\frac{1}{D}\,\frac{\dot w}{1-w^2}+ a\sqrt{1-w^2}\,\frac{1}{D}\,w=\sqrt{1-w^2}\,\frac{1}{D}\,T \tag{14}$$

under the transformation

$$w=\sin\theta \tag{15}$$

With the *partition method* described elsewhere[1,2] the transformed equations are easily solved.

Solution of a First-Order System

Consider a time-varying nonlinear transcendental system whose behavior is described by the following differential equation:

$$(1-t)\frac{dx}{dt}+e^x+t=0 \tag{16}$$

with boundary conditions

$$x(0)=0$$
$$\dot x(0)=-1 \tag{17}$$

Paper 60-879, recommended by the AIEE Basic Sciences Committee and approved by the AIEE Technical Operations Department for presentation at the AIEE Summer General Meeting, Atlantic City, N. J., June 19–24, 1960. Manuscript submitted February 1, 1960; made available for printing April 26, 1960.

ALFRED A. WOLF is with the Stromberg-Carlson Company, Division of General Dynamics Corporation, Rochester, N. Y.

The author is deeply indebted to Dr. Y. H. Ku for his assistance and constant advice; and Dr. H. Sohon, Dr. J. G. Brainerd, Dr. R. Weller, and K. M. Lord for their generous and encouraging support. Grateful acknowledgment is made to the National Science Foundation for their support and encouragement in the preliminary aspects of this research, and to the Stromberg-Carlson Company for its support in continuing this work.

Following the artifice described, let

$$w = e^{x} \tag{18}$$

or

$$x = \log w \tag{19}$$

Substituting equation 19 into equation 16 yields

$$(1-t)\frac{\dot{w}}{w} + w = -t \tag{20}$$

Partitioning equation 20 at the $\dot{w}$ term gives

$$\dot{w} = -tw - w^{2} + t\dot{w} \tag{20A}$$

from which equation 21, and 22 the auxiliary equation, are obtained:

$$\dot{w} = \sum_{n=0}^{\infty} C_n t^{n} \tag{21}$$

$$\sum_{n=0}^{\infty} C_n t^{n} = -tw - w^{2} + t\dot{w} \tag{22}$$

Integrating equation 21 once,

$$w = \sum_{n=0}^{\infty} \frac{C_n}{n+1} t^{n-1} + K \tag{23}$$

where $K=1$, in order to satisfy the given boundary conditions. Combining equation 23 with equation 22 yields the recurrence relation

$$C_n = -\frac{C_{n-2}}{n-1} - C_{n-1}{}^{(0)} - C_{n-2,0}{}^{(2)} - \frac{2C_{n-1}}{n} - C_n{}^{(0)} + C_{n-1} \tag{24}$$

Solving the recurrence relation by successive substitution yields:

For $n=0$:

$$C_0 = -1 \tag{25}$$

For $n=1$:

$$C_1 = -1 - 2C_0 + C_0 = 0 \tag{26}$$

For $n=2$:

$$C_2 = -C_0 - C_{0,0}{}^{(2)} - 2\frac{C_1}{2} + C_1 \tag{27}$$

Since

$$C_{n-2,0}{}^{(2)} = \sum_{k=0}^{n-2} \frac{C_k}{k+1}\frac{C_{n-k-2}}{n-k-1} \tag{28}$$

then

$$C_{0,0}{}^{(2)} = C_0{}^{2} \tag{29}$$

Hence

$$C_2 = -C_0 - C_0{}^{2} = 1 - 1 = 0 \tag{30}$$

For $n=3$

$$C_n = -\frac{C_{n-2}}{n-1} - \sum_{k=0}^{n-2} -\frac{C_k C_{n-k-2}}{(k+1)(n-k-1)} - \frac{2C_{n-1}}{n} + C_{n-1} \tag{31}$$

Since each term of the right member will depend on C_1 and C_2 for $n=3$, then $C_3=0$, and since successively higher terms will depend on, first, C_2, C_3 which are zero, then C_3, C_4, which are also zero, it may be concluded that

$$C_n = 0 \text{ for all } n \geq 3 \tag{32}$$

Substituting the values of the C's as determined above into equation 23 gives

$$w = 1 - t \tag{33}$$

Applying the inverse transformation, equation 19, gives the solution of equation 16 as

$$x(t) = \log(1-t) \tag{34}$$

which satisfies the given boundary conditions.

Limitations and Possibility of Extension

The scheme presented in this paper somewhat extends the method of partition to nonlinear functions other than algebraic types. A limitation of this scheme occurs when the resulting derivative gives rise to nonlinear functions which are not consistent with the required conditions. In some such cases special treatment can be applied to the resulting nonlinearity so as to bring it into consistency with the required conditions. An example of this occurs in equations like equation 4. We see that equation 4 goes into equation 14, which has fractional nonlinearities. These must be treated with special care.

The modified forcing function $A(t)$ which is given in equation 35 by partitioning equation 1 at, say, the linear part, may be expanded in a number of ways:

$$Z(D)x(t) = A(t) \tag{35}$$

One such expansion is a Dirichlet series.[10,11] This is proved in reference 2. Combining this expansion of $A(t)$ with the technique described here increases the power of the method since it is possible to examine periodic and exponential behavior easily.

It is also to be noted that all but the highest-order derivative may be transposed to the right member. In this case the moments of the folded impulse response $y(t)$ given below are power functions. By the moment theorem[1,2] the solution of equation 1, which is the linear combination of all the moments of the folded impulse response of the linear part, is in this case a power series. If the partition is made so as to leave the highest-order derivative, say the kth derivative, and the next lower order derivative, say the $(k$-$1)$ derivative in the left member, then the solution will consist of sums of entire functions of exponential type of order 1 that are nonperiodic. If the kth derivative and the $(k-1)$ derivative remain in the left member after partitioning, the solution will consist of sums of entire functions[12,13] of exponential type of order 1 that are periodic. A detailed development of the partition process and its effect on the nature of the solution may be the subject of a future work.

Conclusions

This paper has presented a simple means of extending the partition theory to the case of nonlinear functions that are transcendental. It was shown that whenever the transcendent is such that its inverse has an algebraic derivative, the differential equation can be transformed into one that contained only algebraic nonlinearities. The solution then followed the method prescribed in earlier work.[1–6] The recurrence relations can be formulated as described in references 1 and 2 or by the Taylor-Cauchy transform given in reference 5.

The method of transformation of variables presented here fails in the case of nonlinear functions consisting of algebraic and transcendental functions. To solve such problems other methods must be applied. An approximate solution to this kind of problem was developed in reference 8. An exact solution of this problem in the sense represented by references 1 and 2 has not yet been determined.

Although the forcing function is assumed to be of an exponential type, it is possible to relax this condition, as described in reference 6, to random functions. It is then possible, with the procedure given here with the Taylor-Cauchy transform, to study, among other things, the effects of saturation on random inputs.

Appendix I. Restrictions

Restrictions are as follows:

1. The forcing function, $g(t)$ is of exponential type, and order 1.
2. The impulse response $y(t)$ given below is of exponential type:

$$y(t) = \frac{1}{2\pi j}\int_{Br} \frac{e^{st}}{Z(s)}\, ds$$

3. The nonlinear part $F(x)$ is a continuous, single-valued function of x; moreover, it must satisfy the following condition:

Given $M>0$ and $a>0$, and two continuous functions $u(t)$ and $v(t)$ which are asymptotically like e^{-at}, then

$$|F(u) - F(v)| < Me^{-at}|u - v|$$

This is a modified Lipshitz condition.[1,2,14]

Appendix II. Summary of Principle of Partition

The principle of partition consists essentially of the following steps satisfying certain mentioned conditions:

1. The dynamic equation representing the system is partitioned so that the linear term with the highest-order derivative are contained in one member of the equation.
2. A modified forcing function $A(t)$ is then obtained which consists of the actual forcing function, nonlinear and/or some linear terms (but not the highest-order derivative).
3. A proper choice is made of the expansion of $A(t)$ according to the particular properties of the linear, nonlinear, and driving functions. An auxiliary equation is thus formed.
4. The properly partitioned differential equation is then solved.
5. Certain coefficients which arise from the auxiliary equation are then calculated.
6. These coefficients which appear in the partitioned equation, are then eliminated to obtain the exact solution.

Theory of 3-Phase Bridge Magnetic Amplifier

II—The Time Constant

HERBERT F. STORM
MEMBER AIEE

CLARENCE W. FLAIRTY
ASSOCIATE MEMBER AIEE

THE OBJECT of this paper is to derive the time constant of a 3-phase bridge-connected magnetic amplifier from its static control characteristic. The bridge connection is the most widely used 3-phase connection because of its high degree of utilization for rectifiers and magnetic components; it was therefore chosen for this study.

The time constant is derived from the static control characteristic of the amplifier, and the dynamic response is presented in the form of a transfer function. Test data and calculated data are compared.

A prerequisite for studying the dynamics of a 3-phase bridge amplifier is an understanding of its steady-state properties. The latter properties are described in detail in Part I of this paper;[1] for further material on 3-phase amplifiers see references 2 through 16.

Circuit Connections and Supply System

The circuit under consideration is shown in Fig. 1(A); it is called a 3-phase bridge magnetic amplifier. The amplifier consists of six identical saturable reactors $A, C' \ldots, B'$, and six identical rectifiers rec A, rec $C' \ldots$, rec B'. The load is a pure resistance.

The terminals 1, 2, and 3 are connected to a symmetrical 3-phase system, having the star voltages

$$e_{1-0}=\frac{E_m}{\sqrt{3}}\cos\theta \tag{1A}$$

$$e_{2-0}=\frac{E_m}{\sqrt{3}}\cos\left(\theta-\frac{2\pi}{3}\right) \tag{1B}$$

$$e_{3-0}=\frac{E_m}{\sqrt{3}}\cos\left(\theta-\frac{4\pi}{3}\right) \tag{1C}$$

with

$$\theta=\omega t \tag{2}$$

and

$$\omega=2\pi f \tag{3}$$

The line-to-line voltages e_{1-2}, e_{2-3}, e_{3-1} are defined by equations

$$e_{1-2}=e_{1-0}-e_{2-0} \tag{4A}$$

$$e_{2-3}=e_{2-0}-e_{3-0} \tag{4B}$$

$$e_{3-1}=e_{3-0}-e_{1-0} \tag{4C}$$

and, when substituted in equations 1, they result in

$$e_{1-2}=E_m\sin\left(\theta+\frac{2\pi}{3}\right) \tag{5A}$$

$$e_{2-3}=E_m\sin\theta \tag{5B}$$

$$e_{3-1}=E_m\sin\left(\theta-\frac{2\pi}{3}\right) \tag{5C}$$

The supply voltages are shown in Fig. 1(B) in phasor form and in Fig. 1(C) in sinusoidal form. With the use of the phasor diagram the instantaneous values of the voltages are obtained by rotating the entire phasor diagram counterclockwise and by taking the projections of the phasors on the stationary base line, indicated by $\theta=0$.

The dots in Fig. 1 signify winding polarities. The voltage across a winding is defined as positive when the terminal with the dot is more positive than the other terminal. A current is called positive when it flows in the direction of the arrow. The magnetomotive force is called positive when derived from a positive current and the core fluxes are called positive

when derived from positive magnetomotive forces.

Control Circuit

The resistances of the control windings and any external circuit resistance are lumped into the control circuit resistance R_C; see Fig. 1(A). Then, the equation for the control circuit is

$$E_C=e_{C,A}+e_{C,C'}+e_{C,B}+e_{C,A'}+e_{C,C}+e_{C,B'}+i_CR_C \quad (6)$$

If we consider magnetic flux due to ferromagnetism only, the above voltages can be expressed in terms of the core fluxes of the saturable reactors:

$$e_{C,A}=\frac{d\phi_A}{dt}\,\frac{N_C}{10^8} \quad (7A)$$

$$e_{C,C'}=\frac{d\phi_{C'}}{dt}\,\frac{N_C}{10^8} \quad (7B)$$

$$\vdots$$

$$e_{C,B'}=\frac{d\phi_{B'}}{dt}\,\frac{N_C}{10^8} \quad (7F)$$

Denoting the total flux linkage as seen by the control circuit by

$$\psi_C=(\phi_A+\phi_{C'}+\phi_B+\phi_{A'}+\phi_C+\phi_{B'})N_C \quad (8)$$

yields from equations 6 through 8

$$E_C=i_CR_C+\frac{d\psi_C}{dt}\,10^{-8} \quad (9)$$

Equation 9 bears considerable similarity to the differential equation of a linear reactor circuit. For instance, in both cases and with zero circuit resistance, the total flux linkage increases linearly with time, if the control voltage E_C is a pure d-c quantity and remains constant. One difference between the two circuits consists in the presence of ripple in the case of the magnetic amplifier. This ripple has a fundamental frequency of $6f$, and higher harmonics. The ripple not only pervades the core flux, but also practically all other electrical quantities occurring in the amplifier.

For the purpose of further analysis, the various quantities will be separated into an average component and an alternating component. For instance, the flux linkage ψ_C can be written

$$\psi_C=\Psi_C+\psi_{C,a-c} \quad (10A)$$

where Ψ_C is the average component

$$\Psi_C=\frac{3}{\pi}\int_0^{\pi/3}\psi_C\,d\theta \quad (10B)$$

Similarly, the control current i_C is

$$i_C=I_C+i_{C,a-c} \quad (10C)$$

where I_C is the average component

$$I_C=\frac{3}{\pi}\int_0^{\pi/3}i_C\,d\theta \quad (10D)$$

When, from equation 10A, c is substituted into equation 9, the five terms can be grouped into E_C, I_C, Ψ_C, and $i_{C,a-c}$, $\psi_{C,a-c}$. If we stipulate that this analysis shall be applied to transients whose duration is long by comparison to the duration of an averaging cycle ($\Delta t=1/6f$), the a-c components cancel each other, resulting in

$$E_C=I_CR_C+\frac{\Delta\Psi_C}{\Delta t}\,10^{-8} \quad (11)$$

The differential quotient in equation 9 was replaced by a difference quotient because of the sampled character of the average quantities.

Assumptions

The following assumptions will be made: The duration of the transient is long by comparison with the duration of $1/6f$. The saturation branches of the hysteresis loops of the reactor cores are horizontal. Fluxes due only to ferromagnetism are considered. At the so-called minimum load point M in Fig. 2 the core fluxes swing just from negative saturation to positive saturation (normal excitation). The rectifier reverse resistance is infinity. The resistance of the control circuit is small by comparison with the (unsaturated)

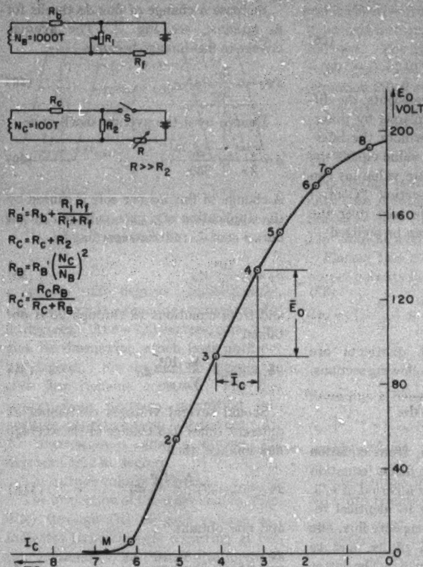

Fig. 2. Control characteristic of amplifier. Numbers on curve representing characteristic refer to measurements of transients in Table I

magnetizing reactance formed by the series-connected control windings. Gate resistance R_G and rectifier forward resistances R_f are lumped externally into a resistance in series with the load resistance R_L; the total of these resistances form the output circuit, and its value R_0 is called the output resistance:

$$R_0 = R_L + 2R_G + 2R_f \tag{12}$$

The contributions of the magnetizing currents of the saturable reactors to the magnitude of the current flowing in the output circuit will be neglected.

A magnetic amplifier such as shown in Fig. 1 can be viewed as a switching device which will admit the supply voltage to the load resistance for a controllable fraction of the period of the supply voltage. The supply voltage when applied to the output circuit is called the output voltage e_0. Hence, the load current i_L becomes

$$i_L = \frac{e_0}{R_0} \tag{13A}$$

The average E_0,

$$E_0 = \frac{3}{\pi}\int_0^{\pi/3} e_0 d\theta \tag{13B}$$

and the average load current I_L,

$$I_L = \frac{E_0}{R_0} \tag{13C}$$

In calculating the performance of feedback-control systems by means of Bode or Nyquist diagrams, only the changes of the variables called the incremental variables are of interest. The following analysis will deal mostly with incremental variables, designated by a bar over the symbol. Where the transient response has to be finally expressed in absolute values, the law of superposition is applied: The instantaneous absolute value of the variable during the transient equals the variable before the transient, plus the incremental variable during the transient.

In terms of incremental values, equation 11 becomes

$$E_C = \bar{I}_C R_C + \frac{\Delta\Psi_C}{\Delta t} 10^{-8} \tag{14}$$

Derivation of Response

The first term of equation 14 can be expressed by

$$E_C = I_C R_C \tag{15}$$

Defining the incremental voltage gain K_E of the amplifier by

$$K_E = \frac{E_0}{E_C} \tag{16}$$

and expanding the second term in equation 14 yields

$$E_C = \frac{E_0}{K_E} + \frac{\Delta\Psi_C}{\Delta E_0}\frac{\Delta E_0}{\Delta t} 10^{-8} \tag{17}$$

Based on the assumption of long transients, the difference quotient $\Delta E_0/\Delta t$ is approximated by the differential quotient dE_0/dt. With Heaviside notation

$$\frac{dE_0}{dt} = pE_0 \tag{18}$$

To accentuate the similarities in dynamic response between single-phase and 3-phase bridge amplifiers, the factor m is introduced:

$$m = \frac{\Delta\bar{\Psi}_C}{\Delta E_0} 2f \frac{N_G}{N_C} 10^{-8} \tag{19}$$

Substituting equations 18 and 19 in equation 14 yields

$$E_C = \frac{E_0}{K_E} + pE_0 \frac{1}{2f}\frac{N_C}{N_G} m \tag{20}$$

For incremental variations of the control voltage E_C, the voltage gain K_E and the factor m can be considered constant, and one obtains as the solution of equation 20:

$$E_0 = \frac{E_C K_E}{1 + p\frac{1}{2f} K_E \frac{N_C}{N_G} m} \tag{21}$$

Equation 21 signifies an exponential response with the so-called control circuit time constant T_C

$$T_C = \frac{1}{2f} K_E \frac{N_C}{N_G} m \tag{22}$$

With a single-phase bridge magnetic amplifier, $m = 1$ (see reference 4, p. 145).

If no other circuits, such as bias circuits, are coupled to the control windings, the total time constant T of the magnetic amplifier is equal to the control circuit time constant T_C. With other resistive circuits coupled to the control windings,

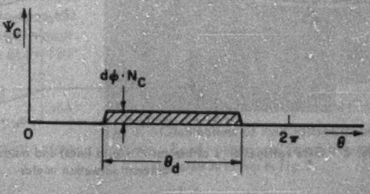

Fig. 3. Illustration for calculation of average flux linkages; see equation 28

T consists of the sum of T_C and the other time constants, explained in reference 4, p. 161.

From equations 21 and 22 one obtains for the transient response of the output voltage

$$E_0 = K_E E_C \frac{1}{1+pT_C} \tag{23}$$

The transient response of I_L becomes (equation 13C)

$$I_L = \frac{E_C K_E}{R_0} \frac{1}{1+pT_C} \tag{24}$$

and the response of the control current I_C becomes

$$I_C = \frac{E_C}{R_C} \frac{1}{1+pT_C} \tag{25}$$

For the qualitative determination of the transient response, K_E (equation 16) and m (equation 19) need to be known. The incremental voltage gain can be determined from a static control characteristic such as shown in Fig. 2, with the use of equations 15 and 16; m is determined analytically. To do this, the saturation angle α is parametrically introduced into the difference quotient of equation 19. To simplify the notations the saturation angle will be called α (not α_s as in part I of the paper).

$$\frac{\Delta\bar{\Psi}_C}{\Delta\bar{E}_0} = \frac{\dfrac{\Delta\bar{\Psi}_C}{\Delta\bar{\alpha}}}{\dfrac{\Delta\bar{E}_0}{\Delta\bar{\alpha}}} \tag{26}$$

As we consider long transients, the difference quotients are replaced by differential quotients. Furthermore, the differential of an incremental value equals the differential of the absolute value (as can be deduced from the section "Control Circuit") and hence, the bars over the symbols of differentials can be omitted:

$$m = \frac{\dfrac{d\Psi_C}{d\alpha}}{\dfrac{dE_0}{d\alpha}} 2f \frac{N_G}{N_C} 10^{-8} \tag{27}$$

How these differential quotients are obtained is shown in the following sections.

Determination of $d\Psi_C/d\alpha$

To determine $d\Psi_C/d\alpha$, from equation 27, the sum of all six core fluxes (equation 8) may be averaged over a period of $\pi/3$. Another method leading to identical results is to consider only one core flux, but averaged over a period of 2π, and to multiply this average by 6. The latter method is more practical, and will be subsequently used.

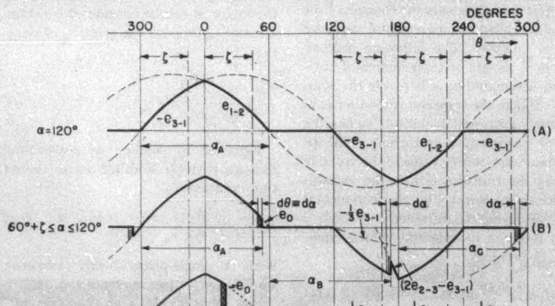

Fig. 4. Gate voltages $e_{G,A}$ of reactor A (solid lines) and output voltages e_0 (dashed lines) for different saturation angles

Suppose a change of flux $d\phi$ dwells for θ_d radians; see Fig. 3. The average change in flux linkage becomes

$$d\Psi_C = 6 \frac{\theta_d}{2\pi} d\phi N_C \tag{28}$$

Denote by ϑ the average dwell of $d\phi$

$$\vartheta = \frac{\theta_d^{\text{rad}}}{2\pi} \text{ or } \frac{\theta_d^{\circ}}{360} \tag{29}$$

A change of flux $d\phi$ per core is caused by the application of a gate voltage e_G for a duration of $d\alpha$ radians according to

$$d\phi = e_G \frac{10^8}{\omega N_G} d\alpha \tag{30}$$

and from equations 28 through 30 is obtained

$$d\Psi_C = 6(e_G\vartheta) \frac{N_C}{N_G} \frac{10^8}{\omega} d\alpha \tag{31}$$

Should several voltages contribute at different times to a change of the average flux linkage, then

$$d\Psi_C = 6\Sigma(e_G\vartheta) \frac{N_C}{N_G} \frac{10^8}{\omega} d\alpha \tag{32A}$$

and one obtains

$$\frac{d\Psi_C}{d\alpha} = 6\Sigma(e_G\vartheta) \frac{N_C}{N_G} \frac{10^8}{\omega} \tag{32B}$$

The gate voltages e_G have been determined;[1] hence equation 32B can be evaluated. The gate voltages are shown in Fig. 4 for the gate voltage $e_{G,A}$ of reactor A. The voltages of the other gates have the same wave shape, but are phase-displaced sequentially by 60 degrees, following in the order of A, C', B, A', C, B'.

The assumptions under which these wave shapes were obtained are the same as those outlined in the section "Assumptions." More specifically, the hysteresis loop of the saturable reactor is shown in Fig. 5(A). The slopes of the dynamic loop may vary from zero to infinity, and no restrictions are placed on the width of the d-c hysteresis loop. The hysteresis loop may also have the form shown in Fig. 5(B), provided

$$\frac{AT_{c,dc}}{AT_{c,0}} \geq 1 - 2(\sqrt{3}-1) \tag{33}$$

Determination of Factor m, Equation 27

Minimum Load Point $\alpha = 120$ Degrees. The gate voltage $e_{G,A}$ for saturable reactor A is shown in Fig. 4(A). The saturation angle α is counted from the instant when the flux begins its upswing until saturation is reached. The upswing of the flux in core A begins at $\theta = 300$ degrees and ends at $\theta = 60$ degrees; hence

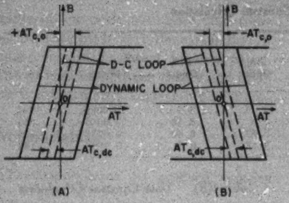

Fig. 5. Dynamic and d-c B-H loops; see equation 33

α equals 120 degrees. Subsequently, the core flux remains constant for 60 degrees. At $\theta = 120$ degrees, core A begins its downswing which lasts until $\theta = 240$ degrees. For the next 60 degrees the core flux remains constant. The flux swings from negative saturation into positive saturation from 300 degrees $\leq \theta \leq$ 60 degrees, and returns during 120 degrees $\leq \theta \leq 240$ degrees.

The output voltage e_0 is zero.

The inspection of the wave shapes, Figs. 4(A) through (E) of gate voltage $e_{G,A}$ indicates basic changes occurring at certain boundaries, and hence the factor m is determined separately for the various ranges.

From Fig. 4(B) $60° + \zeta \leq \alpha \leq 120°$. Suppose the saturation of core A occurs at $\theta = -60° + \alpha_A$; at this instant the gate voltage $e_{G,A}$ vanishes from A and reappears in the output circuit as the output voltage e_0, shown by a dashed line in Fig. 4(B). At $\theta = 60° + \alpha_B$, core B saturates and, as a result, the gate voltage $e_{G,A}$ drops to $(2e_{2-3} - e_{3-1})$. At $\theta = 180° + \alpha_C$, core C saturates and $e_{G,A}$ reappears. The angles α_A, α_B, and α_C are identical in magnitude, and different indexes merely point to that core which goes into saturation.

Let us now introduce a change of control voltage in the positive direction. As a result, corresponding changes follow for the saturation angle, control current, and gate and output voltages. The voltage changes are shown in Fig. 4 by various forms of shading: the changes in output voltage by crosshatching, the changes in gate voltage by vertical or horizontal shading, for positive and negative differential contributions respectively. The contributions of the vertically or horizontally shaded gate voltages produce the change of flux linkages according to equation 32A. In the case shown in Fig. 4(B) there are two contributions to change the flux linkage; The first occurs at $\theta = 60° + \alpha$; the contributing voltage is

$$e_{G,A} = -e_{3-1} - (2e_{2-3} - e_{3-1}) = -2e_{2-3} \quad \text{(34A)}$$

and is effective from $\theta = 60° + \alpha$, until core A returns into positive saturation at $\theta = 300° + \alpha$. The dwell angle $\theta_d = (300° + \alpha) - (60° + \alpha) = 240°$, and the average dwell (equation 29) $\vartheta = 2/3$.

The second contribution occurs at $\theta = 180° + \alpha$. The contributing voltage is

$$e_{G,A} = -e_{3-1} \quad \text{(34B)}$$

This voltage is effective from $\theta = 180° + \alpha$ until core A returns into positive saturation at $\theta = 300° + \alpha$. The dwell angle $\theta_d = 120°$ and the average dwell $\vartheta = 1/3$.

Placing this contributing voltage with proper polarity into equation 32A yields

$$d\Psi_C = 6\left(-\frac{4}{3}\,e_{2-3}\Big|^{60°+\alpha} + \frac{1}{3}\,e_{3-1}\Big|^{180°+\alpha}\right) \times \frac{N_C}{N_G}\,\frac{10^8}{\omega}\,d\alpha \quad \text{(35A)}$$

From Fig. 1(B) and (C)

$$e_{2-3}\Big|^{60°+\alpha} = -e_{3-1}\Big|^{\alpha} \quad \text{(34C)}$$

$$e_{3-1}\Big|^{180°+\alpha} = -e_{3-1}\Big|^{\alpha} \quad \text{(34D)}$$

Substituting from equations 34C and 34D into equation 35A yields

$$\frac{d\Psi_C}{d\alpha} = 6e_{3-1}\Big|^{\alpha}\,\frac{N_C}{N_G}\,\frac{10^8}{\omega} \quad \text{(35B)}$$

and the numerator of equation 27 is thus obtained.

The denominator of equation 27 is the differential of the output voltage dE_0. As shown in Fig. 4(B) the output voltage e_0 equals voltage e_{1-2} from $\theta = -60° + \alpha$ to $\theta = 60°$. Hence

$$dE_0 = 6\,\frac{1}{2\pi}\,(-e_{1-2})\Big|^{-60°+\alpha} d\alpha \quad \text{(35C)}$$

From Fig. 1(B) and (C)

$$-e_{1-2}\Big|^{60°+\alpha} = e_{3-1}\Big|^{\alpha} \quad \text{(34E)}$$

Substituting from equation 34E in equation 35C yields

$$\frac{dE_0}{d\alpha} = \frac{3}{\pi}\,e_{3-1}\Big|^{\alpha} \quad \text{(35D)}$$

Applying equations 35B and 35D to equation 27 yields, finally, for m

$$m = 2 \quad \text{(35E)}$$

As the control current is increased in the positive direction, α continues to decline, and one end point of the voltage contribution follows along the voltage $(2e_{2-3} - e_{3-1})$ until this voltage intersects with voltage $-1/3\ e_{3-1}$, whereupon the end point follows along the latter voltage. The above intersection occurs at $\theta = 120° + \zeta$; hence ζ follows from

$$-\frac{1}{3}\,e_{3-1} = 2e_{2-3} - e_{3-1} \quad \text{(36A)}$$

Simplifying and substituting into equation 5 results in

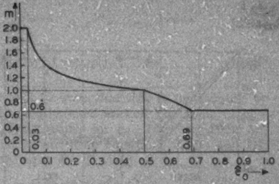

Fig. 6. Factor m, for equation 22, as function of per-unit output voltage $\hat{e}_0$

$$\zeta = 46.1° \quad \text{(36B)}$$

One concludes that $m = 2$ is valid only for saturation angles between 106.1° and 120°. The angle expressed by equation 36B was termed θ_u in Part I of this paper.

Sometimes it is more illustrative to describe the validity range for m in terms of the per-unit output voltage $\hat{e}_0$:

$$\hat{e}_0 = \frac{E_0}{E_{0,m}} \quad \text{(37A)}$$

where E_0 is the average value of the output voltage, and $E_{0,m}$ its maximum average value (at full saturation). This $\hat{e}_0$ is obtainable from Part I of the paper.

$$\hat{e}_0 = 1 - \sin(\alpha - 30°) \quad \text{(37B)}$$
$$60° \leq \alpha \leq 120°$$

$$\hat{e}_0 = \cos\alpha \quad \text{(37C)}$$
$$0 \leq \alpha \leq 60°$$

For the angular range $60° + \zeta \leq \alpha \leq 120°$, one obtains from equations 36B and 37B the validity range for m in terms of per unit output voltage $0 \leq \hat{e}_0 \leq 0.03$.

From Fig. 4(C), $60° \leq \alpha \leq 60° + \zeta$. In this case the flux linkage is affected by three contributions, as outlined in Appendix I, resulting in

$$m = 1 + \frac{1}{3}\,\frac{\sin(\alpha - 60°)}{\sin(120° - \alpha)} \quad \text{(38E)}$$

The validity range for m in terms of $\hat{e}_0$ follows from equation 37B: $0.03 \leq \hat{e}_0 \leq 0.5$.

From Fig. 4(D), $\zeta \leq \alpha \leq 60°$. As shown in Appendix II,

Fig. 7. Oscillograms of load voltage during transient. Load voltage was varied between points as shown in Fig. 2

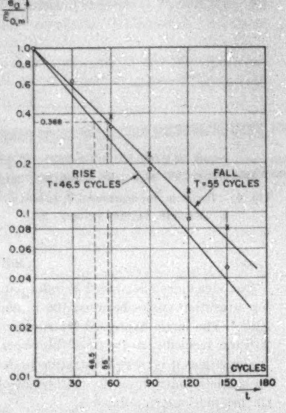

Fig. 8. Transients of Fig. 7 plotted on semilog paper

$$m = 1 - \frac{\sin(60° - \alpha)}{\sin 60°} \qquad (39F)$$

The validity range for equation 39 follows from equation 37C: $0.5 \le \bar{e}_0 \le 0.693$.

From Fig. 4(E), $\theta \le \alpha \le \zeta$. In Appendix III,

$$m = \frac{2}{3} \qquad (40B)$$

The validity range is $0.693 \le \bar{e}_0 \le 1.0$.

To facilitate the calculation of the time constant (equation 22), m was evaluated for various saturation angles (equations 35E, 38E, 39F, and 40B), and plotted versus $\bar{e}_0$ (equations 37B, and 37C) in Fig. 6.

For single-phase bridge amplifiers m is constant (equaling unity). It follows that for the single-phase amplifier the output voltage E_0 and the flux linkages Ψ_C are proportional throughout the entire control range. In contrast, with 3-phase bridge amplifiers m varies from 2 to 2/3; hence, the output voltage and the flux linkages are no longer proportional throughout the entire control range. Prior to this theoretical analysis, this difference between single-phase and 3-phase bridge amplifiers was discovered experimentally by L. C. Harriott and F. J. Ellert of the General Electric Company.

Tests

Tests were conducted on an amplifier connected as shown in Fig. 1. The cores are of toroidal construction, with the use of 4-mil Deltamax tape. The rectifiers are of the germanium type *G.E. 4JA211 CH1AC5*. The maximum power output of the amplifier is 1 kw, with a supply frequency of 60 cycles per second.

Table I(A). Time Constant Calculation

Measured Span	ΔE_0, Volts	ΔI_C, Ma	R_C, Ohms	R_B, Ohms	R_C', Ohms	$\Delta I_C R_C'$, Volts	$\frac{\Delta E_0}{\Delta I_C R_C'}$
1-2	49.6	11.3	34.7	7.11	5.9	0.0666	745
3-4	40.1	10	34.7	7.5	6.16	0.0616	651
5-6	24.2	11.3	34.7	7.87	6.42	0.0725	334
7-8	11.8	11.6	34.7	8.13	6.6	0.0765	154

As the theory is based on long transients, the first checks were aimed at this category. The saw-tooth wave shape of the output voltage makes its evaluation tedious when average values are sought. To simplify the measurement of the average values, a low-pass filter was connected to the output of the amplifier. Such a low-pass filter, however, has the drawback of modifying the transient response as measured. By keeping the filter time constant small with respect to the time constant of the amplifier, the effect of the filter time constant appears only at the beginning of the transient. Two transients of the output voltage of the amplifier including the filter are shown in Fig. 7. One transient is for rising output voltage, the other for falling output voltage. To determine the character of these transients the voltage ratios $e_0/E_{0,m}$ are plotted on semilog paper, resulting in the points marked in Fig. 8; $E_{0,m}$ is the maximum steady-state change of the load voltage, and e_0 signifies the change of load voltage that is necessary to reach $E_{0,m}$.

For true exponential response, the points should lie on a straight line out of the origin. Actually, the points near the origin form a curve, which straightens out as time increases. By drawing through the origin a line parallel to the straight section of the response (Fig. 8), and intersecting it at $e_0/E_{0,m} = 1/\epsilon = 0.368$, two time constants are obtained: for rise, $T = 46.5$ cycles; for fall, $T = 55$ cycles. The fall time constant is somewhat higher because the control voltage can induce voltages in the gate windings which are in the forward direction of the rectifiers and thus may create coupled circuits. In this case, the time constants of the coupled circuits add to the control circuit time constant T_C.

In the calculation of the time constant according to equation 22, and shown in Table I, no coupled circuits through rectifiers were considered, and therefore the calculated values should be compared with the measured data for rise time constants. The time constants in Table I are expressed in cycles, and are obtainable from equation 22 by omitting the frequency f.

Table I(B). Time Constant Calculation

Measured Span	$\frac{\Delta E_0 N_G}{\Delta I_G R_G' N_C}$	m	Time Constant, Cycles: Transient Increasing, Calculated	Time Constant, Cycles: Transient Increasing, Measured	Time Constant, Cycles: Transient Decreasing, Measured
1-2	111	1.3	72	78	
3-4	97	0.9	43.6	46.5	55
5-6	49.8	2/3	16.7	18	26
7-8	23	2/3	7.7	10	14

The ranges over which the time constants of Table I were measured are indicated by numerals in Fig. 2. The insert of Fig. 2 shows the control arrangement, where a bias winding was used to establish one starting point of the transient, and the control winding was used to produce the change in control voltage. Table I is presented not only to provide a comparison between theory and practice, but also to indicate the steps necessary for the calculation of the time constant.

Tests were also conducted to check the validity of equation 22 for relatively smaller time constants, a sample being shown in Table II. In measuring small time constants, a low-pass filter in the output circuit is no longer practical for obtaining average values. Instead, it becomes necessary to determine geometrically the voltage areas in the oscillograms, a procedure not characterized by high precision. In addition, the dead-time effect (not analyzed in this paper) requires consideration.

Conclusions

The time constant of a 3-phase magnetic amplifier can be readily determined from its static control characteristic. Measured data are shown for time con-

Table II. Smaller Time Constant Calculation

stants of one cycle and more, and comparisons are made with the calculation of time constant proposed in this paper. The correlation between theory and practice is within normal engineering accuracy.

Nomenclature

AT_c = ampere-turns to produce coercive force H_c
$AT_{c,dc}$ = ampere-turns to produce static hysteresis loop
E_C = control voltage, volts, average
E_0 = output voltage, volts, average
$E_{0,m}$ = maximum output voltage, volts, average
E_m = supply voltage, line-to-line voltage, maximum (crest)
$e_{C,A}$, $e_{C,C'}$, $\ldots e_{C,B'}$ = voltage across control winding of saturable reactors A, C', $\ldots B'$ respectively, volts, instantaneous
$e_{G,A}$, $e_{G,C'}$, $\ldots e_{G,B'}$ = voltage across gate winding of saturable reactors A, C', $\ldots B'$ respectively, volts, instantaneous
e_0 = output voltage, volts, instantaneous
e_{1-0}, e_{2-0}, e_{3-0} = line-to-neutral voltage, volts, instantaneous
e_{1-2}, e_{2-3}, e_{3-1} = line-to-line voltage, volts, instantaneous
$\hat{e}_0$ = per-unit output voltage, equation 37
f = supply frequency, cycles per second
H_c = dynamic coercive force, oersteds
I_C = control current, amperes, average
i_C = control current, amperes, instantaneous
i_L = load current, amperes, instantaneous
K_E = differential voltage gain, equation 16
m = factor for equation 22, also shown in Fig. 6
N = number of turns
N_C = number of turns of one control winding
N_G = number of turns of one gate winding
p = Heaviside operator
R_C = resistance of entire control circuit, ohms
R_G = resistance of gate winding, ohms
R_L = load resistance, ohms
R_0 = total resistance encountered by load current, ohms
R_f = rectifier forward resistance, ohms
T_C = time constant of control circuit, with no other circuits coupled, seconds
α = saturation (firing) angle, degrees or radians
ζ = boundary angle, equation 36b, degrees
θ = angular variable, degrees or radians
θ_d = dwell angle, degrees or radians
ϑ = average dwell, unity
ϕ_A, $\phi_{C'} \ldots \phi_{B'}$ = core flux in saturable reactors A, $C' \ldots B'$ respectively, maxwells, instantaneous
ψ_C = total flux linkage with control windings, maxwell turns, instantaneous
Ψ_B = total flux linkage with control windings, maxwell turns, average
ω = angular velocity of line voltage, radians per second

Incremental quantities are indicated by bar over symbol.

Appendix I

Conforming to equation 32A, the flux linkage change is

$$d\Psi_C = 6\left[(e_{G,A}\vartheta)\Big|^{60+\alpha} + (e_{G,A}\vartheta)\Big|^{120+\alpha} - (e_{G,A}\vartheta)\Big|^{180+\alpha}\right]\frac{N_C}{N_G}\frac{10^8}{\omega}\,d\alpha \qquad (38A)$$

From Figs. 4(C) and 1(B) and 1(C):

$e_{G,A}$	ϑ
$-\frac{2}{3}e_{3-1}\Big\|^{60+\alpha} = \frac{2}{3}e_{1-2}\Big\|^{\alpha}$ …………………………	$\frac{2}{3}$
$\left(e_{1-2}-\frac{1}{3}e_{2-3}\right)\Big\|^{120+\alpha} = -e_{1-2}\Big\|^{-60+\alpha} - \frac{e_{1-2}}{3}\Big\|^{\alpha}$ ……	$\frac{1}{2}$
$-\frac{1}{3}e_{1-2}\Big\|^{180+\alpha} = +\frac{1}{3}e_{1-2}\Big\|^{\alpha}$ …………………………	$\frac{1}{3}$

Substituting into equation 38A yields

$$\frac{d\Psi_C}{d\alpha} = 6\left(\frac{1}{6}e_{1-2}\Big|^{\alpha} - \frac{1}{2}e_{1-2}\Big|^{-60+\alpha}\right)\frac{N_C}{N_G}\frac{10^8}{\omega} \qquad (38B)$$

The change in the average of the output voltage dE_0

$$dE_0 = -\frac{3}{\pi}e_{1-2}\Big|^{-60+\alpha}d\alpha \qquad (38C)$$

$$\frac{dE_0}{d\alpha} = -\frac{3}{\pi}e_{1-2}\Big|^{-60+\alpha} \qquad (38D)$$

Substituting for e_{1-2} from equation 5A yields from the above equations and equation 27

$$\frac{d\Psi_C}{dE_0} = \left[1+\frac{1}{3}\,\frac{\sin(\alpha-60°)}{\sin(120°-\alpha)}\right]\frac{N_G}{N_G}\frac{10^8}{2f} \qquad (38E)$$

$$m = 1+\frac{1}{3}\,\frac{\sin(\alpha-60°)}{\sin(120°-\alpha)} \qquad (38F)$$

Appendix II

The change in flux linkage is, from equation 32A,

$$d\Psi_C = 6\left[(e_{G,A}\vartheta)\Big|^{120+\alpha} + (e_{G,A}\vartheta)\Big|^{180+\alpha} + (e_{G,A}\vartheta)\Big|^{240+\alpha}\right]\frac{N_C}{N_G}\frac{10^8}{\omega}\,d\alpha \qquad (39A)$$

from Figs. 4(D) and 1(B) and (C)

$e_{G,A}$	ϑ
$(2e_{2-3}-e_{3-1})\Big\|^{120+\alpha} = -2e_{3-1}\Big\|^{60+\alpha} - e_{3-1}\Big\|^{60-\alpha}$ ……	$\frac{1}{2}$
$e_{1-2}\Big\|^{180+\alpha} = e_{3-1}\Big\|^{60+\alpha}$ …………………………	$\frac{1}{3}$
$-e_{2-3}\Big\|^{240+\alpha} = e_{3-1}\Big\|^{60+\alpha}$ …………………………	$\frac{1}{6}$

Substituting into equation 39A yields

$$\frac{d\Psi_C}{d\alpha} = 6\left(-\frac{1}{2}e_{3-1}\Big|^{60+\alpha} - \frac{1}{2}e_{3-1}\Big|^{60-\alpha}\right)\frac{N_C}{N_G}\frac{10^8}{\omega} \qquad (39B)$$

The change of output voltage dE_0 consists of two components:

$$dE_0 = -\frac{3}{\pi}\left[e_{1-2}\Big|^{-60+\alpha} - e_{1-2}\Big|^{\alpha}\right]d\alpha \qquad (39C)$$

From Figs. 1(B) and (C) or equations 5A and 5C

$$e_{1-2}\Big|^{-60+\alpha} - e_{1-2}\Big|^{\alpha} = -e_{3-1}\Big|^{-60+\alpha} \qquad (39D)$$

$$dE_0 = -\frac{3}{\pi}(-e_{3-1})\Big|^{-60+\alpha}d\alpha \qquad (39E)$$

It will be seen that dE_0 is represented by the crosshatched area of Fig. 4(D).

Substituting for e_{3-1} from equation 5C, and substituting equations 39(B) and (E) into equation 27 yields

$$m = 1-\frac{\sin(60°-\alpha)}{\sin 60°} \qquad (39F)$$

Appendix III

The change in flux linkage is given by equation 39A. From Figs. 4(E) and 1(B) and (C)

$e_{G,A}$	ϑ
$-\frac{1}{3}e_{3-1}\Big\|^{120+\alpha} = \frac{1}{3}e_{3-1}\Big\|^{-60+\alpha}$ …………………………	$\frac{1}{2}$
$\frac{1}{3}e_{1-2}\Big\|^{180+\alpha} = \frac{1}{3}e_{3-1}\Big\|^{-60+\alpha}$ …………………………	$\frac{1}{3}$
$-\frac{1}{3}e_{2-3}\Big\|^{240+\alpha} = \frac{1}{3}e_{3-1}\Big\|^{-60+\alpha}$ …………………………	$\frac{1}{6}$

Substituting into equation 32B yields

$$\frac{d\Psi_C}{d\alpha} = 6\times\frac{1}{3}e_{3-1}\Big|^{-60+\alpha}\frac{N_C}{N_G}\frac{10^8}{\omega} \qquad (40A)$$

The change in dE_0 is again

$$dE_0 = -\frac{3}{\pi}(-e_{3-1})\Big|^{-60+\alpha}d\alpha \qquad (39E)$$

Substituting equations 40A and 39E into equation 27 yields

$$m = \frac{2}{3} \qquad (40B)$$

A Generalized Chemical Processing Model for the Investigation of Computer Control

THEODORE J. WILLIAMS
NONMEMBER AIEE

ROBERT E. OTTO
NONMEMBER AIEE

AT PRESENT there is no direct method of comparing the relative applicability of the many computer-control schemes which have recently been proposed for use by the chemical and petroleum processing industries. While many of the computer manufacturers involved have undertaken joint study programs with several of the chemical and petroleum companies, proprietary considerations have to date prevented a direct comparison of the results obtained.

For this reason the Monsanto Chemical Company has proposed the use of the chemical processing model described herein to those interested in computer control with the hope that it may serve as a basis for a direct comparison of the available computers and of their relative capabilities.

Every effort has been made to have this model include as many as possible of the effects present in typical chemical manufacturing plants. Reaction, heat exchange, multiple separation steps, and recycle streams have, therefore, been included, since these will usually be part of a typical process.

Monsanto will welcome all suggestions from any interested reader which may serve to increase the generality of the model. We will also appreciate suggestions for further uses to which this or other processing models may be put to increase the application and knowledge of advanced process-control principles and practices.

Statement of Problem

The plant considered here is to manufacture 40,000,000 pounds per year of a chemical product, *P*, whose exact nature need not be specified at this time. The chemical kinetics of the reaction involved in making *P* are well known and are described later along with a discussion of the reactor scheme to be used.

It will be assumed that a plant has already been designed and built for producing *P*. However, considerable difficulty has been experienced with the stability of operation of the plant, and it is desired to investigate the feasibility of applying computer control in an effort to achieve stable operation. At the same time, it is desired that the computer maintain an optimum balance of plant operating conditions to assure that the maximum return on investment is being obtained.

Existing instrumentation is indicated in the details of the various plant units given in the paper. All existing instruments are pneumatic. The process is equipped with a control house and all indicators and controllers are either mounted on the "flow-chart" type of panel board in the control house or have a remote reader at that location.

It has been requested that the computer manufacturers specify any changes in the the present instrumentation system which they feel are necessary. All new instrumentation specified must be capitalized with the computer. Any present instrumentation retained may be used without cost to the computer installation, since it has already been included in plant depreciation costs.

An extensive study has been made of the economics of this process and the results are indicated in the section on Cost Factors. It has been found that the plant, when at steady state, should operate at very close to the optimum return on investment. However, the instabilities encountered have prevented the attainment of such results, hence this request for a study of the applicability of computer control.

In the interests of reducing the possible work load in investigating this problem, it is requested that the computer manufacturers confine their efforts to the economics of plant operation. No effort should be spent on chemical engineering studies looking toward process improvement by the redesign of plant units or by the addition of further processing equipment. Since all companies considering this problem will not have equivalent chemical engineering staffs, inclusion of such studies, however desirable, would work a hardship on some participants in the study.

Plant Sizing

Fig. 1 shows a block diagram of the plant as now operated with the present flow rates and associated stream temperatures indicated. Each of the plant units is described in detail in the following sections of this report.

Table I presents the chemical analysis data and component flow rates for each stream in the plant.

Physical Properties

Appendix I and its associated Figs. 2–5 present the pertinent physical data on the

Paper 60-119, recommended by the AIEE Computing Devices Committee and approved by the AIEE Technical Operations Department for presentation at the AIEE Winter General Meeting, New York, N. Y., January 31–February 5, 1960. Manuscript submitted November 2, 1959; made available for printing April 7, 1960.

Theodore J. Williams and Robert E. Otto are with the Monsanto Chemical Company, St. Louis, Mo.

This model is a further development of the generalized model proposed by L. Cooper and T. J. Williams before the AIEE Workshop on Control Computers, University of Colorado, Boulder, Colo., May 21–22, 1959. The authors are indebted to D. P. Eckman of Case Institute of Technology for his many suggestions concerning the model and its use. The help of many of their associates at Monsanto is also gratefully acknowledged, especially that of William E. Ball.

Vol.
Pt. 1

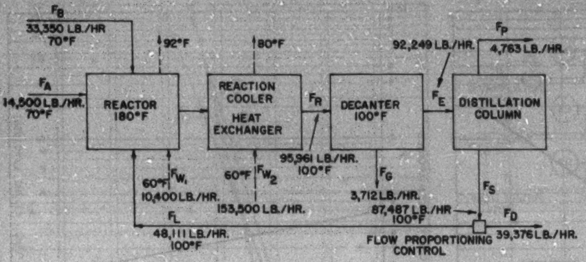

Fig. 1. Process showing relationship of process units, main stream rates, and stream temperatures

components and mixtures involved in this generalized process.

The vapor pressure of the reactor effluent mixture as given in Fig. 2 determines that the operating pressure of the reactor will be 3 atm (atmospheres) and that of the distillation column to be approximately 350 mm (millimeters) of mercury (Hg). It can be assumed that the vapor-pressure temperature curve does not vary greatly from that given in Fig. 2 as reactor conditions vary. This is because the fractional composition of components *A*, *B*, and *E* will always remain high under recycle conditions and all of these have properties very close to those of the example mixture. Therefore those properties ascribed to the reactor effluent mixture, F_R, may be used for any pertinent stream with negligible error.

Reactor and Chemical Reaction Involved

DETAILS OF CHEMICAL REACTION

P is produced by or takes part in the following chemical reactions:

1. $A+B \rightarrow C$, reaction coefficient, k_1 (1)
2. $C+B \rightarrow P+E$, reaction coefficient, k_2 (2)
3. $P+C \rightarrow G$, reaction coefficient, k_3 (3)

Initial reactant materials, *A* and *B*, are available in pure form from previous processing units of the over-all plant complex or outside sources as discussed later.

Components *C* and *E* are intermediates and/or by-products of the reaction. They have no sale value as chemical products but can be disposed of as fuels. The same is true of streams of mixed components such as the discard stream from the column bottoms.

By-product *G* is a heavy oily material which must be disposed of as a waste material.

The reaction coefficients k_1, k_2, and k_3 have been evaluated. Their values can be expressed in graphical form as in Fig. 6 or by the Arrhenius equation,

$$k_i = A_i e^{-B_i/T} \qquad (4)$$

where

$A_1 = 5.9755 \times 10^9$/hour, weight fraction
$B_1 = 12{,}000$ R (degrees Rankine), basis, 1 pound of *A* or *B*
$A_2 = 2.5962 \times 10^{12}$/hour, weight fraction
$B_2 = 15{,}000$ R, basis, 1 pound of *B*
$A_3 = 9.6283 \times 10^{15}$/hour, weight fraction
$B_3 = 20{,}000$ R, basis, 1 pound of *C*

Note that the volume dimension in the reaction coefficient, *k*, is "pound of mixture" rather than cubic feet or other strictly volume dimension. This is satisfactory since specific gravity is considered a constant in the reactor.

Heats of reaction of the three reactions are as follows:

Reaction 1: $H_1 = -125$ Btu per pound of *C* produced.

Reaction 2: $H_2 = -50$ Btu per pound of $E+P$ produced.

Reaction 3: $H_3 = -143$ Btu per pound of *G* produced.

That is, all reactions are exothermic.

DETAILS OF CHEMICAL-REACTOR DESIGN

Fig. 7 diagrams the pertinent details of the continuous stirred-tank reactor used for producing *P*. Appendix II lists the pertinent design data other than the kinetics already discussed.

Reaction-Cooler Heat Exchanger

To avoid an overproduction of the heavy oil waste material, *G*, and a subsequent reduction in product, *P*, it is necessary that the reaction be cooled to such a degree that the reaction is effectively stopped. In addition, as shown by Fig. 4, material *G* becomes insoluble in the reaction mixture when the temperature has been reduced below a certain value. Therefore, a cooler has been installed to reduce the temperature of the reaction mixture to 100 C (degrees centigrade) or below in order to satisfy both requirements. Fig. 8 diagrams the exchanger chosen and Appendix III gives its specifications.

Decanter

Since the heavy oil waste material, *G*, is insoluble at stream temperatures of 100 F (degrees Fahrenheit) or below, and since it has a considerably higher specific gravity than the carrier stream in which it is suspended, it may be removed by settling. The decanting vessel diagramed in Fig. 9 carries out this separation. The vessel is constructed of steel and need not be a pressure vessel as is the reactor. The effective liquid volume of 185 feet³ allows

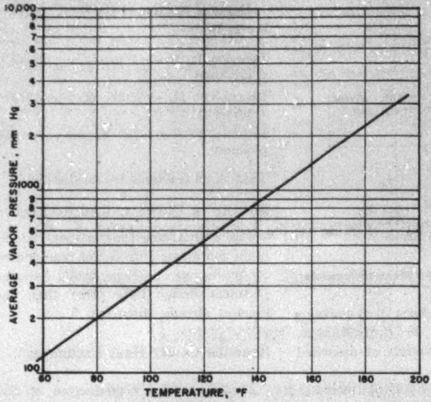

Fig. 2. Vapor pressure relationships for reactant mixture (less G) as feed to distillation column

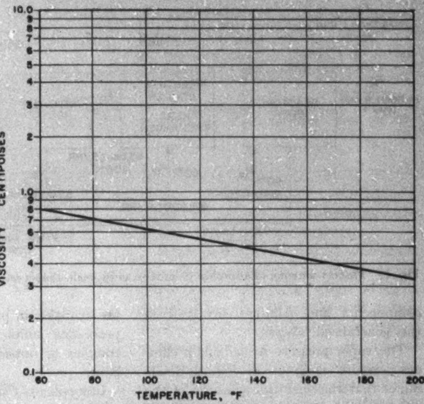

Fig. 3. Viscosity relationships for reactant mixture of composition equal to F_R stream

an average residence time of the liquid of 5.8 minutes which is sufficient to allow the required separation.

It must be kept in mind that should the temperature of the material in the decanter ever rise above that temperature at which G becomes insoluble, the interface between the column feed material and G will disappear and G will mix throughout the available volume. At that time, reactor effluent material will be discharged in the F_G stream and G will be included in the feed to the column and be returned to the reactor in the F_L stream. Thus, under improper temperature control, G could build up to high levels in all streams, except F_P.

Distillation Column

Product P is separated from the effluent stream from the decanter, F_R, by distillation. Specifications of the column are given in Appendix IV. A flow chart of pertinent column stream rates is shown in Fig. 10. Figs. 11 and 12 and Appendixes V and VI give the design data for column reboiler and condenser and Fig. 13 that for a typical tray. The distillation column has been designed in such a way that the column condenser (Fig. 11) is just limiting at the design production rate (Table I) for the maximum coolant temperature, 75 F. However, the column itself will handle up to 1.77 times the design capacity (column flood point) provided the condenser could handle the resulting heat duty. Therefore, since the coolant temperature varies quite radically both diurnally and seasonally (Figs. 24 and 25), the resulting plant capacity is likewise quite variable.

The required coolant temperature is a function of the vapor pressure existing at the condenser and the temperature at which product P condenses at that particular pressure. The base pressure (325 mm Hg and 100 F) is established by the need to suppress further reaction taking place outside the reactor. Condenser pressure is, therefore, the base pressure less the total pressure drop of the column and of the condenser itself combined. Graphs of the variations of these pressure drops with throughput are given in Figs. 14 and 15. The resulting vapor condensation temperatures can then be derived from Fig. 2. Fig. 16 summarizes these data by pre-

senting the resulting required coolant temperature versus plant throughput as a function of the base design rate of Table I.

Fig. 17 diagrams the instrumentation used at present. As shown in Fig. 5, product P forms a high-boiling azeotrope with the intermediate by-product E. Thus, some P appears in the column bottoms stream, F_S, and therefore in the discard stream, F_D, and the recycle stream F_L.

Recycle Control

The instrumentation presently used to regulate the recycle and discard streams is illustrated in Fig. 18. Notice that the discard stream, F_D, is regulated as a certain fraction of the column bottoms flow, F_S. The recycle stream, F_L, then takes all excess and returns it to the reactor.

Cost Factors

This section itemizes the costs involved in the operation of the plant manufacturing P.

Appendix VII gives the raw material costs and conditions as well as selling prices and associated conditions. Appendix VIII lists the data used in deriving the manufacturing cost estimate, Fig. 19, while the over-all cost estimate for the plant operating case used is given in Table II.

Since the kinetics of this process are well known, it lends itself to extensive steady-state optimization. This has been done using the following equations:

$$\%\ \text{Return} = \frac{100\,[8400(M)-2.22(F_R)-0.124\,\{8400/(0.30F_P+0.0068F_D)\}-276{,}000]}{2{,}780{,}000} \qquad (5)$$

Fig. 10. Flow rates and relationships in distillation column

where

$$M=0.30F_P+0.0068F_D-0.02F_A-0.03F_B-0.01F_G \quad (6)$$

and

$$F_P \leq 4{,}763 \text{ pounds/hour} \quad (7)$$

In these equations, M is the gross return per hour; \$276,000 represents the plant fixed charges, such as depreciation, labor, etc.; $2.22F_R$ represents utility charges which can be tied to plant flow rates; 0.124 (8400)$(0.30F_P+0.0068F_D)$ represent the SARE (sales, administration, research, and engineering) charges; and \$2,780,000 is the total investment involved.

When these equations are optimized on a digital computer for the four main plant variables (temperature, recycle ratio, flow rate of reactant A, and flow rate of reactant B) the results shown in Figs. 20–23 are obtained.

External Factors Important to Plant Operation

As mentioned earlier, this plant has shown considerable instability in its operation. A considerable amount of data has, therefore, been taken on those external variables which might have a bearing on its operation. Cooling water temperatures have been kept for some years at this location and the average annual variation of temperature due to the seasons and the average daily variation due to day and night, are shown in Figs. 24 and 25. Temperature data on the reactant streams A and B have been kept for a much shorter period of time; therefore, only approximate daily variations in temperature are known at this time. These are given in Fig. 26.

Perhaps the largest upset to which the plant is subjected is due to flow variations in reactant stream A. This material is manufactured in another unit of the plant where the unit making P is located. A is used in several batch processes, in addition to the continuous process used for making P. Thus the stream flow rate can fluctuate considerably when it is necessary to fill one or more of the batch reactors.

While the actual batch-filling cycle is random due to the number and variability of operation of these reactors, their effect upon the availability of A to the reactor used for making P can be characterized as follows:

$$F_A=14{,}500 \pm 2{,}100 \text{ pounds/hour} \quad (8)$$

where the variation of ±2,100 pounds per hour can be considered as a positive or negative step function with a duration of 20 minutes and an average repetition rate (one complete cycle, including both plus and minus variation) of once per hour.

Dynamic Equations

Because of the nature of the upsets imposed and the fact that plant operation has already been quite well optimized, the main need for computer control in

B—Typical cross section

this plant is to smooth out the dynamic operation of the unit.

For this reason, a suggested set of differential equations is included here, which can be used to define the dynamic operation. The reader is, of course, free to use another set, either simpler or more complex, if he so desires.

SIMPLIFYING ASSUMPTIONS

Several simplifying assumptions may be made based upon knowledge of the plant design described earlier:

1. The reactor can be considered well stirred and reactants and products are at all times completely mixed.

2. The decanter can be considered well mixed in the layer of material serving as feed to the distillation column. There is no mixing between the light layer (V_E, distillation column feed) and the heavy layer (G) in the decanter.

3. Since P is readily separated from the other feed-stream components by the distillation column, the column may be treated as an instantaneous separator of F_P, i.e., F_E does not mix in the column. For purposes of computing column compositions as a function of time, the very approximate assumption may be made that the distillation column is a well-mixed tank with a volume equal to the total holdup of the column. Likewise, the reboiler may be considered as another well-mixed tank with a volume equal to its given holdup.

4. The dynamics of the heat exchanger for purposes of a first approximation may be considered as those of two well-mixed tanks, one for the reactor effluent stream and one for the coolant. This assumption requires a correction factor for the effective cooling area which is given in the equations presented.

5. Since every effort has been made to keep the plant as compact as possible, consider that fluid-line dead time between the various plant units is negligible. Likewise, no dead times have been considered in connection with any of the plant units.

6. Reboiler temperatures and consequently recycle line temperatures are a function of column operation and not of the temperature of the column feed stream, F_E. Therefore, temperature mixing equations have not been included for the column or the reboiler.

7. Loss of heat to the atmosphere has been considered negligible for all units.

8. Reboiler boilup has the same composition as reboiler liquid. Since the vapor-liquid equilibrium relations are not given, the exact composition of reboiler vapor cannot be determined.

The resulting equations are given in the following sections. All symbols are defined in the Nomenclature. Fig. 27 shows a block diagram of the actual dynamic system represented by the set of equations presented.

In these equations, all volumes will be expressed as pounds of contained liquid of a density of 50 pounds per cubic foot. All compositions will be expressed as weight fractions. Over-all reaction rates will be given as pounds of the component in question produced per hour per pound of reactor volume.

REACTOR EQUATIONS

$$\frac{dA_R}{dt}=\frac{F_A}{V_R}+\frac{F_L}{V_R}(A_L)-\frac{F_R}{V_R}(A_R)-k_1(A_R)(B_R) \tag{9}$$

Nomenclature

A = reactant; frequency factor in Arrhenius equation; area
$\bar{A}_H$ = effective heat-transfer area
B = reactant; as subscript, refers to this reactant stream; activation energy in Arrhenius equation
C = intermediate component; as subscript, refers to distillation column

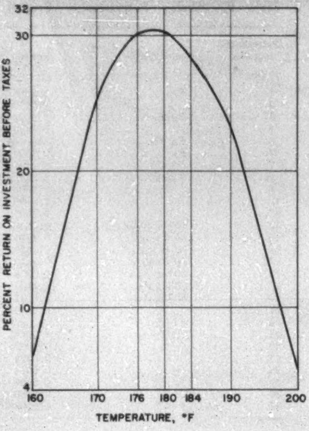

Fig. 20 (left). Effect of reactor temperature on per-cent return on investment

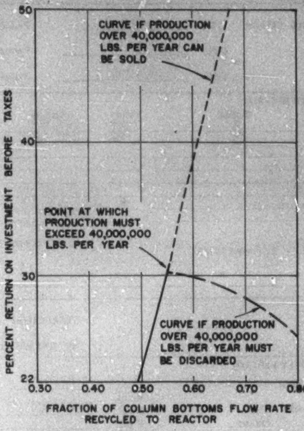
Fig. 21 (right). Effect of recycle on per-cent return on investment



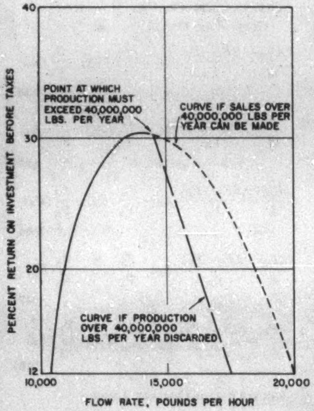


Fig. 22 (left). Effect of flow rate of reactant A on per-cent return from process

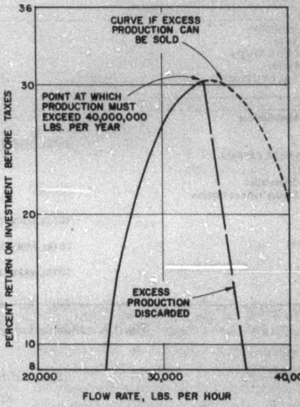
Fig. 23 (right). Effect of flow rate of reactant B on return on investment



C_P = heat capacity; subscript gives stream
D = as subscript, refers to discard stream
E = intermediate component; as subscript, refers to decanter material used as distillation column feed
F = flow rate; subscript refers to origin of stream or its identity
G = by-product, heavy oil; as subscript, refers to heavy oil stream
H = heat of reaction; subscript gives reaction; as subscript, refers to reaction-cooler heat exchanger; second subscript identifies material involved
L = as subscript, refers to recycle stream
M = thousand; net hourly value of sales less raw material and waste-disposal charges
P = product; as subscript, refers to product stream
R = thermodynamic factor; as subscript, refers to reactor
S = as subscript, refers to column reboiler
T = temperature, may be F or R, depending on application; subscript defines location or stream involved
T' = average reaction-cooler heat-exchanger temperatures; subscript defines stream and location involved
V = volume; subscript defines location
W = as subscript, refers to water used as coolant
h = over-all heat-transfer coefficient
k = reaction rate constant; subscript defines reaction step considered
s = as subscript, refers to steam
t = time, usually in hours
RH = reaction effluent mixture in tube side of reaction-cooler heat exchanger
WH = coolant in shell side of reaction-cooler heat exchanger
HT = tube side of reaction-cooler heat exchanger
HS = shell side of reaction-cooler heat exchanger
ln mean = logarithmic mean (natural logarithms)
ϵ = base of Naperian logarithm
ρ = specific gravity referred to reactor effluent mixture of density equal to 50 pounds per cubic foot

The following are from the illustrations:

FR = flow recorder
FRC = flow recorder-controller
FC = flow controller
LC or LLC = level controller
PRA = pressure-recorder alarm
TRC = temperature-recorder controller
PRC = pressure-recorder controller

 = valve

 = pressure-relief valve

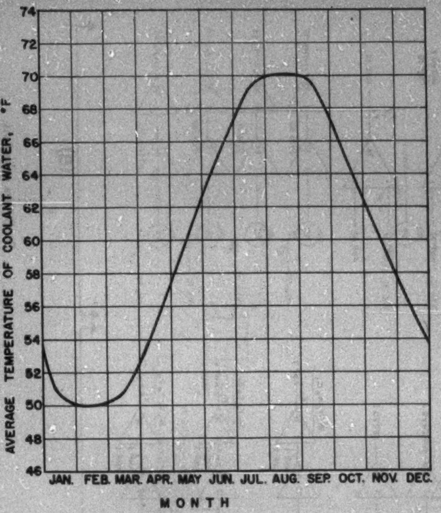


Fig. 24. Average annual variation of coolant water temperature

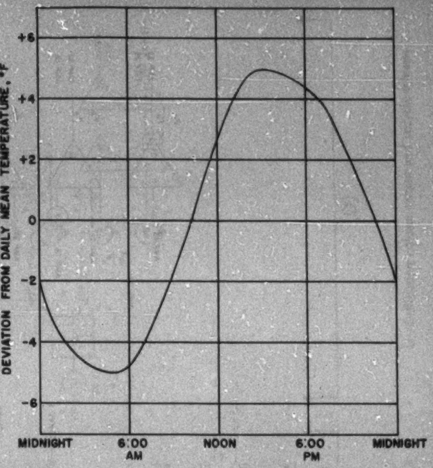

Fig. 25. Average diurnal variation of coolant water temperature

Appendix I. Physical Properties of Component Materials

A, B, P: molecular weight = 100
C, E: molecular weight = 200
Typical reactant mixture:
Density, $\rho = 50$ pounds/foot^3
Viscosity, μ = see Fig 3
Vapor pressure = see Fig. 2
$k = 0.086$ Btu/(hour)(feet^2)(F/foot)
Heat of vaporization = 95 Btu/pound
Heat capacity = 0.40 Btu/pound, F
G: molecular weight = 300; density, ρ = 68.6 pounds/foot^3

Vapor liquid equilibria: product P has a relative volatility, α, of 2.2 in comparison with liquid of average of F_S stream, including P trapped in azeotrope form with material E.

Appendix II. Design Data from Reactor

Effective liquid volume = 4,640 pounds
Excess heat produced/hour:
Gross materials formed: 18,540 pounds C/hour; 15,007 pounds E/hour; 7,501 pounds P/hour; 3,721 pounds G/hour.
Heat of reaction involved: 3,973,616 Btu/hr.
Heat required to bring input streams to reaction temperature: 3,644,952 Btu/hour.
Excess heat produced: 328,564 Btu/hour
Cooling coils installed:
382 foot BWG (Birmingham wire gage) *18*, 1-inch copper
$U = 50$ Btu/foot^2, F, hour
Effective coolant volume = 1.70 feet^3
Effective area = 100 feet^2

F—Economic equation

Heating coils installed:
- 382 feet BWG *18*, 1-inch copper
- $U = 100$ Btu/foot^2, F, hour
- Effective heating fluid volume = 1.70 feet^3
- Effective area = 100 feet^2

Operating pressure = 3 atm
Construction material = steel

Since reactor is well insulated, heat loss to the atmosphere is negligible.

Appendix III. Design Details of Reaction-Cooler Heat Exchanger

Shell side:
- Diameter = 16 inches
- Length = 16 feet
- Baffle spacing = 16 inches
- Baffle cut = 35%
- Pressure drop = 2.2 psi (pounds per square inch)
- Flow rate = 153,500 pounds/hour, water
- Inlet temperature = 60 F
- Outlet temperature = 80 F
- Over-all heat-transfer coefficient = 82.5 Btu, F, feet^2, hour
- Coolant volume, $V_{HS} = 13.3$ feet^3 = 830 pounds water

Tube side:
- Area = 569 feet^2
- Number of tubes = 184
- Number of tube passes = 4
- Diameter of tubes (external) = 3/4 inch
- Gage = BWG *14*
- Pitch (triangular) = 15/16 inch
- Velocity = 4.4 feet/second
- Pressure drop = 7.4 psi
- Tube-side volume, $V_{HT} = 274$ pounds

Construction material = steel

Appendix IV. Distillation Column Specifications

Bubble cap trays = 20
Plate spacing = 2 feet
Vapor velocity = 4.5 feet/second
Plate diameter = 10.0 feet
Weir length = 6 feet
Weir head = 0.136 foot or 1.65 inches
Bubble caps = 151 per tray
- Diameter of caps = 6 inches
- Spacing of caps = 9 inches equilateral spacing
- Skirt clearance = 1.75 inches
- Rectangular slots = 0.25 inch wide, 1.25 inches deep
- Liquid seal = 2.0 inches

Pressure drop = 4.0 mm Hg/tray
Still pot pressure = 350 mm Hg
Condenser inlet pressure = 270 mm Hg
Condensate temperature = 89 F
Down-comer area = 2.5 feet^2
Construction material = steel
Holdup per tray = 1,182 pounds

Appendix V. Design Details of Column Condenser

Shell side:
- Diameter = 39 inches
- Length = 20 feet
- Baffle spacing = 3 feet
- Baffle cut = 45%
- Pressure drop = 28 mm Hg
- Flow rate = 92,249 pounds/hour

Inlet temperature = 94 F
Outlet temperature = 89 F
Over-all heat-transfer coefficient = 150 Btu, F, feet², hour
Vapor to be condensed is on shell side
Shell side is split flow
Construction material = steel

Tube side:
Number of tubes = 1,258
Number of tube passes = 4
Diameter of tubes = 3/4 inch
Pitch (triangular) = 15/16 inch
Gage = BWG *14* steel
Coolant = water at 75 F maximum, 60 F average
Flow rate = 356,000 pounds/hour

Appendix VI. Design Details of Column Reboiler Heat Exchanger

Shell side:
Diameter = 40 inches
Length = 12 feet
Baffle spacing = 20 inches
Baffle cut = 25%
Heating medium on shell side = hot water
Flow rate = 437,500 pounds/hour
Sparge steam added = 8,780 pounds/hour
Fouling factor, R_d = (0.003 F, feet², hours)/Btu
Mean temperature gradient = 31 F
Construction material = steel
Outside heat-transfer coefficient = 700 Btu, F, feet², hours

Tube side:
Number of tubes = 1,176
Number of tube passes = 2
Diameter of tubes = 3/4 inch
Pitch (triangular) = 1 inch
Gage = BWG *14* steel
Heated medium = material to be vaporized
Flow rate = 462,000 pounds
Heated liquid is flashed at reduced pressure to provide vapor flow, V_L, to column; amount vaporized = 20%
Inside heat-transfer coefficient = 260 Btu, F, feet², hours
Pressure drop = 111 mm Hg
Total holdup (exchanger plus sump) = 10,080 pounds

Appendix VII. Raw Material and Product Data

Product, *P:*
Total sales available = 40,000,000 pounds/year
Excess production must be discarded
Sale price = $0.30/pound

By-product (discard stream):
Fuel value = $0.0068/pound
All available may be utilized

Reactant, *A:*
Cost = $0.02/pound
Available from another process unit in same plant complex. Supply under some restrictions as shown in equation 8

Reactant, *B:*
Cost = $0.03/pound
Available from external supplier in whatever quantity desired

Fig. 29. Main Fortran program for computation of steady-state values

Appendix VIII. Factors for Computing Manufacturing Costs

Unit price of main plant components = $382,000
Total installed cost with all accessories, i.e., manufacturing capital = $1,035,000

Nonmanufacturing capital:
Steam production capacity, 10,000 pounds/hour at $20/pound/hour = $200,000
Electric power capacity, 50 kw at $100/kw = 5,000
Others, at 1.0% of manufacturing costs = 116,000; $321,000

Utility costs:
Steam costs = $1.00/M pounds
Water costs = $0.25/M gallons
Electricity costs = $0.01/kw-hr (kilowatt-hour)
Waste disposal = $0.01/pound *G*

Labor required, per shift:
1 operator
1 helper
1 plant chemist
1 part-time supervisor

Appendix IX. Analog and Digital Steady-State Calculations

Optimization Procedure

In the steady-state optimization of the process under discussion, the analog and digital computers were used sequentially. Initially, the steady-state process equations and the economic equations were solved on the analog computer in order that wide ranges of the independent variables would be studied and a "feel" for the importance of the process variables could be developed. During this stage, the plant size (considered to be directly related to the volume of the reactor) was considered a variable, in addition to the reactor temperature, the amount of recycle, and ratio of the two reactants. The optimization was achieved by simply allowing the computer to reach steady state and then "trimming" the potentiometers representing the four independent variables, until the per-cent return reached a maximum.

Once the region of the optimum was found, the problem was transferred to the IBM (International Business Machines Corporation) *704* computer in order to pinpoint the optimum. During this stage, the process size (reactor volume) was fixed to allow a sharper calculation of the process economics and design details. The four independent variables were flow rate of reactant *A*, flow rate of reactant *B*, reactor temperature, and amount of recycle. At this point also the restriction that the excess product must be discarded was added because the plant was no longer of variable size as in the analog program. That is to say, the rough optimization on the analog allowed the process size to be just large enough to produce exactly 40,000,000 pounds/year of product. The *704* program with the plant size fixed by the analog optimization could, under some conditions (see Fig. 21, for example), produce more product, hence greater percentage return, than the specified 40,000,000 pounds/year.

The analog and *704* computers yielded flow rates which were within 2% of each other under identical conditions.

Fig. 32. Sample format of output, optimum case

Analog Wiring Diagram

The analog wiring diagram is shown in Fig. 28. Although the steady-state equations are a set of algebraic nonlinear equations, one will note that integrators are used in the reactor and reboiler sections. These are used for the elimination of noise within the many loops of the circuit. Physically, the equations as represented in the wiring diagram describe the start-up of a plant simpler than the one reported, but having the same steady-state values. Reactant *A* is initially in all lines. Reactant *B* is added at the time of operation. Note that the reported economic equations 5 and 6 were calculated on the analog as:

$$\frac{0.6V_R}{F_A}(\%\ \text{return}+10)=220.8\frac{F_P}{F_A}-16.8-$$

$$25.2\frac{F_B}{F_A}-0.84\frac{F_G}{F_A}-0.222\frac{F_R}{F_A}+5.0\frac{F_D}{F_A}$$

which is equivalent to equations 5 and 6 when $V_R=4{,}640$ pounds.

All flow rates and the reactor volume are presented as ratios of the reactant stream, F_A. This procedure was followed in order to eliminate a major rescaling of the problem as process parameters were changed over wide ranges.

Table II gives the appropriate potentiometer settings. Approximately 30 seconds are required to reach steady state. The time constant of the integrators was 1 second.

Fortran II Program

The IBM FORTRAN II program is illustrated in Figs. 29 through 32. The steady-state nonlinear equations are solved through numerical integration of differential equations similar to the technique used on the analog computer.

Fig. 29 shows one of the main programs used. The particular one shown gives the steady-state solution for one set of parameters. Other programs (not shown) printed the steady-state solutions to all combinations of incremental changes in the parameters. This latter program was used to calculate Figs. 15 through 18, for instance. No sophisticated optimization techniques (such as the Box technique) were used in the digital program, because the region of the optimum had been well established on the analog computer.

Fig. 30 gives the subroutine for the reactor calculations. The subroutine calculates an incremental change in reactor concentrations and flow rates or, alternately, returns steady-state values for a given input. This second feature, with some modification, will probably be used in the dynamic analysis of the reactor and was not used in the optimization. The numerical integration procedure used is a fourth-degree Runge-Kutta technique.

The steady-state separation of flow streams and the economic equations are solved in one subroutine shown in Fig. 31.

Fig. 32 illustrates the output format for the optimum case.

Appendix X defines the FORTRAN variables in terms of variables listed in the Nomenclature and also the functions of the sense switches.

The approximate running time for the program shown was: 15 seconds, read in; 12 seconds, calculation; 15 seconds, print out.

Time Response Constant and Transfer Function of Magnetic Amplifiers

E. W. MANTEUFFEL
ASSOCIATE MEMBER AIEE

This paper is an additional contribution to the general theory of magnetic amplifiers and deals with the relationship of the time response constant to the actual transfer function of such amplifiers. Under certain conditions this constant is not the same as that generally understood to be the time constant of an exponential function. In presenting the information given in this paper the author has obtained permission from Dr. Buchhold to review certain basic relationships, contained in Dr. Buchhold's report.

SEVERAL years ago Dr. T. A. Buchhold of the General Electric Company, while still associated with Redstone Arsenal and later with Ford Instrument Company, made theoretical investigations about the transient performance of magnetic amplifiers. In the course of his work the concept of the specific dynamic resistance of square loop core materials and, directly related to it, the concept of the dynamic resistance of magnetic amplifiers was established as a convenient means to express mathematically the performance of such amplifiers. Although Dr. Buchhold presented his findings in an internal company report, his work has unfortunately never been published as a paper. This situation causes certain difficulties in presenting a paper which uses the foregoing concept without at the same time referring in at least some detail to Dr. Buchhold's original work.

Paper 60-875, recommended by the AIEE Magnetic Amplifiers Committee and approved by the AIEE Technical Operations Department for presentation at the AIEE Summer General Meeting, Atlantic City, N. J., June 19–24, 1960. Manuscript submitted June 16, 1959; made available for printing May 23, 1960.

E. W. MANTEUFFEL is with the General Electric Company Advanced Electronics Center at Cornell University, Ithaca, N. Y.

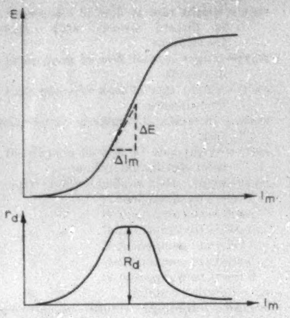

Fig. 1. Dynamic core characteristic

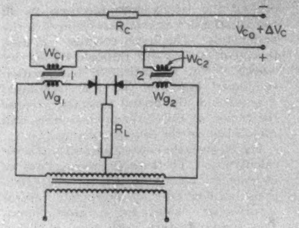

Fig. 2. Center-tap amplifier

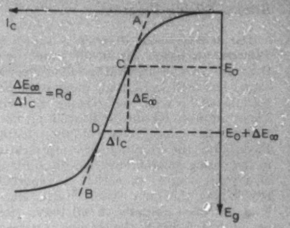

Fig. 3. Dynamic amplifier characteristic E_g versus I_c

Dynamic Resistance, Time Response Constant, and Voltage Gain

Assume that a magnetic core of square loop core material with cross section A and mean magnetic path length l_m is wound with a winding of N turns and energized from an a-c source. If one determines by known methods the relationship between the half-cyclic average value of electromotive force E and the average value of magnetizing current I_m, the dynamic characteristic illustrated in Fig. 1 is obtained. For the following consideration it is of minor importance how this characteristic is determined. It may, for example, be measured with the well-known constant-current flux reset method. Buchhold has shown that in the case of square loop core materials, it also can be measured by simply increasing the a-c supply voltage from zero to some maximum value and by recording the half-cyclic average values of magnetizing current and electromotive force. The author and several of his associates have obtained good results with the latter method but the scope of this report does not allow going into all the details.

The slope $\Delta E/\Delta I_m$ at any point of the dynamic characteristic expresses a certain dynamic resistance r_d which is plotted in the lower portion of Fig. 1. Since in most practical applications magnetic amplifiers are operated within the linear region of their characteristic, the maximum slope at the center portion of the dynamic characteristic is simply called the dynamic resistance R_d. Since this value R_d is related to particular core dimensions and number of turns, it is preferable to express it in per-unit terms as

$$R_{d_0} = \frac{\Delta E_0}{\Delta I_{m_0}}[\text{ohms/cm (per centimeter)}] \qquad (1)$$

where

ΔE_0 = change of half-cyclic average value of emf (electromotive force) per turn per cm² cross section

and

ΔI_{m_0} = change of half-cyclic average value of magnetizing ampere-turns per cm magnetic path length

This value R_{d_0}, called the specific dynamic resistance, is a significant parameter of a given core. Its value depends on the kind of core material, the supply frequency, the ratio of inside to outside diameter of the core, and also to a certain degree on temperature. The actual dynamic resistance R_d is then related to R_{d_0} as follows:

$$R_d = R_{d_0} \cdot N^2 \cdot \frac{A}{l_m} \qquad (2)$$

Because of secondary effects, the specific dynamic resistance determined from the actual transfer characteristic of a magnetic amplifier is generally not the same as that obtained from core measurements. Deviations result from rectifier leakage, effects of gate limiting, and the actual ratio of control circuit resistance to dynamic resistance. Rectifier leakage is almost negligible for silicon rectifiers. The other effects can be taken into account by correlation factors. For the following discussion it is assumed that the actual dynamic characteristic including those secondary effects is known. This characteristic can always be measured by recording the actual half-cyclic average values of gate emf as a function of control current and referring both values either to the number of control turns N_c or turns of the gate winding N_g.

In order to explain in some detail the influences of dynamic resistance R_d and control circuit resistance R_c on the time response constant T and the specific volt-

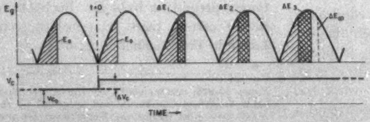

Fig. 4 (above). Gate emf's versus control voltage step function

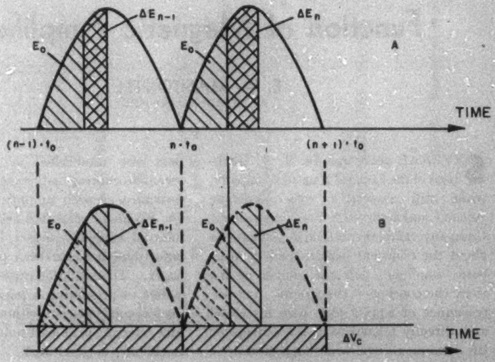

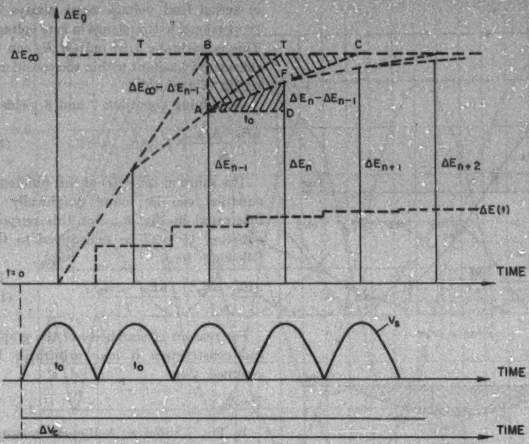

Fig. 6. Graphical construction of function $\frac{\Delta E_n-\Delta E_{n-1}}{t_o}=\frac{\Delta E_\infty-\Delta E_{n-1}}{T}$

age gain G_v, of a magnetic amplifier, the well-known center-tap amplifier is to be investigated. The basic circuit configuration of such an amplifier is illustrated in Fig. 2. An actual dynamic characteristic

$$E_g=f(I_c)$$

as described before is shown in Fig. 3. This characteristic is intentionally plotted within the third quadrant to show better its resemblance to the transfer characteristic of an amplifier. In its center portion the dynamic characteristic is approximated by a straight line AB. For the following considerations the number of control and gate turns may be made equal.

As a starting point it is assumed that a bias voltage V_{c_o} had been previously impressed on the control circuit and that the amplifier is in steady-state operation with a firing angle somewhat smaller than 90 degrees. This condition is indicated as point C in Fig. 3. It is also shown in Fig. 4, where the single-hatched areas indicate the steady-state gate emf, E_0. Let us now assume that at time $t=0$, at the start of a half cycle, the voltage at the control circuit is increased in step-fashion by an amount ΔV_c as shown in the lower portion of Fig. 4. The result will be, as is generally known, that in following half cycles the gate voltage will become larger by increasing amounts ΔE_1, ΔE_2, $\Delta E_3 \ldots$ (indicated by cross-hatched areas) until finally in the new steady-state operation an increase ΔE_∞ is reached. This value is shown as a dashed line in Fig. 4 and corresponds to point D in Fig. 3. The sequence of events as they occur from half cycle to half cycle will now be described mathematically by considering conditions at the $(n-1)$th and nth half-period after the step voltage ΔV_c was applied. The time will be measured in multiples of time t_o of one half cycle.

$$t_o=\frac{1}{2f}$$

where f is the frequency of the supply source.

The half cycle which starts at the time $(n-1)\ t_o$ will be investigated. During this time interval, the gate electromotive force E_g, which in the course of preceding half cycles has already increased from E_o to $E_o+\Delta E_{n-1}$, may arbitrarily exist at winding W_{g2} of core 2 during its gating half cycle. This condition is shown in Fig. 5(A). This same voltage $E_o+\Delta E_{n-1}$ is also induced in winding W_{c_2} of the control circuit since equal numbers of turns were assumed. Its polarity is such that it adds to the total control voltage $V_{c_o}+\Delta V_c$ and assists in resetting core 1 during this half cycle.

Since as a starting condition, steady-state operation of the amplifier at point C, Fig. 3, was assumed, it is sufficient to consider only variations of the gate voltage under the influence of ΔV_c. Therefore, the change in resulting electromotive force is actually caused by ΔV_c and ΔE_{n-1} as indicated by the solidly hatched area of Fig. 5(B). These areas are considered as half-cyclic average values. The change in average gate voltage of core 1 is designated as ΔE_n since ΔE_n is the change of E_g during the gating half cycle starting at time nt_o. Therefore the following relationship between ΔE_n, ΔE_{n-1}, and ΔV_c must exist:

$$\Delta E_n=\left(\Delta V_{c_{n-1}}+\Delta E_{n-1}\right)\frac{R_d}{R_d+R_c} \tag{3}$$

For a more general consideration it may be assumed that additional external electric feedback is employed. This feedback can be expressed by a factor (1-h_e) associated with ΔE_{n-1}. Equation 3 changes then to

$$\Delta E_n=\left[\Delta V_{c_{n-1}}+(1-h_e)\,\Delta E_{n-1}\right]\frac{R_d}{R_d+R_c} \tag{4}$$

By rearranging terms and observing

Fig. 8. Graphical construction of function $\int \Delta E_g(t)$ for sinusoidally varying control voltage

that $\Delta V_{c_{n-1}} = \Delta V_c$ for all half cycles, this equation becomes

$$(\Delta E_n - \Delta E_{n-1}) \frac{R_c + R_d}{R_c + h_e \cdot R_d} + \Delta E_{n-1} = \Delta V_c \frac{R_d}{R_c + h_e \cdot R_d}$$

If the numerator and denominator of the first term are multiplied by $t_0 = 1/2f$ one obtains

$$\frac{\Delta E_n - \Delta E_{n-1}}{t_0} \cdot \frac{R_c + R_d}{R_c + h_e \cdot R_d} \cdot \frac{1}{2f} + \Delta E_{n-1} = \Delta V_c \frac{R_d}{R_c + h_e \cdot R_d} \qquad (5)$$

Making the substitution

$$T = \frac{1}{2f} \cdot \frac{R_c + R_d}{R_c + h_e \cdot R_d} \qquad (6)$$

yields

$$(\Delta E_n - \Delta E_{n-1}) \frac{T}{t_0} + \Delta E_{n-1} = \Delta V_c \frac{R_d}{R_c + h_e \cdot R_d} \qquad (7)$$

The final value $\Delta E_{n-1} = \Delta E \infty$ will be approached if the difference between ΔE_{n-1} and ΔE_n becomes zero

$$\Delta E_n - \Delta E_{n-1} = 0$$

Then equation 7 yields

$$\Delta E_\infty = \Delta V_c \cdot \frac{R_d}{R_c + h_e \cdot R_d} \qquad (8)$$

The ratio

$$\frac{AE_\infty}{V\Delta_c} = \frac{R_d}{R_c + h_e \cdot R_d} = G_{v_s} \qquad (9)$$

is called the specific voltage gain of the amplifier, which is a theoretical value. The actual voltage gain G_v can then be found by taking into account the influence of gate circuit resistance R_g and the turns ratio N_g/N_c which will in general be different from "one."

$$G_v = \frac{\Delta V_L}{\Delta V_c} = \frac{R_d}{R_c + h_e \cdot R_d} \cdot \frac{R_L}{R_L + R_g} \cdot \frac{N_g}{N_c} \qquad (10)$$

The value ΔV_L can without restriction be used in this equation since the change in actual load voltage must always be proportional to the change in gate voltage. This is naturally true only if R_d can be considered constant within the considered region of variations.

Combining equations 7 and 8 yields

$$\frac{\Delta E_n - \Delta E_{n-1}}{t_0} \cdot T + \Delta E_{n-1} = \Delta E_\infty \qquad (11)$$

The solution $\Delta E = f(t)$ of this difference equation can be found graphically as illustrated in Fig. 6. For this purpose equation 11 shall be rearranged to the following form:

$$\frac{\Delta E_n - \Delta E_{n-1}}{t_0} = \frac{\Delta E_\infty - \Delta E_{n-1}}{T} \qquad (12)$$

For reasons of simplicity of the graphical construction it may arbitrarily be assumed that

$$T = 2t_0$$

In Fig. 6 different half-cyclic average values ΔE are plotted at intervals of t_0. They are shown as arrows ΔE_{n-1}, ΔE_n, ΔE_{n+1} . . . and placed at the centers of the corresponding half cycles of the supply voltage which is indicated below as a rectified sine wave. The instant where ΔV_c is applied is shown in correspondence with Fig. 4 at $t = 0$. The final value $\Delta E \infty$ determined by equation 8 is indicated as a dashed horizontal line. The values of ΔE at each half cycle can be found by a simple graphical construction. For example, the value of ΔE_n can be determined by connecting point A of arrow ΔE_{n-1} with point C on the horizontal $\Delta E \infty$ line by a

straight line where point C is time-wise by T apart from ΔE_{n-1}. ΔE_n is then found at point F at the time distance t_0 from ΔE_{n-1}. The correctness of this construction is verified if one considers the two shaded similar triangles ABC and ADF whose ratios of corresponding sides

$$\frac{AB}{BC}=\frac{DF}{AD}$$

are nothing other than an expression of equation 12.

The value

$$T=\frac{1}{2f}\cdot\frac{R_c+R_d}{R_c+h_e\cdot R_e} \tag{6}$$

now becomes meaningful. It is the time response constant of a magnetic amplifier which is not identical with the time constant τ of an exponential function. Agreement between T and τ will be only approached when

$$T>>t_0$$

In Fig. 6, average half-cyclic values ΔE are also indicated as a dashed staircase line. One can show mathematically that the difference equation describing this function is given by

$$\Delta E_n(t)=\Delta E_\infty\left[1-\left(1-\frac{t_0}{T}\right)^n\right] \tag{13}$$

This equation permits the value of ΔE_n to be calculated at any given half cycle n after application of the step signal ΔV_c.

In Fig. 7 several time functions for different values of T/t_0 together with the exponential function are illustrated. The time response constant T is the same for all the curves but the carrier-frequency f and, therefore, t_0 is different. Values of T/t_0 are indicated in this figure by numbers. Points at different half cycles are connected by straight lines for better display, although in reality the function $\Delta E=f(t)$ is a jump-function.

The ratio T/t_0 can in general be changed according to equation 6 by different R_e values or various amounts of external feedback. If no external feedback is employed ($h_e=0$), equation 6 becomes

$$T=\frac{1}{2f}\left(1+\frac{R_d}{R_e}\right) \tag{14}$$

The specific voltage gain expressed by equation 9 is then

$$G_{v_s}=\frac{R_d}{R_c} \tag{15}$$

If 100% external feedback ($h_e=1$) is used, meaning that the external has compensated the internal feedback, equation 6 indicates that the time response constant T reduces now to

$$T=\frac{1}{2f}=t_0 \tag{16}$$

Under this condition, the center-tap amplifier behaves like a half-wave amplifier since its final value ΔE_∞ is reached after the time $t=t_0$, which is also apparent from equation 11. The voltage gain, equation 9, yields then

$$G_{v_s}=\frac{R_d}{R_d+R_c}=G_{v_{s0}} \tag{17}$$

If the performance of a simple half-wave amplifier is investigated, the same equation 17 will be obtained for its specific voltage gain.

Transfer Function of Magnetic Amplifier

The response of the discussed center-tap amplifier to a sinusoidally varying control signal voltage

$$\Delta V_c=\Delta V_{c_{\max}}\sin\omega_s t \quad (\omega_s=2\pi f_s) \tag{18}$$

will now be investigated. $\Delta V_{c_{\max}}$ is hereby the amplitude and f_s the frequency of the signal. The graphical construction scheme of Fig. 6 can with advantage be used for this purpose. The method of determining the half-cyclic average values of variations in gate emf ΔE_g as a result of control voltage variations is illustrated in Fig. 8. The following assumptions were arbitrarily made for this construction.

$$T=2\times t_0=\frac{1}{f}$$

$$f/f_s=\lambda=5$$

It is further assumed that the control signal starts at time $t=0$ at the beginning

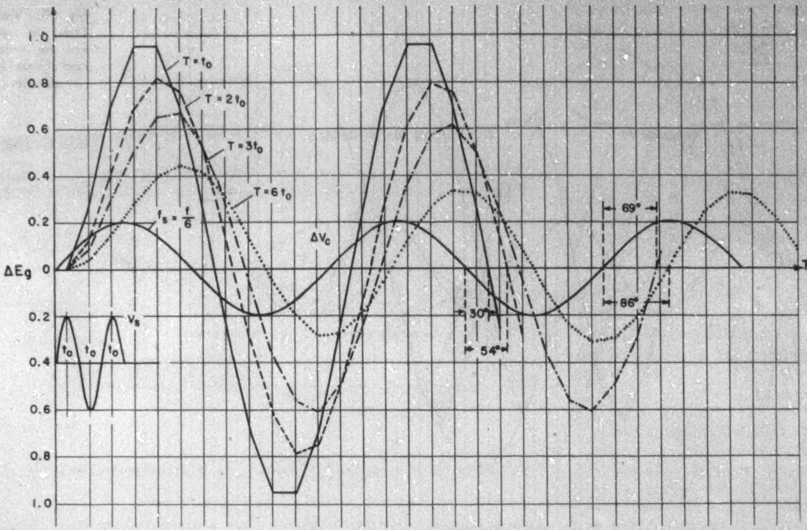

Fig. 11. Variations in gate emf at constant signal frequency for various ratios T/t₀

of a half-period t_o. The control voltage is shown as curve

$$\Delta V_c = f(t)$$

During each half-cycle t_o different half-cyclic average values of control voltages ΔV_{c1}, ΔV_{c2}, ΔV_{c3}, ... act on the control circuit of the magnetic amplifier. These voltages are shown as differently hatched areas in Fig. 8. If each of these voltages existed for an indefinitely long time, they would result in final gate emf's $\Delta E_{\infty 1}$, $\Delta E_{\infty 2}$, $\Delta E_{\infty 3}$, ... as determined by equation 8.

The particular values ΔV_{c_n} for each half cycle are given by

$$\Delta V_{c_n} = \frac{\lambda}{\pi}\left[\cos\frac{(n-1)\pi}{\lambda} - \cos\frac{n\pi}{\lambda}\right]\Delta V_{c_{max}} \tag{19}$$

The values of $\Delta E_{\infty n}$ are then

$$\Delta E_{\infty n} = \Delta V_{c_n} \cdot G_{v_s} \tag{20}$$

They are indicted as dot-dashed horizontal lines on the left of Fig. 8. For the construction a line *M-N* is drawn in parallel to the ordinate axis at a distance *T*. A second parallel line *P-Q* at a distance t_o from line *M-N* is also indicated. The trace of lines 0-1-2-3-4- ... 18-19 shows how values ΔE_1, ΔE_2, ΔE_3 ... can be successively determined. Starting at point 0 a line is drawn connecting 0 with $\Delta E_{\infty 1}$ at the ordinate axis. The point 1, where this line intersects with line *P-Q*, determines the value ΔE_1. Returning now in a horizontal direction to point 2, a line connecting 2 with $\Delta E_{\infty 2}$ is drawn and ΔE_2 is then found at point 3. The construction continues then in the same fashion. The values ΔE_1, ΔE_2, ΔE_3, ... are plotted at the center of corresponding half cycles. The solid line *a-b-c-d* ... *k*-1 ... then represents the variation of the gate emf ΔE_g on an average basis. On this basis, a median dead time lag

$$t_d = \frac{t_o}{2} = \frac{1}{4f} \tag{21}$$

exists. The construction scheme of Fig. 8 can be used for any kind of function of control voltage versus time. Fig. 9 shows as an example the response when an exponentially rising control voltage

$$\Delta V_c = \Delta V_{c_\infty}[1 - \epsilon^{-t/\tau}]$$

is applied to the amplifier. For the construction, τ was arbitrarily chosen to

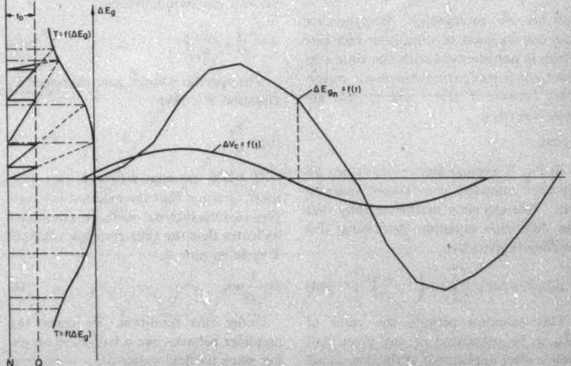

Fig. 12. Nonlinear response to sinusoidally varying control voltage

$\tau = 3t_o$

while the time response constant $T = 2t_o$ remained the same as in Fig. 8.

Fig. 10 illustrates variations in gate emf for various control signal frequencies for the case $T = 2t_o$. If no additional external feedback is assumed ($h_e = 0$), this represents the case where the control circuit resistance R_c is equal to the dynamic resistance R_d as is apparent from equations 14 and 15. Phase lag angles for the different frequencies are indicated in this figure. Relative values of amplitudes of ΔE_g are apparent.

In Fig. 11 the signal frequency is held constant at $f = f/6$ while response time constants T are varied by means of external electric feedback from $T = t_o$ to $T = 6t_o$. Note that, for the case $T = t_o$, half-cycle response, a phase lag of 30 degrees equivalent to one half cycle of the carrier frequency exists. It may be mentioned that the described graphical method will allow taking roughly into account nonlinear operation of a magnetic amplifier, as will result from large changes of control voltage. Since, under such conditions, the dynamic resistance and the specific voltage gain are subject to variations, the distance T of Fig. 8 therefore has to be gradually changed as a function of ΔE_g.

Also the values $\Delta E_{\omega n}$ must be determined in correspondence with the dynamic characteristic of the amplifier. The general scheme of graphical construction for this case is shown in Fig. 12, where the reference values $\Delta E_{\omega 1}$, $\Delta E_{\omega 2}$ ... are now located on the curve $T = f(\Delta E_g)$.

The response of the magnetic amplifier to a sinusoidally varying control signal voltage will now be investigated mathematically as follows: It was shown before that the relationship between gate emf's at succeeding half cycles is expressed by

$$(\Delta E_n - \Delta E_{n-1})\frac{T}{t_o} + \Delta E_{n-1} = \Delta V_{c_{n-1}} \cdot \frac{R_d}{R_c + h_e \cdot R_d}$$

from equation 7.

The control signal voltage is

$$\Delta V_c = \Delta V_{c_{max}} \sin \omega_s t$$

as expressed in equation 18.

Assuming an arbitrary phase angle of ΔV_c, one can also write

$$\Delta V_c = \Delta V_{c_{max}} \epsilon^{j\omega_s t} \tag{22}$$

The average value of ΔV_c during the $(n-1)$th half-cycle is then

$$\Delta V_{c_{n-1}} = \frac{1}{t_o}\int_{(n-1)t_o}^{nt_o} \Delta V_{c_{max}} \epsilon^{j\omega_s t}\, dt \tag{23}$$

$$\Delta V_{c_{n-1}} = \frac{\Delta V_{c_{max}}}{t_o}\left[\frac{\epsilon^{j\omega_s t}}{j\omega_s}\right]_{(n-1)t_o}^{nt_o}$$

or

$$\Delta V_{c_{n-1}} = \frac{\Delta V_{c_{max}}}{j\omega_s t_o}\left[\epsilon^{j\omega_s t_o} - \epsilon^{j\omega_s (n-1)t_o}\right] \tag{24}$$

The gate emf's existing during the $(n-1)$th and nth half-cycle can generally be expressed as follows:

$$\Delta E_{n-1} = \Delta E_{max} \epsilon^{j\omega_s (n-1)t_o} \tag{25}$$

and

$$\Delta E_n = \Delta E_{max} \epsilon^{j\omega_s n t_o} \tag{26}$$

where an unknown phase angle and magnitude are attributed to ΔE_{max}.

Introducing equations 24, 25, and 26 into equation 7 yields:

$$\frac{\Delta E_{max} T}{t_o}\left[\epsilon^{j\omega_s n t_o} - \epsilon^{j\omega_s (n-1)t_o}\right] + \Delta E_{max} \epsilon^{j\omega_s (n-1)t_o} = \frac{\Delta V_{c_{max}}}{j\omega_s t_o} \frac{R_d}{R_c + h_e \cdot R_d}\left[\epsilon^{j\omega_s n t_o} - \epsilon^{j\omega_s (n-1)t_o}\right] \tag{27}$$

Multiplying both sides of equation 27 by $\epsilon^{-j\omega_s (n-1)t_o}$ yields

$$\frac{\Delta E_{max} T}{t_o} \epsilon^{j\omega_s t_o} - 1 + \Delta E_{max} = \frac{\Delta V_{c_{max}}}{j\omega_s t_o} \frac{R_d}{R_c + h_e \cdot R_d}\left[\epsilon^{j\omega_s t_o} - 1\right] \tag{28}$$

By rearranging terms:

$$\frac{\Delta E_{max} T}{t_o}\left[\epsilon^{j\omega_s t_o} - 1 + \frac{t_o}{T}\right] = \frac{\Delta V_{c_{max}}}{j\omega_s t_o} \frac{R_d}{R_c + h_e \cdot R_d}\left(\epsilon^{j\omega_s t_o} - 1\right)$$

or

$$\frac{\Delta E_{max}}{\Delta V_{c_{max}}} = \frac{R_d}{R_c + h_e \cdot R_d} \frac{1}{j\omega_s T} \frac{\epsilon^{j\omega_s t_o} - 1}{\epsilon^{j\omega_s t_o} - 1 + \frac{t_o}{T}} \tag{29}$$

$$\frac{\Delta E_{max}}{\Delta V_{c_{max}}} = G_{v_s} \frac{1}{\frac{j\omega_s t_o}{\epsilon^{j\omega_s t_o} - 1} + j\omega_s T} \tag{30}$$

Equation 30 has to be multiplied by $\epsilon^{-j\omega_s t_o/2}$ in order to account for the median transportation lag $t_d = t_o/2$; see equation 21. Therefore one obtains

$$\frac{\Delta E_{max}}{\Delta V_{c_{max}}} = G_{v_s} \frac{\epsilon^{-j\omega_s t_o/2}}{\frac{j\omega_s t_o}{\epsilon^{j\omega_s t_o} - 1} + j\omega_s T} \tag{31}$$

By applying l'Hospital's rule to the first term of the denominator, one finds that

$$lim \frac{j\omega_s t_o}{\epsilon^{j\omega_s t_o} - 1} = 1 \text{ for } \omega_s t_o \rightarrow 0$$

This indicates that for the condition of small values of the ratio f_s/f equation 31 can be replaced by

$$\frac{\Delta E_{max}}{\Delta V_{c_{max}}} \cong \frac{G_{v_s}}{1 + j\omega_s T}. \tag{32}$$

This is obviously the conventionally employed form of the trausfer function for a magnetic amplifier; it is valid only with the above-mentioned restrictions. Often this equation is used in a form where the median transportation lag

$$\epsilon^{-j\omega_s t_o/2}$$

is introduced as a factor into the numerator. As soon as this term gains importance with regard to phase lag, the term

$$j\omega_s t_o / (\epsilon^{j\omega_s t_o} - 1)$$

of equation 31, which contributes essentially to a phase lead, must gain equal importance. Therefore, it is more correct to use equation 31 instead of modifying equation 32.

Using Laplace notation, equation 31 can be written

$$G_{th}(s) = \frac{G_{v_s} \epsilon^{-st_o/2}}{\frac{st_o}{\epsilon^{st_o} - 1} + sT} \tag{33}$$

This is the theoretical transfer function of a magnetic amplifier, which relates variations in control voltage to variations in gate emf on an equal turns basis.

The over-all transfer function which takes into account turns ratio N_g/N_c and internal voltage drops is then determined by:

$$G(s) = G_{v_s} \frac{N_g}{N_c} \frac{R_L}{R_L + R_g} \frac{\epsilon^{-st_o/2}}{\frac{st_o}{\epsilon^{st_o} - 1} + sT} \tag{34}$$

Equation 31 can also be written in a somewhat different fashion if one remembers that the ratio G_{v_s}/T amounts according to equations 6 and 9 to

$$\frac{G_{v_s}}{T} = 2f \frac{R_d}{R_c + R_d} \tag{35}$$

where

$$\frac{R_d}{R_c + R_d} = G_{v_{s0}}$$

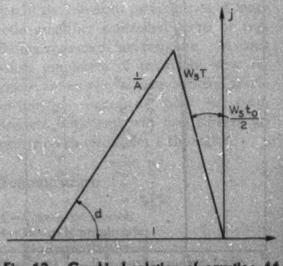

Fig. 13. Graphical solution of equation 44

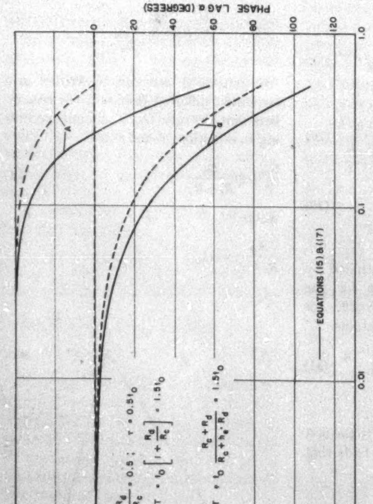

Fig. 14. Attenuation and phase angle versus ratio f_s/f for $R_d/R_c=0.5$

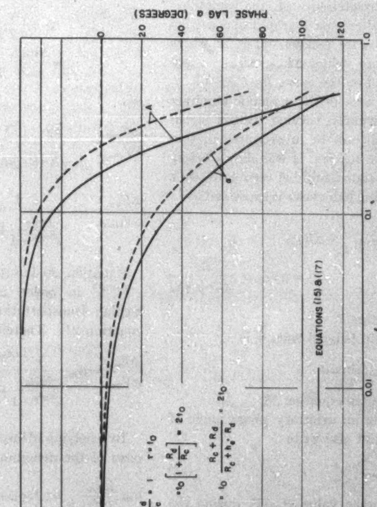

Fig. 15. Attenuation and phase angle versus ratio f_s/f for $R_d/R_c=1$

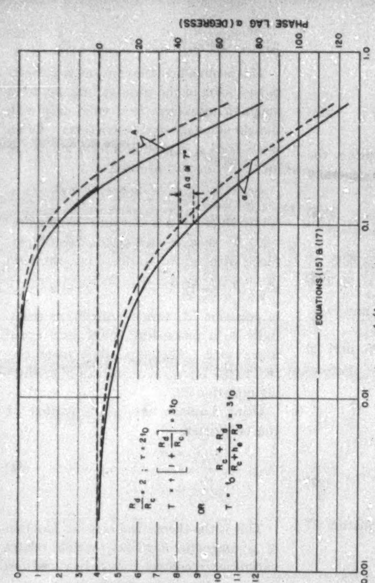

Fig. 16. Attenuation and phase angle versus ratio f_s/f for $R_d/R_c=2$

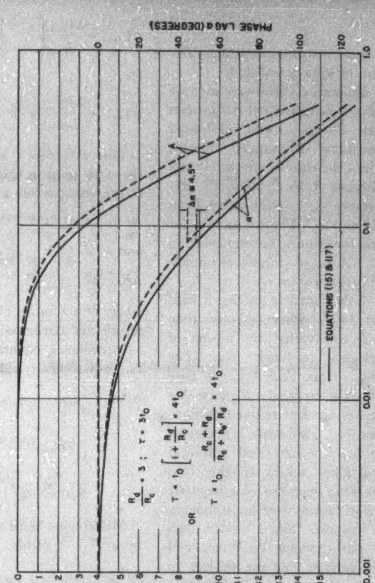

Fig. 17. Attenuation and phase angle versus ratio f_s/f for $R_d/R_c=3$

equation 17 is the specific voltage gain of an equivalent half-wave amplifier. Combining equations 35 and 31 yields:

$$\frac{\Delta E_{max}}{\Delta V_{c_{max}}}=2f\frac{R_d}{R_c+R_d}\frac{\epsilon^{-j\omega_s t_0/2}}{j\omega_s+\dfrac{j\omega_s}{\epsilon^{j\omega_s t_0}-1}\dfrac{t_0}{T}} \tag{36}$$

Letting $T=t_0$ (half-cycle response) equation 36 after rearrangement of terms becomes

$$\frac{\Delta E_{max}}{\Delta V_{c_{max}}}=\frac{R_d}{R_c+R_d}\frac{\epsilon^{j\omega_s t_0/2}-\epsilon^{-j\omega_s t_0/2}}{j\omega_s t_0\cdot\epsilon^{j\omega_s t_0}} \tag{37}$$

or in different form

$$\frac{\Delta E_{max}}{\Delta V_{c_{max}}}=\frac{R_d}{R_c+R_d}\frac{2\sin\omega_s\dfrac{t_0}{2}}{\omega_s t_0}\epsilon^{-j\omega_s t_0} \tag{38}$$

Equation 38 indicates that the phase lag of the half-cycle response amplifier amounts to

$$\alpha=\omega_s t_0=\pi\frac{f_s}{f}\text{ (radians)}$$

which is a generally known fact. The same result was, as mentioned earlier, obtained by graphical means shown in Fig. 11.

In the existing literature the "time constant" of a magnetic amplifier is often expressed as follows:

$$\tau=\frac{1}{2f}\frac{R_0}{R_c}\frac{N_c}{N_g}\frac{\Delta I_L}{\Delta I_c} \tag{39}$$

where

$$R_0=R_L+R_g$$

Letting

$$N_c/N_g=1\text{ and }\Delta I_L(R_L+R_g)=\Delta E_g$$

$$\tau=\frac{1}{2f}\frac{1}{R_c}\frac{\Delta E_g}{\Delta I_c}$$

but

$$\frac{\Delta E_g}{\Delta I_c}=R_d\text{ (as defined in this report)}$$

Therefore

$$\tau=\frac{1}{2f}\frac{R_d}{R_c} \tag{40}$$

Comparing equation 40 with equation 14, one realizes that the term 1 is obviously missing. Therefore equation 40 should furnish wrong results, especially in cases where R_d/R_c is not considerably larger than 1. In many practical applications this ratio should be made at least comparable to 1 since the time response constant must be kept at a suitable low value. In addition, it is known that a large R_d/R_c ratio results in quite a considerable deviation of the transfer-characteristic from linearity. From a theoretical viewpoint, as R_d/R_c becomes smaller equation 40 indicates a time constant approaching zero for very large R_c values. This cannot be true, since the minimum response time obtainable should still be the time of one half cycle, namely $t_0=1/2f$. The more correct relationship is therefore given by equation 14 and, in case of external electric feedback, by equation 6.

In addition, the conventionally used transfer function

$$G(\omega_s)=G_v\frac{\epsilon^{-j\omega_s t_0/2}}{1+j\omega_s\tau}\quad\left[\tau=\frac{1}{2f}\frac{R_d}{R_c}\right] \tag{41}$$

should be, at least in all cases where R_d/R_c is comparable to 1, replaced by the function

$$G(\omega_s)=G_v\frac{\epsilon^{-j\omega_s t_0/2}}{\dfrac{j\omega_s t_0}{\epsilon^{j\omega_s t_0}-1}+j\omega_s T}\quad\left[T=\frac{1}{2f}\left(1+\frac{R_d}{R_c}\right)\right] \tag{42}$$

A study of the first term of the denominator of equation 42 will reveal that

$$\epsilon^{-j\omega_s t_0/2}\cong\frac{j\omega_s t_0}{\epsilon^{j\omega_s t_0}-1} \tag{43}$$

can be substituted for all values of $\omega_s t_0$ smaller than $\pi/4$. Introducing equation 43 in equation 42 and rearranging terms gives

$$G(\omega_s)\cong G_v\frac{1}{1+j\omega_s T\cdot\epsilon^{j\omega_s t_0/2}}\quad(\omega_s t_0<\pi/4) \tag{44}$$

Phase lag angle α and relative amplitude A of this function can be determined by a simple graphical construction as illustrated in Fig. 13, which is self-explanatory. In order to demonstrate actual differences in results obtained from equation 41, and equations 44 or 42, respectively, calculations of phase lag angles α and per-unit amplitudes A were made for a variety of conditions assuming G_v to be unity. Calculations were made for values R_d/R_c ranging from 0.5 to 3.0 and various ratios f_s/f ranging from 0.01 to 0.5. Results are illustrated in Figs. 14 to 17. As was to be expected, differences in results obtained by equation 41 versus equations 42 or 44 respectively, become smaller with increasing values R_d/R_c.

It is of interest to note that in the cases of larger R_d/R_c values an almost constant additional phase lag $\Delta\alpha$ can be observed above a certain signal-to-carrier-frequency ratio, if one compares the more accurate values of equations 42 and 44 with those of equation 41. For the case $R_d/R_c=2$, this angle $\Delta\alpha$ amounts to about 7 degrees for $f_s/f>0.08$, while for $R_d/R_c=3$ it is approximately 4.5 degrees for $f_s/f>0.05$. Such additional phase lags may well be taken into account in the design of certain fast responding control or regulating systems, especially where two or three magnetic amplifiers are used in cascade. Also, in systems where problems of structural resonance occur these phase lags should be considered; see Figs. 16 and 17.

Table I. Values from Fig. 10

$T=2t_0$ f_s/f	From Equation 44		From Graph	
	A	α	A	α
1/12	0.943	29	0.930	28.5
1/8	0.870	42.5	0.860	42.5
1/6	0.804	54.2	0.790	54
1/4	0.665	74	0.660	74

Table II. Values from Fig. 11

$f_s/f=1/6$ T	From Equation 44		From Graph	
	A	α	A	α
t_0	0.990	30	0.955	30
$2t_0$	0.804	54.2	0.790	54
$3t_0$	0.614	69	0.610	69
$6t_0$	0.328	86.5	0.320	86

In order to have a comparison between results obtained by the previous discussed graphical method and results from equation 44, values of A and α were also calculated for the conditions illustrated in Figs. 10 and 11. These calculated values and values taken from those figures are given in Tables I and II.

It may be stated that in the case of large R_d/R_c values, if external electric feedback is employed, equation 6 for the time response constant simply reduces to:

$$T\cong\frac{t_0}{h_e}\cong\frac{1}{2fh_e}$$

This occurs quite often in practice, if fast response is combined with reasonable power gain.

Conclusions

Equations and graphical methods presented will permit more accurate prediction of the transient performance of magnetic amplifier controlled servo or regulating systems of fast response. In cases where amplifiers of relatively slow response are employed, conventional transfer-function equations may be used. Readers interested will find further information in references 1 through 4.

I_c = Control current
I_L = Load current
ΔI_{m_0} = Change of half-cyclic average magnetizing ampere-turns per cm path length
I_m = Magnetizing current
l_m = Mean magnetic path length
N = Number of turns
N_g = Number of turns of gate winding
N_c = Number of turns of control winding
R_d = Dynamic resistance
R_{d_0} = Specific dynamic resistance
R_c = Control circuit resistance
R_L = Load resistance
R_g = Gate circuit resistance
R_o = Total resistance of load circuit, $R_o = R_L + R_g$
t_0 = Time of one half cycle
T = Time response constant
V_s = Supply voltage impressed on gate circuit
V_c = Control voltage
ΔV_c = Change of control voltage
V_{c0} = Bias voltage
$\Delta V_{c(n-1)}$ = Total change of half-cyclic average value of control voltage at $(n-1)$th half cycle
ΔV_{c_n} = Total change of half-cyclic average value of control voltage at nth half cycle
W_c = Control winding
W_g = Gate winding
α = Phase lag angle
ϵ = Basis of natural logarithm
λ = Ratio of carrier to signal frequency
τ = Time constant
ω_s = Signal frequency in radians per second

Discussion

G. E. Lynn (Westinghouse Electric Corporation, Baltimore, Md.): The author is to be thanked for an interesting discussion of the problem of transfer function representation of magnetic amplifiers. The literature has lacked a comprehensive paper on the subject and Mr. Manteuffel's contribution goes a long way toward filling the void. Several aspects of this subject have, however, been covered in previous papers by various authors[1–3] and it seems fitting that the attention of the interested reader be directed to the earlier work.

A particularly illuminating correlation was established by Mr. Manteuffel in comparing equations 14 and 40 in his paper. In working with an equivalent resistance, R_d, the fact that the time constant cannot be less than $1/2f$ is occasionally lost sight of. The treatment accorded this point in the paper should fix it thoroughly in the reader's mind.

Magnetization in Tape-Wound Cores

R. C. BARKER
ASSOCIATE MEMBER AIEE

IN RECENT years it has been noted in several phases of the electronics industry that advanced engineering developments follow the developments in related components. As a more extensive knowledge of the components and their operation becomes commonplace among engineers, their application becomes greatly accelerated. An example of this is found in the technology of thermionic devices, where the knowledge of electron dynamics led from the vacuum tube to the cathode-ray tube, the photomultiplier, the traveling-wave tube, and a host of other components. Also, in a few short years we have seen advances in the knowledge of semiconductors lead from the dry-disk rectifier to more advanced semiconductor junction rectifiers, transistors, and other components, which seem to be increasing in number almost monthly.

The same pattern of events characterizes the development of modern magnetic materials. The early technology surrounding soft magnetic materials was developed from a fairly crude understanding of magnetic properties, and almost no knowledge of the basic theory of ferromagnetism. Recent developments in magnetic materials have lead to spectacular advances in their application, resulting in a technology generally called magnetic amplifiers, for several years. But developments have been so rapid, it now appears that magnetic amplifiers will soon represent only a small portion of a larger technological field[1] more conservatively called "nonlinear magnetic devices."

It frequently happens that in the rapid development of such a field, the new applications appear in the literature where they can be easily found, while the more basic descriptions of the components are found scattered throughout the literature. An occasional tutorial paper is sometimes helpful in summarizing the knowledge of the components. Accordingly, the purpose of this paper is to summarize the state of knowledge of soft magnetic materials, specifically as used in commercially available tape-wound cores. The summary is written from the electrical engineering standpoint, and the language is purposely nonmathematical. The intent is to give a qualitative description of the physical and electrical properties of magnetic tapes in terms of simple experiments that can be performed in most laboratories without excessive special equipment. The first section of the paper is basic enough to be applicable to all magnetic materials, whether hard or soft, metallic or nonmetallic. The remainder, however, is directed toward tape-wound, toroidal cores. The alloys discussed are

Paper 60-873, recommended by the AIEE Magnetic Amplifiers Committee and approved by the AIEE Technical Operations Department for presentation at the AIEE Summer General Meeting, Atlantic City, N. J., June 19–24, 1960. Manuscript submitted November 4, 1959; made available for printing June 3, 1960.

R. C. BARKER is with Yale University, New Haven, Conn.

The author wishes to acknowledge the co-operation of his colleague, Dr. Charles B. Wakeman, and of Magnetics, Inc., Butler, Pa. Much of the original work described was done under the sponsorship of the Air Force Flight Control Laboratory, *WCLCX-2*, at Wright Air Development Center.

the 50%/50% nickel-iron, 80%/20% nickel-iron, and 3%/97% silicon-iron alloys, but the general line of reasoning is applicable to many other combinations, even though their properties may be entirely different.

Having obtained a qualitative understanding of the properties of these materials, the reader may wish to investigate the metallurgical or magnetic properties further. It is hoped that the references[1-40] will be found useful for this purpose. The list is not complete by any means, but the items listed include many references to further literature in the fields of specific interest.

Five important sources of information that represent recent advances in magnetism and magnetic materials are the proceedings of conferences that have taken place in the United States and Great Britain in the past several years.[3-6] There are also several textbooks that deal with ferromagnetism,[7-10] and two excellent reviews[11,12] that bring the subject up to date.

Magnetization in Single Crystals

BASIC THEORY

A single crystal is characterized by its uniform lattice structure, disturbed only by occasional lattice imperfections and impurities. Because of the periodic structure of the lattice in the 3-dimensional space occupied by the crystal, many theoretical problems can be formulated by means of group theory in a relatively simple manner.[13] When the lattice is not periodic, it becomes virtually impossible to formulate such problems. Polycrystalline materials fall into this category. They are made up of small crystals. Those varying in size from a fraction of a millimeter are commonly called crystallites. When the size increases to a fraction of an inch or larger they are commonly called grains. A periodic lattice structure exists within the crystallites or grains, but on a larger scale the lattice structure is obviously not periodic.

Thus, the single crystal constitutes the ideal solid in which ferromagnetism occurs, and consequently the introductory discussion of ferromagnetic domains applies to single crystals. Interaction forces leading to ferromagnetism have been calculated and experiments have been performed on some single crystals specially grown for the purpose. The ferromagnetism of polycrystalline materials is treated as a modification of the single-crystal model.

The discussion to follow deals with the ferromagnetism of magnetically soft materials, beginning with the qualitative description of ferromagnetic domains. The atomic theory and energy-band theory are not discussed because they are highly theoretical in nature and require an extensive background in quantum physics. However, it is difficult to reject the topic categorically without making at least one or two comments to summarize the state of knowledge and to give references to the interested reader.

An electron associated with an atom is found to have an intrinsic magnetic moment arising from a hypothetical "spin" about its hypothetical "axis." The directions in which this electron spin can point relative to the electron distribution about the atom are governed by quantum mechanics, and the behavior of this little permanent magnet is not at all analogous to classical magnets. In some materials, it is found that when electron spins on adjacent atoms are parallel, such that their magnetic moments add, the energy of the material is less than if they are antiparallel, such that their magnetic moments cancel. The "forces" that bring this about are called exchange forces; they are electrostatic rather than magnetic in origin, and have no classical analog. The conditions under which the exchange forces are large enough to produce ferromagnetism are found only when the radius of certain electron shells and the interatomic spacing in the crystal lattice are related in just the right way. This explains why it is that only a small number of elements in a restricted portion of the periodic table are ferromagnetic. It also accounts for the fact that alloying and processing, which affect the type and dimensions of a crystal lattice, are important in determining magnetic properties.

The theory of ferromagnetism is far from complete, and important contributions are still found from time to time in the current literature. Thus, in addition to the references listed on the general theory of ferromagnetism, the reader is advised to consult the recent and current literature for the latest developments.[14-18] In the remainder of this paper, the discussion will deal with relatively large-scale models, and atomic scale effects will appear only in the background.

FERROMAGNETIC DOMAINS

The theory of ferromagnetic domains and the molecular field was introduced by Weiss in 1907[11,19] in order to account for two simple and commonly known experimental facts:

1. By applying a very weak field, say 5 ampere-turns/meter (0.063 oersted), it is possible, in a ferromagnetic specimen, to obtain a flux density of approximately 1.5 webers/ square meter (15 kilogausses), a very much larger value than that obtained in air or in paramagnetic substances.
2. It is possible for a bar-shaped specimen of the same type of material to have practically zero external magnetization with zero applied field.

The thermal energy of atoms at room temperature is so large that their random motion would require a strong field to produce alignment of their magnetic moments if acted upon independently. Thus Weiss proposed that there is an internal or molecular field acting to align the elementary magnetic particles. The molecular field was assumed to be the result of the interaction, which we now call exchange interaction, of each elementary magnet with its neighbors, and calculations indicate that it would have to be in the neighborhood of 8×10^8 ampere-turns per meter, or about 10^7 oersteds. This is in the order of 10 times the largest field ever produced in the laboratory. With the assumption that this field is present, it is difficult to imagine that the very small field mentioned could reverse the magnetization of the specimen, or that the specimen could have nearly zero magnetization with zero applied field. Weiss recognized that the molecular field is a point function of space that can vary its direction throughout the volume of the material. Thus, by postulating thin boundaries between saturated regions of the material, Weiss was able to account for the absence of apparent magnetization external to the sample while maintaining completely saturated domains with boundaries placed so that the magnetic flux path closes within the material.

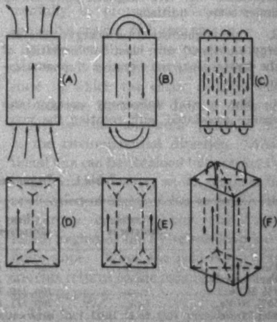

Fig. 1. **Magnetic states of a bar sample**

The state of exactly zero external field was not necessary to Weiss's argument, and is rarely possible experimentally. Fig. 1 shows the manner in which the boundaries between fully saturated regions in a bar-shaped specimen can be placed so as to have a very large external field, a very small external field, and virtually zero external field. The arrows show the directions of saturation of the material, and the dotted lines show the boundaries between the saturated domains. These boundaries are often called, "domain boundaries," "domain walls," or "Bloch walls." In Fig. 1(D), the vertical wall is called a 180-degree wall, and the four short walls extending to the corners of the specimen are called 90-degree walls. The upper domains, which are saturated horizontally, are called domains of closure, because they allow the magnetic flux to form a closed path within the material. Even in the specimen of Fig. 1(D), however, the external field is not exactly zero. There are small local fields in the vicinity of the domain boundaries. Because of these local fields concentrated near domain boundaries, it is possible to place a suspension of very fine magnetic particles on a surface such as that shown and observe the motion and positions of domain boundaries.[11,20]

The sketches shown in Fig. 1 are typical for plane symmetry throughout a thin slab. In thicker specimens, the domains may take on a 3-dimensional pattern such as that shown in Fig. 1(F).

THE ENERGY OF MAGNETIZATION

There are four components of energy involved when a specimen is magnetized. These are:

1. The exchange energy: the difference between the energy of the specimen with antiparallel electron spins and that with parallel spins.

2. The magnetostatic energy: the energy associated with free magnetic poles set up under some conditions.

3. The magnetostriction energy: the energy associated with elastic deformation of the crystal along the direction of magnetization.

4. The crystal anisotropy energy: the energy associated with rotating the magnetization vector with respect to the crystal lattice, away from the preferred or "easy" direction of magnetization.

The first of these components is dependent only on the relative directions of neighboring spins and not on their relation to the crystal lattice. The other three are definitely dependent upon the the direction of magnetization with respect to the lattice, the microstructure within the materials, and the over-all geometry of the specimen. Thus, we say the exchange energy is isotropic, and the other three are anisotropic. The anisotropy energy referred to frequently in the technical literature may include one or more of the latter three components. Common crystal systems are discussed by Barrett,[21] and the crystal systems of common ferromagnetic alloys and their directional properties are treated extensively by Bozorth.[7] A very brief summary of these properties is given in Table I, where the axes of magnetization are given in the order of increasing difficulty of magnetization. It should be noted that the nominally 80% nickel-iron alloy (the Permalloy series) has a very low anisotropy constant, which means that it does not require much more energy to magnetize it in its most difficult direction than it does in its easiest direction.

As a result of our discussion of the four energy components of magnetization, we can now comment on the various magnetic states represented by Fig. 1. In Fig. 1(A), the magnetization is in the same direction throughout the material. The energy of magnetization in this specimen, as in the other three, depends upon whether the bar is cut parallel to the crystal cube edges or otherwise, because of the crystalline anisotropy and magnetostriction constants. For the present, let us suppose that the specimen is cut parallel to the crystal axes. Then the principal reduction in energy that can take place is the reduction of the magnetostatic energy associated with the large external field. In Fig. 1(B), the magnetostatic energy is reduced, but a domain wall has been included. In the domain wall, adjacent atoms do not have parallel spins, as shown in Fig. 2, a model suggested by Kittel.[11] The rapid directional change of the magnetization vector within the wall indicates that anisotropy and magnetostriction energy terms are present. Thus, the reduction in magnetostatic energy in Fig. 1(B) is partially offset by the increase in energy associated with the domain wall within the material. Whether the configuration of Fig. 1(A) or Fig. 1(B) is energetically favorable depends upon whether the magnetostatic energy reduction minus the wall energy gain is positive or negative. If it is positive, Fig. 1(B) is energetically favorable over Fig. 1(A). In the more common iron alloys, the subdivision normally continues as in Fig. 1(C) until a rather large number of domains is formed, perhaps as many as 1,000 per centimeter.

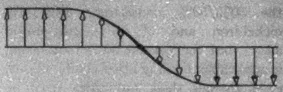

Fig. 2. Vectors representing the change in magnetization through a domain wall

Table I. Properties of Magnetic Alloys

	Crystal Structures	Easy Directions	Crystal Anisotropy Constants in ergs/cm^3	
Pure iron	b.c.c.	*100, 110, 111*	$K_1=42\times10^4$	$K_2=15\times10^4$
Pure nickel	f.c.c.	*111, 110, 100*	$K_1=-34\times10^4$	$K_2=53\times10^4$
3% Si-Fe	b.c.c.	*100, 110, 111*	$K_1=28\times10^4$	$K_2=10\times10^4$
50% Ni-Fe	f.c.c.	*100, 111, 110*	$K_1=3\times10^4$	$K_2=-18\times10^4$
80% Ni-Fe	f.c.c.	substantially isotropic	$K_1=-0.2\times10^4$	$K_2=-2\times10^4$

In many materials, such as the alloys listed in Table I, there are three preferred directions of magnetization because of the symmetry of the cubic crystal systems. In such cases, it may be found that the magnetostatic energy can be reduced nearly to zero without the formation of a large number of domains, by the introduction of domains of closure as shown in Fig. 1(D). The four magnetization vectors are all in equally preferred directions. However, since the magnetostriction results in an elongation, or contraction, in the direction of the magnetization vector, there is an elastic deformation in the specimen that represents energy. Whether the closure domains form, and if so the number that form, depends upon the relative magnitudes of the energies represented and the method by which the material is magnetized. The history of magnetization is important because there are often quasi minima of energy that do not correspond to the absolute minimum.

This brief and qualitative description suggests that the magnetization process takes place by the growth of domains saturated in one direction at the expense of those saturated in another direction. The magnetization of modern soft magnetic materials is unmistakably a process of this kind, even in polycrystalline specimens. However, even when the material consists of just one fully saturated domain, the magnetization vector, which is parallel to the preferred crystallographic direction,

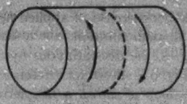

Fig. 3. Cylindrical shell with zero total flux

may not be parallel to the applied field. Thus, further flux may be obtained in this direction by rotating the magnetization vector into alignment with the applied field. This is done at fields higher than those required to propagate domain walls because of the anisotropy energy characteristic of the particular crystal. Domain rotation will be discussed further in a later section.

MAGNETIZATION IN THE THIN CYLINDRICAL SHELL

The toroidal core is a structure that has essentially no air gap. Therefore, the magnetostatic energy does not play as important a part in the magnetic properties of the specimen as it does in the rectangular bar of Fig. 1. Consequently, it is to our advantage to develop the concepts of magnetization by domains by means of a closed configuration. It is convenient to use the cylindrical shell as the starting point. The cylindrical shell is shown in Fig. 3. It is assumed for this example that the shell is a single crystal with its cubic axes directed circumferentially, axially, and normal to the surface. A domain wall is shown dividing two regions of complete saturation. According to our previous qualitative argument, there is a certain amount of energy associated with this domain wall, and this should not depend upon its location in the shell. Thus, it should require zero energy to move the domain wall from one edge of the shell to the other, i.e., to reverse its magnetization. However, when the shell is completely saturated, the domain wall is absent entirely. To reverse the magnetization from one completely saturated direction to the other requires that a field be applied sufficiently large to establish the domain of reverse magnetization. This field is commonly called the "starting field" or the "nucleating field." Once the nucleus of reverse magnetization has been established, it requires a vanishingly small magnetizing force to propagate it through the shell to the other edge.

The hysteresis loop of the ideal cylindrical shell can be obtained by considering it to be fully saturated, as shown in Fig. 4(A), and applying the field necessary to establish a nucleus of reverse magnetization and propagate it through the shell, leaving it fully saturated in the opposite direction. Fig. 4 shows the hysteresis loop implied by the ideal shell. The total flux ϕ is plotted against the magnetomotive force F. The regions corresponding to the four states of magnetization shown in the figure are indicated by arrows. It is assumed that the magnetomotive force is increased in the negative direction by the experimenter until the domain wall is established, and is then decreased rapidly to zero. The magnetomotive force is then increased to a vanishingly small value, resulting in the motion of the domain wall from the position shown in Fig. 4(B) to the position shown in Fig. 4(C). Further increase in the applied field moves the domain wall out of the shell and leaves it fully saturated in the negative direction as shown in Fig. 4(D). The other half of the hysteresis loop is shown dotted, and is the image of the first half.

In the above described process of flux reversal, it was assumed for the sake of simplicity that the domain of reverse magnetization was nucleated at the left edge of the cylinder. One might think that the return to positive saturation would be accompanied by reverse motion of the domain wall, i.e., from right to left. If there are any physical factors that cause the first reversal to begin at the left edge of the cylinder, these same factors would cause the second reversal to begin also at the left edge. In normal crystals, domains of reverse magnetization would become established at impurities or imperfections near the surfaces, and propagate outward into the cylinder. In the assumed perfect crystal, these centers of flux reversal do not exist, and the domains of reverse magnetization would probably appear at both edges simultaneously at a somewhat higher nucleating field.

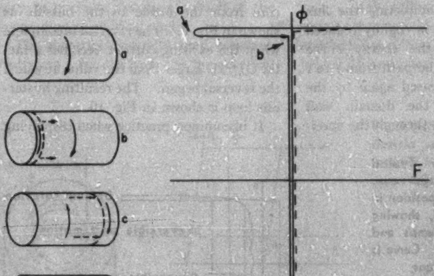

Fig. 4. Ideal hysteresis loop of cylindrical shell, correlating points on the hysteresis loop with domain-wall position

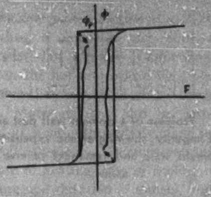

Fig. 5. Hysteresis loop of a single crystal showing domain-nucleation effect

The foregoing is a first approximation to the mechanism of magnetization in a single crystal. The description is qualitative and not rigorous. Any further detail at this stage of the argument, however, would be superfluous because, even in a single crystal, this degree of idealization cannot be realized. Even if the thin shell could be grown as a single crystal, there are two factors that would have to be considered. The first of these is that the crystal orientation would not be exactly directed along the circumference, and secondly, it is not possible experimentally to propagate a domain wall through a crystal with zero energy.

It the event that the crystal orientation is not exactly circumferential, the state in which the entire cylinder constitutes one saturated domain does not result in the maximum possible flux in the circumferential direction. Additional flux can be obtained by rotating the magnetization vector, which requires the application of higher fields to supply the anisotropy energy. Thus, the "saturated" region of the hysteresis loop has a finite slope. When the field is removed, the flux returns to the remanent point, ϕ_r, shown in Fig. 5.

The fact that it is not possible experimentally to move a domain wall with

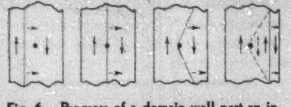

Fig. 6. Progress of a domain wall past an included impurity, showing elastic expansion of the domain wall and remanent reverse domains

zero field even in a single crystal means that there is some "coercive force" required: the flux-current loop has a finite width. The theory of coercive force is still not understood in quantitative detail, but qualitatively, it is believed with good experimental authority that the existence of coercive force is a direct evidence of crystal lattice imperfections and impurities. Experiment shows[7] that when the field is increased until the flux in the core begins to change, this value of field may be sufficient to produce the entire flux reversal. If after the flux begins to change the field is reduced, the flux is prevented from changing further. The field may then be increased again from a small value, and the flux is found to reverse in steps or jumps. The resulting flux-current loop is shown in Fig. 5. It should be noted in Fig. 5 that the field required to propagate the domain through the material is less than the nucleation field. As indicated by Kittel and Bozorth in the foregoing references, these experiments have been made on single crystals[22] of somewhat different dimensions than the cylindrical shell, and polycrystalline materials that have been annealed in the presence of a strong magnetic field applied in the direction of magnetization. Very nearly the same results can be found in commercial-grade tape-wound cores, as will be shown in a later section.

The dependence of coercive force upon impurities and lattice imperfections is worthy of additional comment, since it accounts qualitatively for the "initial permeability" of materials and the well-known Barkhausen discontinuities. The crystal lattice has in it some imperfections such as slip planes, dislocations, missing planes of atoms over short distances, and impurities such as precipitated concentrations of foreign atoms (called inclusions) and some foreign atoms substituted or placed interstitially in the crystal lattice. The percentage of impurity atoms is small and the percentage of volume occupied by imperfections and impurities is small; nevertheless, they are present. Thus the domain wall that moves through the material does not move smoothly, nor does it always have the same length. When a domain wall is pulled over an impurity, or imperfection, it tends to stick to the impurity. As the motion of the domain wall continues, the wall elongates and finally snaps free. The motion of the domain wall is analogous to a taut rubber band being pulled over a rough piece of sandpaper, sections of the band snapping from one piece of grit to another as it moves. Each time a section of the domain snaps forward, the volume through which it sweeps reverses its magnetization. It is easily imagined that these volumes range widely in size. The resulting random discontinuities in flux reversal are called Barkhausen discontinuities, and the noise detected in the material is called Barkhausen noise. The situation described is shown in Fig. 6.

If we could plot the energy of the domain wall as it moves through the shell, a curve such as that shown in Fig. 7 would result. The energy rises in certain areas as the domain wall elongates while passing an impurity, and decreases as it snaps free. If the domain wall is located near an energy minimum, for example at *a* in Fig. 7, changing the applied field by a small amount carries the energy toward *b* or *c*. This is an elastic motion corresponding to an elongation of the domain wall. If the field is removed before the energy either at *b* or at *c* is reached, the wall gives up its energy and returns to *a*. The corresponding small reversible change in magnetic flux with applied field results in the so-called initial permeability. If the field is continually increased, the energy curve follows the path shown with irreversible jumps from *c* to *d*, *e* to *f*, and finally from *g* to *h* completing the flux reversal. If the field is rapidly reduced when jumps occur, the energy curve follows, for example, the path from *f* to *i* until the field is increased again by the experimenter. After the domain wall has moved completely through the specimen, further increase of applied field results in domain rotation.

In Fig. 8, the discontinuous hysteresis loop of Fig. 5 is shown for reference. Inside this loop is shown a magnetization path, a portion of a "minor loop," representing the three regions mentioned above: reversible domain boundary motion, irreversible boundary motion, and domain rotation. This classification of regions is only approximate, however, and applies only to relatively slow changes.

CONCENTRIC CYLINDRICAL SHELLS

For the present purpose, it is convenient to construct a toroid of more reasonable physical dimensions by imagining a large number of our cylindrical shells assembled tightly and concentrically together. It will then be necessary to modify our results in accordance with the particular crystal structure in mind, and the fabrication details of the toroid.

When a toroid is wound with N turns and a current of I amperes is applied, the total magnetomotive force applied to each circumferential magnetic path is the same, namely, NI ampere-turns. But the circumferential magnetic paths are longer at the outer diameter of the toroid than they are at the inner diameter. Thus, the magnetic intensity, NI/π ID (inside diameter) is larger at the inner diameter than it is at the outer diameter, NI/π OD (outside diameter) in ampere-turns per meter. Let us consider first the innermost cylindrical shell, and for the moment consider that the concentric shells magnetize independently. When the magnetomotive force reaches the value corresponding to the nucleating field for the inner shell, its magnetization will reverse. As the current is increased further, the flux reverses in cylinders of increasing diameter. Thus a cylindrically shaped domain wall is formed that increases its diameter, thus reversing the flux in the core from the inside to the outside as shown in Fig. 9. The reversal is complete when the exciting current becomes a factor OD/ID larger than the value at which the reversal began. The resulting hysteresis loop is shown in Fig. 10.

It is common practice when displaying

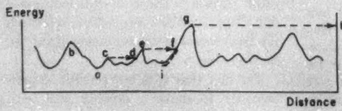

Fig. 7 (left). Typical curve of energy versus domain-wall position in single crystal, showing Barkhausen jumps and quasi minima. Curve is not unique

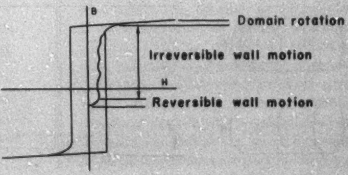
Fig. 8 (right). Contributions to the magnetization process



hysteresis loops to plot flux density **B** against magnetic intensity **H**. The flux density is obtained by dividing the measured flux by the effective cross-sectional area of the core. There is no ambiguity in this process of normalizing, but there may be some error because one does not usually know the exact per cent of the core area occupied by the iron. In normalizing the magnetomotive force to obtain magnetic intensity, it is usual to use the mean magnetic path length. Here, there is some possibility of confusion. The normalizing procedure makes it possible to compare the coercive forces of different materials without having to obtain identical specimens. However, it should be recognized that different portions of the hysteresis loop correspond to flux reversals in different portions of the core. Thus, when one sees magnetic intensity **H** on a hysteresis loop, he should remember that this is the value of magnetic intensity only at the reference magnetic path length. The value of **H** for which the core saturates, in other words, is the magnetic intensity at the center of the core and not at the outer portion of the core, where the flux is changing.

If now, we consider the effect of adjacent concentric shells on each other, we find that after we have exceeded the nucleating field at the inner diameter of the core, there is more than enough magnetomotive force present to cause the nucleated domain to move some distance out into the toroid. This is similar to the spontaneous flux reversal found in the cylindrical shell. But now the domain is approximately cylindrical in shape and is propagated outward into the toroid and grows in size and therefore energy. After it has moved a short distance, a further increase in magnetomotive force is required to produce further flux reversal. The resulting hysteresis loop is shown in Fig. 10. In this case, it is no longer necessary to nucleate domains in each of the succeeding cylindrical shells.

The materials actually used commercially are a far cry from the hypothetical single crystals assumed in the foregoing descriptions. The concepts and simple models developed through these assumptions, however, have a close relationship to the behavior of commercial cores at power frequencies. We shall demonstrate this shortly. But first it is necessary to describe the actual crystalline nature and fabrication of these cores.

Microstructure of Polycrystalline Materials

Commercially available tape-wound cores are fabricated from materials melted under carefully controlled conditions, occasionally in a vacuum where exceptionally high purity is required, but usually under a protective slag. The melt is then cast into ingots and hot-rolled down to a thickness in the neighborhood of 0.1 inch. From this point the material is cold-rolled and annealed in stages down to the final thickness, where it is sheared to the desired width. The material is then sprayed with a magnesium oxide suspension and wound spirally into tape cores which are given a final stress-relief anneal, usually in an atmosphere of dry hydrogen.[7]

With a given alloy, the details of the cold rolling and annealing schedules are crucial in bringing about the magnetic properties desired in the finished product. The details of the rolling and annealing schedules depend not only on the alloy being processed, but also on the finished gage desired. Tape-wound cores are commonly available in 1/8, 1/4, 1/2, 1, 2, 4, and 6 thousands of an inch (mils) thick. Thickness is also given sometimes in microns, where a micron is equal to 10^{-6} meter. A convenient figure to remember is that 25 microns correspond to approximately 1 mil. Thus, for a given alloy, the rolling and annealing schedules may differ greatly from the thickest to the thinnest gage. In the rolling part of the final processing, the variables are the thickness at which hot rolling stops and cold rolling begins, the number of cold-rolling stages, and the degree of reduction at each stage. Annealing is normally not done after each pass, but is more commonly done between the hot and cold rolling phases, and after the material reaches its finished gage. Materials may also be strip annealed at some intermediate stage in the cold-rolling process. In any given anneal, the rate of heating, rate of cooling, temperature and duration of anneal, and the annealing atmosphere are all important variables. It is frequently found that different lots of the same alloy processed to the same gage require different annealing schedules in order to produce equivalent results. With the large number of variables mentioned, it is not surprising that the techniques required to achieve the desired magnetic properties are largely determined empirically. It is also quite likely that processing schedules that differ markedly in detail can be made to produce the same equivalent results.

It is perhaps appropriate to mention at this point that the theory of annealing and the detailed mechanisms by which cold working and annealing determine the microstructure of metals are not understood. However, many of the effects are well understood qualitatively. The factors of importance in magnetic alloys are grain size, relative grain orientation, the character of grain boundaries, the orientation of the lattice in each grain with respect to the plane of rolling, and impurity content. All of these factors are dependent upon cold working and annealing, and it is these factors that one tries to control in producing high quality magnetic materials. Advances in the theory of these processes are reported in the current literature from time to time, and are discussed in detail by Bozorth.[7]

Unfortunately, there is no single reference in the literature, to the author's knowledge, where all the inportant properties of commercial-grade alloys are listed. Most of the information given in this

paper comes from references scattered throughout the literature, from private conversations, and from measurements made at Yale University in the course of past research. Further information on the properties of polycrystalline materials can be found in the book by Bozorth,[7] the current literature,[2-6] a pair of excellent descriptive articles by Randall and Scholefield,[23,24] and the doctoral thesis of Wakeman.[25] Many of Wakeman's results are quoted in this paper.

In the present discussion, we are mainly concerned with the nickel-iron alloys, and 3-97 silicon-iron. It is believed that the effects of cold rolling and annealing are qualitatively the same in these materials. But the discussion applies principally to the nickel-iron alloys. The effects of drastic cold reduction and annealing in the thin gages seem to be most spectacular for these alloys. Consequently, they have been studied in more detail.

Hot rolling is used principally to take the materials down close to their finish gages. The process usually leaves some plastic strains which are removed by annealing at a high temperature, 1,100 C (degrees centigrade) or higher. The process of annealing gives the atomic lattice a large amount of thermal or vibrational energy. This allows some lattice deformations to heal, thus relieving plastic strains. It also tends to break up precipitated impurity inclusions and encourages the impurity atoms, which often are too dissimilar to the principal alloy to substitute in the crystal lattice, to diffuse to the surface where they evaporate or combine chemically with the atmosphere in the furnace. It is also possible that atoms of the annealing atmosphere diffuse into the metal and combine chemically with the immobile impurity atoms, thus making them mobile. The combination may then diffuse out of the material. In any event, all impurities are not removed. A further function of annealing is that it promotes the growth of large regions or grains which are single crystals. A qualitative explanation for this effect is that sufficient thermal energy is given to the atoms that the identity of the lattice structure is lost, or partially lost. In cooling, impurities or intact crystallites act as seeds, and large grains grow with these as centers. This is the situation that is found after the anneal subsequent to hot rolling. The large grains attest to a high degree of purity and relatively low internal strains. These grains may be in the order of half an inch or larger, and can frequently be seen with the naked eye by reflected or polarized light on an oxidized or etched surface.

After hot rolling to about 0.1 inch, and annealing at a fairly high temperature—1,100 to 1,200 C for the nickel-iron alloys—the material is ready for cold working. In thin gages, the nickel-iron alloys are frequently reduced by 98% or more. It is generally found that the beneficial effects of cold rolling are enhanced by making the reduction in many passes. The first stage of cold reduction shatters the large grains leaving very small crystallites, even though the material has not been heavily worked. After as little as 10% cold reduction, the large grain boundaries are still visible in photomicrographs. But X-ray reflection patterns show that the grains are shattered into small undiscernible crystallites.[23] Subsequent heat treatment, however, usually allows the regrowth of these grains. Thus the cold working is generally continued without intermediate annealing. Above 75% cold reduction, the finely divided grains become noticeably smeared out in the direction of rolling by the mechanical action of the rolls. This severe cold working also brings about the orientation of the crystallographic axes of the crystallites. This effect becomes more pronounced with further cold reduction, until at 95% reduction or greater, the crystallites have their crystallographic axes oriented to within 5 degrees or less of the direction of rolling, and the material has a distinctly shredded and fibrous appearance.[23] In the materials with a high degree of cold reduction, annealing at high temperatures usually induces some regrowth of crystal grains. The size and orientation of these grains depend upon the degree of cold reduction and the final tape thickness for any given alloy.

This description is rather general and qualitative. It is most descriptive of the nickel-iron alloys, where the degree of orientation and the effect on the magnetic properties is most pronounced. In the 50-50 nickel-iron alloy the grains are oriented to a high degree, with the cube edges directed along the direction of rolling. The cube edge is also the direction of easy magnetization. In the 80-20 nickel-iron alloy group, the crystallites become oriented with their body diagonals

along the direction of rolling, and become oriented at much thinner gages than the 50-50 alloy. The cube edge, however, is still the direction of easy magnetization. Thus the magnetization in the tape is not in the easy direction. The 3-97 silicon-iron achieves some degree of orientation, but the degree is orders of magnitude below that of the 50-50 nickel-iron alloy.

In the heavier gages, of approximately 4 mils and up, the surface effects may become significant. The relatively small rolls used in the Sendzimer mill,[7] for example, are in the order of an inch in diameter, and show definite tendencies for more severe cold working at the surfaces than is achieved at the center of the tape.[28] Thus the grains in the center of the material are often 10 to 100 times the size of the grains at the surface. This results in a stratification of magnetic properties within the material. These surface effects seem to appear in relatively thick materials and depend upon the processing. To the author's knowledge, they have not been found in commercial-grade, tape-wound cores. As the tape becomes thinner, a condition is approached where the tape is virtually all surface. There is good reason to believe that tapes 1 mil thick or less are about 1 crystallite thick.

The properties measured in three commercial-grade specimens are summarized in the following paragraphs. The specimens were taken from tape-wound cores supplied by Magnetics, Inc., in 1954. The preparation of the specimens is described by Wakeman,[26] who carried out the experimental work. For convenience, the scheme for denoting crystal planes is shown for the cubic crystal in Fig. 11. The crystal axes, or directions, are the normals to these planes. Only three of many possible planes are shown.[21] The cubic crystal is the one most frequently encountered in magnetic materials, but not exclusively. Many cobalt alloys, for example, are hexagonal.

3-97 Silicon-iron: Photomicrographs of 1-mil silicon-iron are shown in Fig. 12. Samples are of material marketed under the name of Magnesil. Fig. 12(C) shows the X-ray diffraction pattern for a 2-mil sample. The spotted nature of the diffraction pattern indicates a granular structure as shown also in the photomicrographs. Note in Fig. 12(B) that the grains go completely through the tape. The "spoked" nature of the diffraction pattern, while not as striking as the pattern for Orthonol, indicates that there is a definite tendency to grain orientation. Fig. 12(A) shows that the largest number of grains are between 1 and 3 mils across. Grains in thicker tapes may be as large as half an inch or larger across. In the ideally oriented material, the crystal axes lie as shown in Fig. 12(D) with respect to the tape surfaces. The earliest work directed toward producing oriented magnetic materials was done with silicon-iron, and was reported by Goss.[27]

4-79-17 Molybdenum-nickel-iron: Samples were taken from commercial cores marketed under the name of HyMu-80 Fig. 13(A) shows a photomicrograph of the surface of a 1-mil sample. It will be noted in this photograph that the process of "twinning," which is the first step in crystal fracturing, is not yet complete.[21] This suggests that further cold reduction would result in a more finely divided and oriented structure. The X-ray diffraction pattern of Fig. 13(B) shows the Debye rings characteristic of a randomly oriented crystal structure. The material is generally reduced about 50% in the final roll, which agrees with the relationship between degree of twinning and final roll reported by Randall and Scholefield.[22] Fig. 13(C) shows the orientation of the crystallites found in the highly oriented specimens. The crystallographic orientation is along the *111* axis. The easy axis of magnetization is the *100* axis.

50-50 Nickel-iron: Samples were taken from material marketed under the trade name of Orthonol. Photomicrographs of samples of 1-, 2-, and 4-mil tape show no signs of grain structure in the material. Further acid etching of the surface shows "etch pits," which when analyzed show that the material has a cubic texture, with its 100 directions perpendicular and parallel to the direction of rolling, and normal to the surface. The photomicrograph of the etched surface is shown in Fig. 14(A). The analysis of the etch pits is given by Wakeman.[26] To corroborate these results, an X-ray transmission pattern was made with the beam normal to the surface of the tape. The tape was 1 mil thick. The cubic structure of the material would predict the fourfold symmetry shown in the transmission pattern. But the pattern, Fig. 14(B), also shows eightfold symmetry. Thus the *100* axis of the crystal may just as well be at 45 degrees with respect to the rolling direction and in the rolling plane. This am-

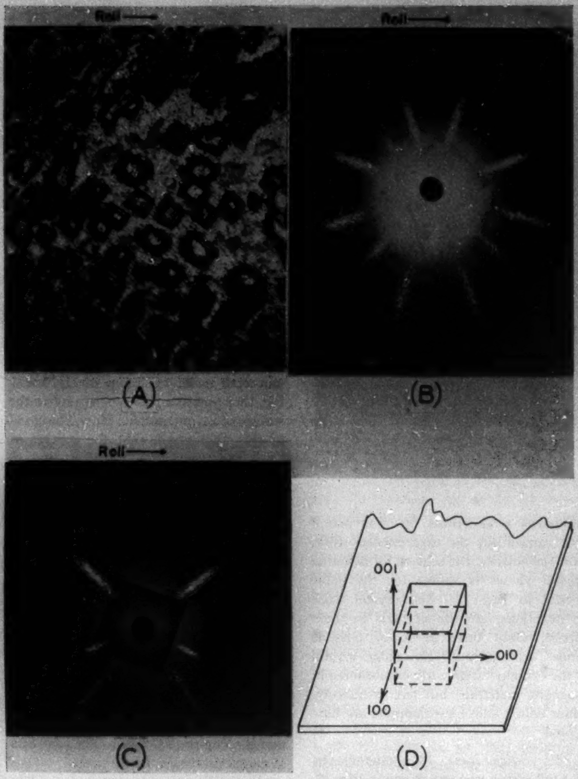

Fig. 14. Photomicrographs and orientation of 50–50 Ni-Fe tape

A—Etch pits ×500. B—X-ray transmission pattern, beam perpendicular to tape surface. C—X-ray transmission pattern, beam 45° to tape surface. D—Orientation of cubic crystal with respect to tape

biguity is removed by tilting the beam 45 degrees with respect to the surface. The resulting twofold symmetry Fig. 14(C), indicates that the *100* axis is indeed parallel to the direction of rolling. The orientation of the cube with respect to the tape surface is shown in Fig. 14(B). If the sample had been a single crystal, the X-ray pattern would have been a series of regularly spaced spots instead of the diffuse spokes shown. This indicates that the crystal sizes are small enough so that a large number lie, within the 1-millimeter X-ray beam used. If, for example, it is assumed that the crystallites are about 1/100 the diameter of the X-ray beam, or 10 microns, the tape is two to three crystallites thick. Also, as in indication of relative sizes, the dimension 10 microns corresponds to about 30,000 atomic layers. The angular spread of the spokes in Fig. 14(B) indicates that the orientation is such that most of the crystallites lie within 3 degrees.

A commercial grade of 50-50 nickel-iron alloy less oriented than Orthonol and its equivalents is also available. The material is marketed under the trade name of 48 Alloy, for example, by Magnetics, Inc., and this is also available from a number of other manufacturers, as are the other alloys discussed. No photomicrographs or X-ray patterns are presently available on this material. It is likely, however, that the same melt is used by a given manufacturer for both this grade of material and the highly oriented grade corresponding to Orthonol. It is probable that tests during the processing determine whether the material will be one or the other, and the processing is then completed accordingly. It is believed that in the 48 Alloy strip, there are some regions with fairly large grains and some regions of finely divided crystallites of fairly high orientation. These regions are probably a fraction of an inch in size, and are of varying shape.

Magnetization in Polycrystalline Tape-Wound Cores

DOMAIN WALLS IN POLYCRYSTALLINE TAPES

We have dealt extensively with the magnetizing process in single crystals even through we do not expect to find them in commercial-grade core materials. It is possible in this manner to discuss the important first-order mechanisms and develop and understanding of the magnetization process without having to complicate the description unnecessarily. Having done that, our task is then to modify the descriptions to take into account the polycrystalline nature of the materials and the fact that the toroid is fabricated by winding a tape spirally, and is not a solid cylindrical section. We shall first describe the effect of polycrystalline structure on domain nucleation, wall motion, and rotation in the magnetic tape. Then we shall describe a model of flux reversal in tape-wound cores. Finally we shall illustrate the model by experiment.

Powder patterns have been made which show the domain walls at the surfaces of polycrystalline materials with fairly large grains. The patterns show that if the grains are sufficiently well oriented, the walls are continuous through the grain boundaries.[11] The situation is aproximately as sketched in Fig. 15. The wall is not straight and therefore is longer and contains more energy than it would in a single crystal. Further, its length continually changes as it moves. Because of the anisotropy energy, the domain walls tend to follow the directions of easy magnetization within the grains. If there were no anisotropy energy required, the domain walls would pass through neighboring crystallites in a straight line without regard for changes in crystal orientation. The shape of the toroidal core, however, helps to keep the flux aligned with the wrapping direction of the tape. If the flux vector were at an angle to the wrapping direction, large magnetostatic fields about the core would be present,

196

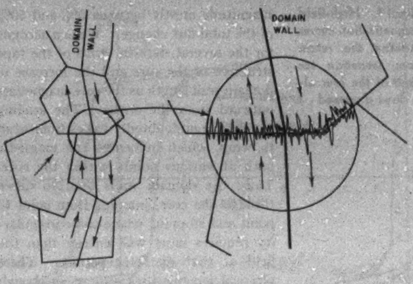

Fig. 15. Continuous domain wall in granular material. Enlarged section shows reverse domains along grain boundaries

requiring a large amount of energy. This gives rise to an effective "shape" anisotropy in the toroidal core.

Breaking the wall at the grain boundary would require that free poles be formed or that complicated closure domains be formed. When the grains are nearly oriented, continuous domain walls require much less energy than is required when the grains have a true random orientation. Thus, the cores with a grain-oriented structure would be expected to resemble closely the single crystal. The grains shown in Fig. 15 are partly oriented.

Note in Fig. 15 that there are a large number of irregular domains of reverse magnetization that cling to the grain boundary. These will persist, changing somewhat in detail, while the domain wall moves through the material. They will be largely but not completely removed with the application of larger field. Some of these domains remain when the material is "completely" saturated, and become nuclei of flux reversal when the field is reversed. Goodenough[28] has extensively treated the subject of nucleating centers and the energy of flux reversal in polycrystalline materials.

In the highly oriented materials such as Orthonol, the crystallites are small and the domain wall passing continuously through large regions is nearly straight. Both from the nature of their crystal structure and measured core properties, it would seem that these materials can be treated as single crystals for most practical purposes. In materials with moderate grain size, as pointed out in the foregoing, it is usually energetically favorable for the domain walls to be continuous over fairly long ranges. When the grains become less oriented, there is a tendency for the long range domain walls to break up into shorter sections. As a result, there is a corresponding tendency for closure domains to form near grain boundaries in order to reduce the number of free poles formed. The resulting domain structure is very complicated. Certainly, there are many more domains of reverse magnetization remaining when the material reaches saturation.

Domain Rotation in Polycrystalline Tapes

When each miniature grain is fully saturated by the application of a field, the direction of its magnetization lies very close to its neighbors and very close to the direction of rolling along the tape. Thus when the domain walls have been moved out of the material, the flux density in the circumferential direction is very nearly as large as can be produced by that volume of material, and is only slightly increased by domain rotation. The contribution of domain rotation to the circumferential flux density may be explained most easily in terms of a partially oriented material. Fig. 16 shows a strip of material of this kind: (A) shows the domain wall moving from left to right in the material, and (B) shows the complete magnetization of each grain, where the magnetization vectors are not closely aligned. The application of larger fields rotates the vectors of magnetization with respect to the crystal axes of the grains, as shown in (C). Larger fields are required because of the anisotropy energy implied in the process of domain rotation. This portion of the magnetization curve is mostly reversible, since the magnetization vectors return to their easy directions when the field is removed. The maximum flux density obtained when all of the magnetization vectors are aligned is called the saturation induction. That remaining when the field is removed is called the residual or remanent induction. The ratio of the two is clearly a measure of the degree of crystal orientation in the direction of rolling.

Domain Nucleation and Flux Reversal in Toroids

The domain nucleation process in polycrystalline tape-wound cores is somewhat different from that found in single crystals. A qualitative explanation, however, follows quite logically from a knowledge of the crystal structure and method of fabrication. As mentioned previously, the exact manner in which the domain walls move in a tape-wound core is not known. It is known, however, that the cores have magnetic characteristics very similar to those found in single crystals. Thus, it is reasonable to suppose that the co-operative phenomena characteristic of the single crystal are also characteristic of the tape-wound core, and that the magnetization by domains proceeds in a similar manner. It is expected that the flux reversal proceeds from the inner diameter outward, and that there may be important magnetic coupling between adjacent layers of tape through the interlaminar space.

Experimentally, it is found that the flux in a tape-wound core does not change discontinuously upon exceeding the starting field, as indicated for the single crystal in Fig. 5. In that example, the flux reversal was attributed to the establishment of a single cylindrical domain wall that propagated outward into the toroid. Even if the cylindrical shape is not a correct assumption, domain walls in the form of some similar surface or surfaces would yield the same general results. But in the tape-wound core, the material is polycrystalline, and the inner surface of the core contains a tape end, and some air gap, which require modification of the reasoning used for the single crystal.

The flux reversal process in polycrystalline tape, discussed in the previous section, leaves some domains of reverse magnetization distributed through the tape at grain boundaries, impurities, and imperfections. These small residual domains act as centers of reverse mag-

C—State of magnetization after individual domains have been rotated into alignment

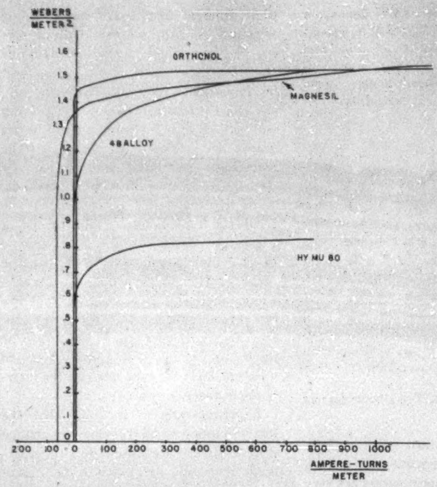

Fig. 17. High-field magnetization curves showing the return from saturation for each of the four alloys discussed

netization when the field is reversed. The type and purity of the alloy determine their distribution.[28,31] The small and isolated regions of reverse magnetization grow independently, resulting in a large amount of domain wall energy for the small amount of flux change. After a certain amount of domain growth, the areas of reverse magnetization begin to overlap. As domain walls begin to combine and shorten it is found that a rather large change in flux can take place without further increase in domain-wall energy. There usually occurs at this point a sudden change in flux with no change in field as the domain walls consolidate and approach some simple surface. The exact shape that the walls take in a tape-wound core is not known.

Thus, the process of nucleating domains of reverse magnetization results in small changes in flux with increasing field as energy is added in the form of domain walls about the nucleating centers. This results in a rounded "knee" on the hysteresis loop prior to the first large discontinuity in the flux. The knee itself is made up of a large number of very small discontinuities.

The amount of field required to reach the point of large discontinuous flux reversals depends upon the number of nucleating centers remaining in the tape after the saturating current has been removed. In Fig. 15, for example, the number of small reverse domains that are present depends upon the magnitude of the saturating field applied before the field is again reversed. The number and size of these domains both reduce with increasing field, and are removed almost entirely for values of field 3 to 10 times the coercive force, depending upon the material. As the field is reduced, rotation of the magnetization vectors back to the easy directions within the grains may leave free magnetic poles at the grain boundaries and precipitates. The total magnetic energy in some cases may be reduced by the formation of the small reverse domains shown in Fig. 15, which tend to alter favorably the distribution of free poles. The distribution of these reverse domains depends upon the material, of course, and the number that are removed at the peak value of the saturating field.

From the above reasoning, it is expected that the field required to nucleate flux reversals at the inner surface of a tape-wound core depends upon the degree of prior saturation of the core. This will be demonstrated by experiment. The amount of flux change corresponding to the process of establishing and expanding domain walls is about 3% of the total flux in a typical Orthonol core. It is somewhat larger in the other alloys.

When the field has reached the value necessary to combine domain walls and produce large discontinuities in flux, the domain walls spread from the inner portion to the outer portion of the core. As mentioned previously, the exact manner of domain-wall growth is not presently known. But the flux reversal takes place in large discontinuous steps, ranging in magnitude mostly between 5% and 50% of the total flux change. We can account for the several steps in terms of the tape structure of the core and the increase in domain-wall length as the core magnetizes outward from the center. The spacing of the tape undoubtedly varies from wrap to wrap, which influences the magnetic path at various points within the core. Thus, the domain walls tend to move through the core, jumping from point to point and stopping where some irregularity requires more wall energy than the field at that diameter permits. These physical irregularities appear as though they were large-scale Barkhausen discontinuities.

EXPERIMENTS

The fundamental character of flux reversal in polycrystalline core materials can be verified experimentally by means of some fairly simple experiments. Some of these are described below with comments that should help the experimenter to reproduce the results for himself. First, we shall show that the measured properties of magnetic tapes described earlier are those that we would expect from their crystalline makeup. Secondly, we shall examine the nucleation and propagation of domain walls in commercial-grade toroids. Finally, an experiment is described in which it is shown that the magnetization of a core proceeds from the inner diameter of the core outward.

Confirmation of the degree of orientation of the various tapes can be obtained by examining the amount of flux that results by reversible domain rotation. For this purpose, some hysteresis loops of the four materials described earlier are shown in Fig. 17. The scale chosen is such that the open portion of the hysteresis loop appears very small. The loops are taken by means of the familiar current-switching method, using the fluxmeter, or overdamped ballistic galvanometer. In all of the ballistic measurements to follow, a Leeds Northrop Type *HS No. 2285 f* reflecting galvanometer was used. This or its equivalent is recommended for its high sensitivity and long period. The fluxmeter made from this galvanometer has a reasonably slow return, making it a good integrator for flux measurements.[29] More refined experiments have recently been made using an integrator and some amplifiers in a Reeves analog computer with an Electronics Research Associates plotting table.

The difference in grain orientation of the chemically similar 48 Alloy and Orthonol is shown by comparing their respective curves in Fig. 17. In Orthonol

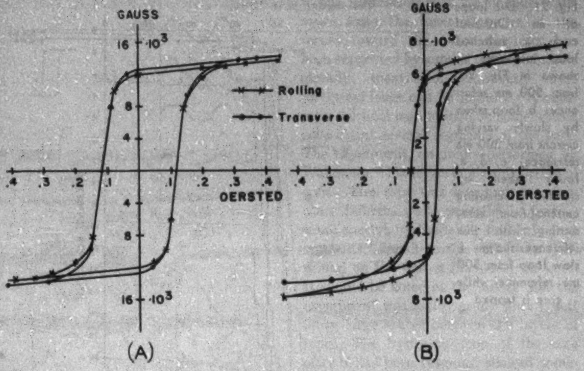

Fig. 18. D-c loops in rolling and transverse directions. A—Orthonol. B—Hy-Mu 80

it is seen that the remanent flux density is approximately 95% of the maximum, while in the 48 Alloy it is about 85%. The flux change in the "saturated region" is due to domain rotation. In the silicon-iron, the domain rotation is not complete until about 1,500 ampere turns per meter have been applied. In 48 Alloy about 800 ampere turns per meter are required. These large fields are a measure of the anisotropy energy required to rotate the domains. For HyMu-80, the rotation is complete with the application of about 150 ampere turns per meter. The comparison between the values of field required for rotation show that the anisotropy energy for the 80-20 nickel-iron alloy is much smaller than that for the other alloys, as expected from the figures in Table I.

Further confirmation of the degree and direction of orientation of the various tapes can be obtained by comparing toroidal cores made from tape cut parallel to the direction of rolling with cores made from tape cut perpendicular to the direction of rolling. The oriented 50-50 nickel-iron, for example, has its crystallites oriented with one cube edge parallel to the direction of rolling, and another perpendicular to the direction of rolling, but in the rolling plane, as shown in Fig. 14. Since the direction along the cube edge is the easy direction of magnetization, the material should magnetize with equal ease along the tape and across the tape. Thus, the two specially prepared cores should show substantially the same magnetic properties. Experiments have been performed by Wakeman[25] on cores of this kind, and confirm the results expected. The special cores were made of 5 wraps of 1-inch tape, 2 mils thick, wound on a 0.312-inch-diameter bobbin. Measurements of the finished cores indicate a stacking factor of only 0.2, which means that only 20% of the volume occupied by the core is actually tape cross section. Thus, there is room for large differences in the fabrication of the cores, and confirmation of theory can be expected only to within the uniformity achieved.

Measurements made on the two special Orthonol cores, shown in Fig. 18(A), confirm our expectations. The difference in height of the loop can easily be accounted for by a difference in effective core area of the two samples.

In HyMu-80 the crystals are randomly oriented. Thus it would be expected that the hysteresis loops measured in the rolling or transverse directions would be the same. The loops measured are shown in Fig. 18(B). Again, the difference in effective areas of the two cores may account for the different heights of the loops. The shapes of the two loops are somewhat different, but this may be accounted for by the different distribution of air gaps wound into the two cores, especially since the cores were made from only five wraps of tape. Note that the hysteresis loops of Figs. 18(A) and (B) show only that the measurements in the rolling and transverse directions are the same. Their similarity does not support the explanation of why they are the same.

In 3-97 silicon-iron, X-ray patterns show that the orientation is not complete. The orientation that exists, however, is expected to be as shown in Fig. 12. Measurements are expected to show two things. First, the percentage of flux reversal that takes place in low fields before domain rotation begins should be lower than that shown by Williams[30] for single crystals. Secondly, the orientation perpendicular to the rolling direction in the rolling plane should be in the *110* direction, and the field required to produce maximum flux density in the cross direction should compare with that required in the rolling direction in the same manner as shown by Williams. The curves obtained for the tape specimens are shown in Fig. 19 with the curves for single crystals. The expectations are therefore borne out by experiment.

Probably the most convincing evidence of magnetization by domain-wall motion is found when measuring d-c hysteresis loops with a reflecting galvanometer connected as a fluxmeter. The standard operating procedure with the fluxmeter, as with the underdamped ballistic galvanometer, is to establish a reference field, well into the saturated region, and then to switch over to a preset value of magnetic intensity on the other side of the loop. The galvanometer deflection then indicates the integral of the voltage induced in a coil on the core, or the flux increment from the reference point. Fig. 20 shows the experiment schematically. The outer loop in Fig. 21 shows the hysteresis loop obtained in this manner for a typical Orthonol core. The core is a Magnetics, Inc., *50039-1A* core made of 1-mil Orthonol, with an inner diameter of 1.25 inches and an outer diameter of 1.50 inches, and an effective cross-sectional area of 0.160 square cm (centimeters) according to published catalog data. It is observed during the course of the experiment that for points along the steep sides of the loop, the total galvanometer deflection proceeds rather sporadically and

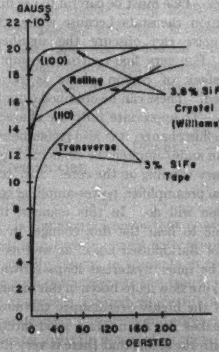

Fig. 19. D-c loops of 3% silicon-iron in rolling and transverse directions compared with loops from single crystals reported by Williams

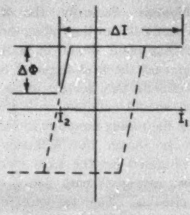

Fig. 20. Schematic representation of flux-current measurements

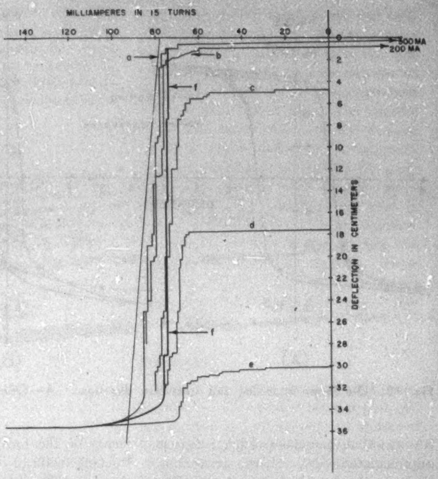

Fig. 21. D-c loops of an Orthonol core: a. switched loop measured as shown in Fig. 20, from 500 ma reference; b. loop taken by slowly varying current from 200 ma reference; c, d, e, loops taken by slowly increasing current from zero, starting with flux references shown; f. slow loop from 500 ma reference while core is tapped

may take a second or more to come to a stop. Then during the next few seconds, the deflection may increase in short jumps accumulating as much as 10% additional deflection. It is also found that when the experiment is repeated several times for a given value of exciting current, the indicated flux deviates from 10 to 25%, and occasionally as much as 50%, from the mean of a series of measurements. The experiment, in other words, is not repeatable. Thus, the steep portion of the d-c loop is not a single distinct curve, but is actually a diffuse region whose density indicates the probability of finding the value of flux for the given value of current.

It is very plain from this experiment, that the flux change takes place by means of domain-wall motion as described earlier. But the demonstration is even more convincing if one measures slow, continuous-current hysteresis loops. That is, instead of switching the exciting current to a preset value, as described in Fig. 20, the exciting current may be brought up from zero by slowly adjusting a sequence of rheostats in series with the battery. One must be careful to use high-resolution rheostats because sliding-contact noise can obscure the significant data. For very fine control, a compression stack of carbon plates is recommended. These can be obtained commercially. To appreciate fully the character of the flux change, it is also recommended that an audio amplifier be connected to an auxiliary winding on the core. Any commercial preamplifier, power-amplifier combination will do. In this manner, it is possible to hear the flux change, in the form of Barkhausen noise, as well as see it. The inner hysteresis loops shown in Fig. 21 are slow loops taken in this manner. Use of the highly overdamped galvanometer makes the fluxmeter a good integrator, with the result that there is very little return of the reflecting coil during the course of the slow measurements. The loops shown were recorded in 1 to 2 minutes. During the latter part of each loop, a drift of approximately 1 cm was accumulated, and has been corrected in the loops shown. Use of the electronic computer removes the drift problem.

For all of the loops shown in Fig. 21, the magnetic intensity is cycled between plus and minus 7 times the coercive force. The actual value used was 75 ampere turns per meter. These points become reference levels, from which all measurements are made. In each case, the core is left at the negative reference point, minus 75 AT/m, and the magnetic intensity is raised to varying positive values, saturating the core to different degrees. Following this, the magnetic intensity is reduced to zero and increased in the negative direction, thus measuring the starting field corresponding to the different levels of prior saturation. The negative halves of the loops are shown in Fig. 21. For part *a*, the saturating magnetic intensity is the positive reference value, or 7 times the coercive force. For *b*, the saturating magnetic intensity is 30 AT/m, or about 3 times the coercive force. For *c*, *d*, and *e*, the flux is not permitted to return all the way to positive saturation, but is arrested by means of the current controls. The values of saturating magnetic intensity for these three loops are only slightly different. Thus the starting fields are seen to be almost equal for these three conditions. For the conditions represented by *a* and *b*, however, the inner portion of the core is subjected to magnetic intensities of about 7 and 3 times the positive magnetic intensities represented by *c*, *d*, and *e*. The consequent increase in starting field is evident from the curves.

Once the magnetization has started to change in large steps, it takes very little to move the domain wall through the material. An interesting loop for the same core is shown in Fig. 21*f*. This loop differs from the loop of *a* in that the core was continually tapped with the eraser end of a pencil while the flux change was in progress. The effect can be described as follows: During the flux reversal, the domain walls proceed outward until they encounter some geometrical irregularity. The flux reversal continues if the current is increased, as shown in the other loops. But it is also possible to dislodge the domain walls from these irregularities, without increasing the current, by tapping the core. In many cases, this brings about further large spontaneous jumps in the flux. The loop shown in Fig. 21*f* is one in which tapping the core produced a loop with very straight sides. The large discontinuities shown are actually accumulated in several shorter steps. The discontinuities shown could have been made longer by tapping the core harder.

It might at first be puzzling to note that negative saturation is approached with different values of magnetic intensity in these several loops. This fact, however, gives us good confirmation that the magnetization takes place from the inner surface of the core outward. In each case, reading from *a* to *e*, saturation is approached by the motion of domain walls closer to the inner diameter of the core. It is expected, therefore, that the corresponding magnetic intensities would be decreased for this sequence of loops.

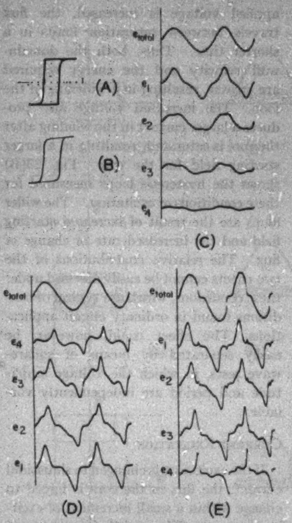

Fig. 22. 400-cycle hysteresis loop on Orthonol core: (A) Before and (B) after search coils were wound on core segments. (C, D, E) waveforms on induced voltage on cores segments for 50%, 100%, and overexcitation. Segments are numbered 1–4 from inside to outside

As explained in connection with Fig. 9, the magnetomotive force corresponding to saturation must be above the value required for domain nucleation because of the increase of domain-wall length in the outer portion of the core. In Fig. 21 a line of this slope is shown, and is seen to correspond approximately to the slope of the measured loop. The nature of the experimental flux reversal, however, indicates that the actual coercive force of a single crystal would be considerably below that of the tape-wound core. Thus the shape of the loop in detail is primarily determined by the difficulty with which the domain walls move through the tape structure. The most convincing evidence of this fact is the loop f of Fig. 21, in which the core was tapped. Since the core properties do not change drastically from the inner to the outer diameter, however, it is expected that the increase in magnetomotive force between the starting value and the saturation value would correspond closely to the increase predicted from the simple calculation indicated in Fig. 9.

The contention that the domain walls move from the inner diameter of the toroid toward the outer diameter has been supported by some of the experiments already mentioned. However, more direct evidence can be found by rewinding a toroidal core to include some search coils about several segments of the core. The experiment, originally performed by Wakeman,[25] made use of a 1-mil Orthonol core. The tape was rewound onto another bobbin, while periodically placing small spacers to divide the core into four segments. Small search coils were then wound on the four segments of the core. It should be noted at the outset that the experiment was rather crude since it left fairly large spaces between the layers of tape. The hysteresis loop of the core after it had been rewound showed somewhat less squareness. However, there was every reason to believe that the core would still magnetize from the inner diameter outward.

The core was excited with a 60-cycle sinusoidal voltage. The voltage induced in the four search coils were then recorded in a multiple-exposure photograph. Photographs were made for the core at full excitation, and about half excitation. The results of the experiment are shown in Fig. 22. In Fig. 22(A), hysteresis loop of the same size but unaltered core is shown. Fig. 22(B) shows the hysteresis loop of the core rewound with spacers and search coils in place. Fig. 22(D) shows the voltages induced in the four segments of the core compared to the total induced voltage with enough excitation to saturate the core fully. Fig. 22(C) shows the same voltages with about half excitation. In Fig. 22(C) and Fig. 22(D), it is obvious that the flux reversal proceeds from the inner segment of the core outward. In Fig. 22(D), where the core is only partially excited, the flux changes are fairly well limited to the inner segments of the core.

If the domain wall in the core were a simple cylinder, as imagined for the single crystal, the induced voltage in three of the search coils would always be zero, while in the fourth, the induced voltage would be equal to the total applied voltage. This induced voltage would switch from coil to coil with much more well-defined switching times than those shown. The photographs, therefore, indicate that the simple construct is not valid for the tape-wound core. But it must be recalled that some fairly large spaces have been left in the core, and these spaces probably contain some reverse domains when the core is saturated. Thus, we would expect the overlapping of induced voltages on the search coils, but it is not known whether the effect would be as large as that measured. A somewhat more refined experiment should provide at least a partial answer to this question.

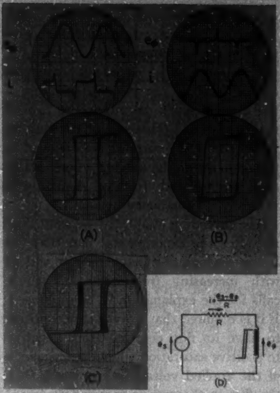

Fig. 23. Hysteresis loops of core under varying conditions of excitation

A—Sinusoidal voltage
B—Sinusoidal current
C—Increasing overexcitation with sinusoidal voltage
D—Circuit connections

An interesting result of this experiment is shown by the small peaks of induced voltage in the search coils at the end of each half-cycle, seen in Fig. 22(E). These are irreversible flux changes that occur only at the end of the half-cycle when the core saturates and the magnetomotive force becomes large. Note that they do not appear in Fig. 22(D) where the core does not saturate. If these voltage pulses were due to domain rotation, there would follow each positive pulse a negative pulse of approximately equal magnitude.

Hysteresis Loops at Power Frequencies

Width of the Loop

It is commonly known that power loss in an iron core increases with frequency. As usually taught to students in connection with power circuits and transformers, the theory is limited to justifying the dependence of hysteresis and eddy-current losses on a certain power of frequency, and graphical methods for separating out the components. Thus, most engineers are imbued with the notion that there is something inherent in the frequency that affects the power loss in a magnetic core. However, magnetization in these cores takes place by domain-wall motion and domain rotation, which are not homogeneous processes. The velocity and area of the domain walls determine the rate of magnetization. Throughout the flux reversal, the eddy currents are confined to the region near the moving domain walls, and are related to the domain-wall velocity, not frequency.

The preceding qualitative account does not alter the experimental fact that the hysteresis loop of a magnetic core widens with increasing frequency. It merely calls for the explanation to be rephrased. If it is required that a given core continue to have its flux changed from negative to positive saturation while the frequency of the applied voltage is increased, then the flux in the core is required to travel between the saturation limits in a shorter time. This requires that the applied voltage be increased proportionately. The domain-wall velocity must increase, resulting in higher eddy-currents and consequently higher power loss in the core.

Suppose that an experiment to show the widening of the loop were to be carried out by increasing the frequency by a factor of 2. The loop in the test core would widen as expected because the domain walls would have to travel twice as fast. The number of volts per turn on the winding would also double, thus requiring twice the applied voltage. If, for comparison, we take a core of the same tape width and the same inner diameter, but with only half the radial build-up, in order to have just half the cross-sectional area, the same applied voltage at the higher frequency would move the domain walls at the same velocity as before, and would still saturate the core at the end of the half-cycle because of the smaller cross-sectional area of the core. Since the velocity of the domain walls is unchanged, the loop has the same width as the larger test core at the lower frequency, but the loop is only half as high if total flux is measured. It is assumed that the ID/OD ratio is large in both cases. Thus, for a given wall velocity, the power loss per unit volume is the same, regardless of frequency. It is seen from this argument that the dependence of loop width on frequency of excitation is the result of core geometry and magnitude of applied voltage. Frequency itself is not directly significant.

VOLTAGE EXCITATION

The shape of the hysteresis loop usually depends upon the combination of several effects. These effects may be qualitatively explained in terms of the model that we have developed. The difference between the hysteresis loops obtained with sinusoidal voltage and sinusoidal current excitation is shown in Fig. 23. Sinusoidal voltage excitation is obtained by making the product of the circuit resistance and the exciting current very small compared to the voltage applied. The sinusoidal current condition is obtained by choosing a winding and series resistance so that the induced voltage in the reactor is small compared to the product of the exciting current and the circuit resistance.

In the case of sinusoidal voltage excitation, the rate of change of flux is prescribed and the current that flows is a measure of the velocity of the domain walls and thus the energy required to reverse the flux at the prescribed rate. The relatively slow establishment of domains of reverse magnetization in the core results in the rise of exciting current to values somewhat in excess of the static starting fields shown in Fig. 21. Subsequent rapid change of flux in the core generates a voltage e_φ that opposes the supply voltage e_s as shown in Fig. 23(D). The current that flows equals the difference between the two voltages divided by the circuit resistance. The result is a dynamic hysteresis loop that is somewhat wider and more rectangular than the d-c loop.

With a sinusoidal voltage applied, very nearly the full half-cycle is available for the flux to travel between its saturated extremes, as shown by Fig. 23(A). If the applied voltage is increased, the flux travels between saturation limits in a shorter time. Thus, both the domain-wall velocity and the energy required are greater, resulting in a widening of the loop. The increased voltage also produces a larger current in the winding after the core is saturated, resulting in a larger starting field for the core. Fig. 23(B) shows the hysteresis loops measured for these conditions of excitation. The wider loops are the result of increased starting field and the increased rate of change of flux. The relative contributions of the two effects cannot be easily assessed under these conditions, which are typical of conditions found in ordinary circuit applications. The effect could, however, be easily separated by means of square-wave tests, in which the voltage amplitude and period are independently variable.

CURRENT EXCITATION

If the excitation is changed to sinusoidal current, the flux in the core is forced to change within a small increment of exciting current. The small increment of exciting current corresponds to a short interval of time. As expected, therefore, the hysteresis loop is somewhat wider than it is for sinusoidal voltage excitation. This is illustrated experimentally in Fig. 23(C).

MINOR LOOPS

Probably the most interesting and to many the most puzzling property of rectangular-loop materials is the fact that minor loops do not "cluster" about the origin, the way they do in lower grade materials. Sets of minor loops for Orthonol, 48 Alloy, HyMu-80, and Magnesil are shown in Fig. 24. The loops cluster about positive saturation in all of these pictures except for Magnesil, the 3% to 97% silicon-iron alloy, which shows no visible sign of a symmetry. The loops may also cluster about negative saturation, of course, if the proper initial conditions are satisfied. Generally in an experiment of this kind, there is no way of knowing at which end the minor loops will be grouped. The excitation voltage used to obtain Fig. 24 is coupled through a transformer, and consequently there is no d-c component present.

The observed clustering of minor loops at one or the other saturation limits can be explained in terms of a set of curves such as those shown in Fig. 21. It is assumed that as higher degrees of saturation are reached, measuring from negative saturation, higher starting fields and therefore exciting currents are required.

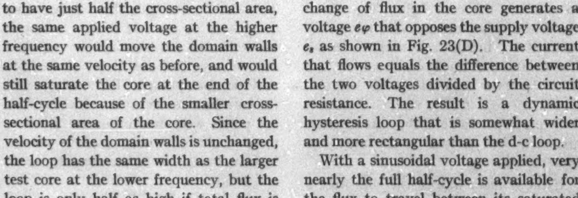

Fig. 24. Clusters of, minor loops of: A—Orthonol. B—HyMu-80. C—48 Alloy. D—Magnesil

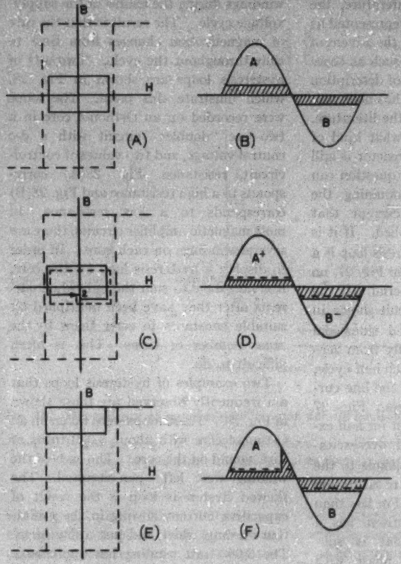

Fig. 25. Mechanism by which minor loops migrate toward saturation

The reasoning behind this assumption is still open to question. Until recently it was believed that the widening of the loop is due to the increased nucleating field with approach to saturation. Observed minor loops under dynamic conditions support this point of view, but it is now believed that the correct explanation is much more complicated. In any event, measurements show that the loop widens with the approach to saturation.

We shall assume that a sinusoidal voltage is applied to a reactor in series with a resistor, as shown in Fig. 23(D). It is assumed that the resistance is small enough so that most of the applied voltage appears across the reactor. The voltage equation for the circuit is

$$e_s = iR + e_\phi \tag{1}$$

It also follows that equation 1 can be integrated over 1 cycle of the supply voltage without destroying the equality.

$$\int_0^T e_s dt = \int_0^T iR dt + \int_0^T e_\phi dt \tag{2}$$

If it is assumed that a symmetrical minor loop exists and is centered about the origin, as shown in Fig. 25(A), the integral of each term in equation 2 is zero separately. The flux in the core and the exciting current are periodic with the period of the supply voltage. The third term in equation 2 represents the increment in flux linkages in the core during the period.

$$\Delta N\phi = \int_0^T e_\phi dt \tag{3}$$

In Fig. 25(B) the terms of equation 2 are shown graphically for one cycle of the supply voltage. The shaded area is the integral of the voltage dropped across the resistor. The steady-state requirement that the flux be periodic means that the unshaded areas *A* and *B* must be equal, since they are numerically proportional to the positive and negative flux increments.

If it is assumed, in contrast, that the hysteresis loop is displaced upward from the origin, with no change in applied voltage, the conditions of symmetry are no longer found. Because of the displacement, the negative exciting current is larger in magnitude than the positive exciting current. Thus, the resistive voltage drop for positive flux increments is smaller than it is for negative flux increments, increasing the area *A* and decreasing the area *B*. This results in a larger positive flux increment than negative flux increment on each succeeding half-cycle. A diagram of such a loop is shown in Fig. 25(C), with the corresponding voltage and current waveforms shown in Fig. 25(D). From equation 2, the net increment of flux linkages in each cycle is given by the relation

$$\Delta N\phi = \int_0^T e_\phi dt = -\int_0^T iR dt \tag{4}$$

The circuit reaches the steady state once more when the net increment of flux during a cycle is zero, or when the integral of the exciting current is zero. But as the transient proceeds, the current during the positive half-cycle decreases and the current during the negative half-cycle increases. Thus the equilibrium condition can be reached only when the core saturates, Fig. 25(E) and Fig. 25(F), thereby adding the necessary positive contribution to the current integral. The waveforms of the Fig. 25(F) show that the areas *A* and *B* are equal once more.

Two equilibrium states have been described, one centered about the origin, Fig. 25(A), and the other at positive saturation, Fig. 25(E). A third equilibrium state exists at negative saturation. When the loop is in the equilibrium state centered about the origin, a displacement in either direction causes the loop gradually to move toward positive or negative saturation. Thus, it is expected that the equilibrium state centered about

the origin is unstable, and the other two are stable. Ordinary experiments indicate that this is true. However, with some care it is possible to establish symmetrical loops and maintain them for some time. In the large majority of cases, the symmetrical loops persist for only fractions of a minute, and frequently for only a few seconds. On one occasion, however, a small symmetrical loop has been maintained for over an hour in an Orthonol core. Usually, switching transients on the power line are enough to upset the balance. It does appear, however, that there is a small range of stability for the symmetrical loops.

Fig. 26(A) shows a set of these symmetrical loops for an Orthonol core. Fig. 26(B) shows the usual asymmetrical group for the same core. Fig. 27(C) shows a small symmetrical loop in the core immediately after it was established, and a few seconds later after it had migrated toward positive saturation. The vertical displacement of the loop does not come through the electronic integrator, but must be put in to correspond to the saturation flux in Fig. 26(A). It is commonly found from experimenting with cores of this kind that it takes from 1 to 10 seconds, and sometimes longer, for the symmetrical loop to travel to one saturation limit or the other. This indicates that the flux increment per cycle is extremely small, which indicates a very small circuit resistance or a very slight widening of the loop with displacement, or both.

Circuit Aspects

The applications of tape-wound cores are many and varied and are rapidly increasing in number. It would not be possible to show in extensive detail those properties of circuits that relate directly to the magnetic phenomena discussed in the preceding paragraphs. There are, however, a few simple experiments that serve to illustrate some of the common circuit manifestations.

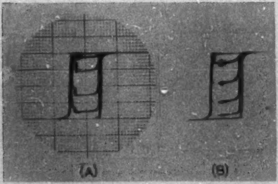

Fig. 28. Hysteresis loops on an Orthonol core in a "doubler" magnetic amplifier with

A—High control-circuit resistance
B—Low control-circuit resistance

In much of the early literature, the saturable core reactor was represented as a variable reactance. With the advent of rectangular-loop materials, such as those we are discussing, this type of description became less successful, and has now vanished almost entirely from the literature. However, the question of what kind of element the saturable-core reactor is still arises upon occasion. This question can be easily answered by examining the hysteresis loop and the current that flows when a voltage is applied. If it is first assumed that the hysteresis loop is a perfect rectangle, as shown in Fig. 27, no energy is stored in the material. If the reactor is placed in the circuit shown in Fig. 23(D) and the applied sinusoidal voltage is increased gradually from zero until the core saturates on each half-cycle, the amplitude and phase of the line current vary over wide ranges. Fig. 27 shows the voltage and current for half excitation, full excitation, and overexcitation. Full excitation corresponds to the maximum flux excursion before saturation occurs on both half-cycles. For less than full excitation, the line current has a fundamental component that is substantially constant, and in phase with the applied voltage. From the standpoint of energy, therefore, the reactor is purely dissipative and generates harmonics in the line current. As the voltage increases, the apparent resistance increases since the fundamental component of line current remains unchanged. For overexcitation, shown in Fig. 27(D), a large component of line current appears that is nearly 90 degrees lagging the line voltage. Thus we have a nonlinear circuit component that draws a lagging current from the line but stores no energy. As the voltage is increased further, the angle of the fundamental component of current again approaches zero. It should be obvious from this experiment that representation of the saturable-core reactor as a variable linear reactance is not possible. From our earlier discussion, we recognize that there is some energy stored in the material in the form of domain walls and domain rotation. Thus the hysteresis loop of Fig. 27(C) is not accurate. But the general circuit behavior of the reactor is not affected by this correction.

It should be apparent from our discussion in the foregoing sections that the hysteresis loop traced for a given core depends upon the manner of excitation. In magnetic-amplifier circuits, for example, a saturable-core reactor is subjected to sinusoidal voltages of different amplitudes and d-c voltages, switched simultaneously or singly onto the various windings during the course of the supply-voltage cycle. The result is that the rate of magnetization changes from time to time throughout the cycle. Two sets of hysteresis loops are shown in Fig. 28, which illustrate this point. The loops were recorded on an Orthonol core in a two-core "doubler" circuit with a d-c control voltage, and two values of control-circuit resistance. Fig. 28(A) corresponds to a high resistance and Fig. 28(B) corresponds to a low resistance. In most magnetic-amplifier circuits, there are several windings on each core. In order to display a hysteresis loop for the core, it is necessary to sum the individual currents after they have been multiplied by suitable constants to refer them to the same number of turns. This is often difficult to do.

Two examples of hysteresis loops that are frequently observed are those shown in Fig. 29. These loops were taken on an Orthonol core with about 3,000 turns of wire wound on the core. The ends of the winding were left open-circuited. The skewed hysteresis loop is the result of capacitive current flowing in the excitation winding, which had just a few turns. The 3,000-turn winding has appreciable interwinding capacity and acts as a capacitively loaded secondary on the core. To confirm this argument, the loop was duplicated by removing the 3,000-turn

winding and placing about 100 turns on the core in its place, with an ordinary capacitor connected to its terminals. The wiggles on the sides of the loop are the result of a 1% eleventh harmonic distortion in the 400-cycle generator. The harmonic has been exaggerated by the winding capacity. When the 400-cycle line was filtered, the loop of Fig. 29(A) resulted. Fig. 29(C) shows the effect of a large number of turns on the output current of a simple magnetic amplifier. A self-oscillation, or "ringing," in the load current is present because of the large winding capacity.

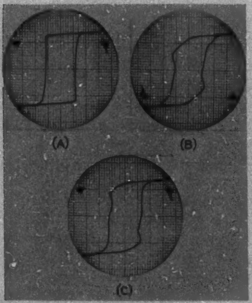

Fig. 31. Hysteresis loops on an uncased Orthonol core

A—Normal
B—Stress applied by squeezing between the fingers
C—With loose wraps introduced about one third of the way radially into the core, measuring from the inner diameter

The phenomena shown in Fig. 29 are not due to the magnetic properties of the core. They are mentioned here because capacitive effects may otherwise be wrongly attributed to the magnetic properties of the core.

Probably the most important effect of "second order" core properties on observed circuit behavior is the instability found in many of the high-gain magnetic amplifiers. As an example, Fig. 30 shows the instability obtained in a half-wave amplifier and the shape of the hysteresis loop for the corresponding core. The core material is Orthonol. The instability is due to the nature of the minor loops discussed in the previous section. In Fig. 30(A), the loop is seen to be very nearly rectangular, and the exciting current for the minor loops is markedly dependent upon the prior approach to saturation. The analysis of the circuit, which includes this property of the dynamic hysteresis loop, predicts a wide range of instability in the static control characteristic. The measured characteristic is shown in Fig. 30(C) and confirms the prediction. When the hysteresis loop is less rectangular, the degree of instability is reduced, according to the analysis. The measured hysteresis loop and corresponding control characteristic are shown in Figs. 30(B) and (C). The experimental conditions are identical in all respects except for the shape of the hysteresis loop. In fact, the cores themselves are identical. The hysteresis loop is altered by placing a small screw clamp across the thickness of the core. Tightening the clamp squeezes the layers of tape together so as to change the hysteresis loop from that shown in (A) to that shown in (B).

The effects of stressing a core are most dramatically illustrated by Orthonol, which is the most stress-sensitive material of those discussed. An annealed core of 4-mil Orthonol without protective case has the hysteresis loop shown in Fig. 31(A) at 60 cycles. This is the expected loop. By squeezing the core into an oval shape, the loop of Fig. 31(B) results. Releasing the stress returns the loop to its former shape. The stress involved in this experiment is much larger than that applied in Fig. 30(B).

If the inner and outer portions of the core are then rotated with respect to each other to increase the tape spacing at a point within the core, the loop in Fig. 32 results. It is difficult to do this without stressing the core as well. But the kink in the side of the loop definitely shows the point at which the exciting current increases in order to magnetize the core beyond the diameter at which the loosened turns occur. With a little care it is possible to return the core to a condition that again yields approximately the hysteresis loop of Fig. 31(A).

Many recent contributions to the literature discuss the properties of magnetic cores in circuits. These contributions discuss the core properties from many different points of view, and give convincing evidence that a knowledge of magnetic materials is important to engineers responsible for circuit design.[32–36]

High-Speed Magnetization

High-speed flux reversal in magnetic materials is a subject of great current interest and research.[4–6,37–40] Nonmetallic ferrites and thin alloy films seem to be of greatest interest at the present time. Our discussion, however, is limited to tape-wound cores.

At high speeds, we still speak of mag-

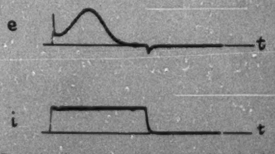

Fig. 32. Typical current and induced voltage waveforms on Magnetics, Inc., No./80004-B bobbin core with 20 wraps of 1/8-mil HyMu-80 tape

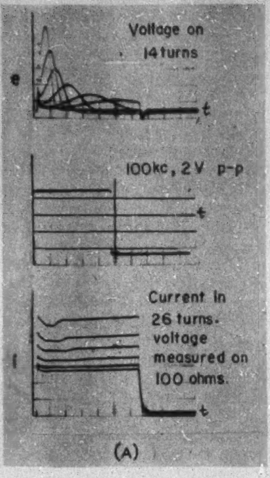

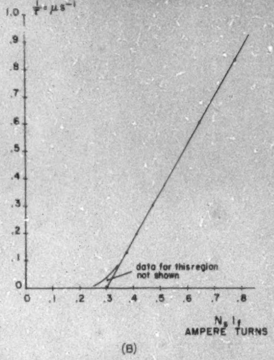

Fig. 33. A—Induced voltages on bobbin core of Fig. 32 with variation of current-pulse amplitude; B—Curve of inverse switching time versus magnetomotive force taken from photographs in A

netization by domain-wall motion and domain rotation. However, the dynamics of domain walls, ignored heretofore, must be explained in terms of the propagation of spin waves, which are expressed in terms of complicated quantum mechanical language. The viscosity of domain walls implies that large fields are required to reverse the flux in a short interval of time. Also, the bobbin cores used for high-speed switching have a small radial build-up and low space factor. Thus, it is probably correct to think of domains being created on all the surfaces of the tape throughout the core rather than at the inside diameter alone. These new factors may be used to modify the model of low-speed flux reversal to obtain a fairly satisfactory explanation of the observed magnetic properties under high-speed conditions.

REVERSALS BY DOMAIN-WALL MOTION

When a tape-wound bobbin core is excited with a rectangular current pulse the induced voltage on a test winding has the form shown in Fig. 32. The tape is 1/8-mil-thick HyMu-80. Two features of the voltage pulse must be explained. The first is the initial sharp peak, and the second is the longer duration pulse with a maximum somewhere near the middle. The current opinion seems to be the following.[37–40] The sharp peak in the voltage waveform is the result of fast but elastic domain-wall motion, which is completely reversible. The remainder is the result of domain walls expanding about their nucleating centers and combining with one another, with the maximum rate of domain-wall annihilation occurring at the voltage peak near the middle of the pulse. Increasing the current pulse has the effect of accelerating the entire process.

The initial sharp peak in the voltage waveform is supposed to be the result of reversible domain-wall motion against elastic forces. Experimentally, this is verified by applying a pulse of short duration corresponding to this portion of the voltage wave. Presumably, this does not allow sufficient time for the irreversible growth of domain walls. When the short current pulse is removed after about 0.1 microsecond, a voltage pulse of the opposite polarity is induced and area equal in magnitude to the positive pulse. Thus the reversibility of the process is established. But from calculations of domain-wall energy, Newhouse[38] argues that the range of reversible domain-wall motion is much shorter than necessary to account for the large reversible voltage pulse in question. In fact, measurements have shown that this reversible flux change can be made as large as from 20 to 50% of the total irreversible flux change. Thus other contributory mechanisms are indicated. The problem has not been solved as yet, but one obvious reversible contributor could be domain rotation. Whether or not this contribution would be sufficient to account for the additional flux change that takes place in this short period is questionable.

The explanation of the second maximum in the voltage pulse is that the regions of reverse magnetization expand about their nuclei until they begin to overlap. Overlapping of domains results in domain-wall annihilation and subsequent rapid changes in flux. This model of domain growth is the same as that used to explain the behavior of slow hysteresis loops, shown in Fig. 21. The time required for the domain growth differs, of course, but the qualitative similarity is apparent. One major difference in the mechanism is related to the high applied field and the low stacking factor of the bobbin core. The large fields applied for high-speed switching are from 10 to 50 times the coercive force of the material. Thus, the field is more than adequate to reverse the flux anywhere in the core. The concept of the domain walls sweeping outward radially after nucleating at the inner surface is no longer tenable. It is more likely that reverse domains grow about nucleating centers over the entire tape surface, spreading over the surface and penetrating into the tape.[39]

The time required for switching the magnetization in a core from one saturation limit to the other depends upon the field applied. Fig. 33(A) shows a series of rectangular current pulses and the corresponding induced voltages. As the current pulses increase in amplitude, the time required for switching reduces. The pulse amplitude in magnetic intensity is customarily plotted against the corresponding inverse switching time. Such a curve, taken from the data in Fig. 33(A), is shown in Fig. 33(B). The slope of the curve is often taken as the figure of merit for the particular core. It would be expected from our understanding of domain-wall motion that when current pulses just large enough to switch the core are applied, the switching time would vary. It is not surprising to find, then, that the lower part of the curve in Fig. 33 (B) is not repeatable, but defines a diffuse region.

It is not possible to give a complete account of high-speed switching in magnetic materials without including alloy films and ferrites. The present discussion however, is limited to tape-wound cores. Further information on films and ferrites may be found in the list of references.

Discussion

W. C. Bullock (Westinghouse Electric Corporation, Baltimore, Md.): Dr. Barker is to be commended for an excellent discussion of factors affecting the performance of tape-wound magnetic cores. Many years' experience with high-performance tape-wound cores, both in magnetic-amplifier design and manufacturing and in tape-wound core application engineering, have convinced me that the characteristics of cores so clearly presented by Dr. Barker, if more widely understood by device designers, would resolve many of the engineering problems associated with the use of high-performance tape-wound cores.

In the section entitled "Circuit Aspects," Dr. Barker discusses very briefly an instability frequently encountered in high-gain magnetic amplifiers which results from "core triggering." The reasons for core triggering are clearly explained as an instability of minor loops when located at other than saturation following phenomenological treatments of Batdorf and Johnson[1] and Finzi and Critchlow (see reference 36 of the paper). Unfortunately, Dr. Barker leaves one with the impression that the cure for core triggering is the choice of a less rectangular loop material or stressing the core to reduce squareness.

The choice of a less rectangular loop, for example, replacing Orthonol with 48 Alloy, will not completely eliminate core triggering and anyone who intentionally permanently stresses a high-performance tape-wound core may experience many other difficulties because the stressing of the core cannot be controlled.

The solution offered by Lynn, et al.,[2] is to increase the gating volt-seconds applied to the core so that the core can never operate on a minor loop. When push-pull circuits are used, it is frequently possible to balance the amplifier so that core triggering occurs in a region of the control characteristic which is less critical for the application intended.

A second point which should be clarified is the stressing of a core by first squeezing it into an oval shape and then releasing. Frequently, during the core anneal, if the insulating coating on the tape is not perfect, turns of the core may weld and the cooling of the core may result in stress. Squeezing the core, provided the elastic limit of the metal is not exceeded, will frequently break these welds and result in a more nearly square flux-current loop and lower losses.

Harold W. Lord (General Electric Research Laboratory, Schenectady, N. Y.): Although Dr. Barker does not definitely describe just how the domain walls travel from the inner diameter to the outer diameter of a toroid, one gets the impression that it may be by means of a domain boundary moving substantially lengthwise of the tape. This discussion is submitted to show that such a concept is not a valid one.

It is interesting to compare the average velocity of a domain wall that would be required by such an interpretation of the propagation within a tape-wound core with direct experiments on unwound tapes.[1] While the dimensions of this particular core are not given, if they are similar to those of other cores Dr. Barker employed, the total tape length is approximately 10 meters. Since the experiment was made at 400 cycles, the average velocity inferred from this interpretation is about 8×10^3 meters/sec. The velocity (V) of domain wall propagation is found to be of the form: $V = A(H - H_o)$, where H is the applied field, H_o is a sticking field that is very nearly equal to the d-c coercive force, and A is a characteristic mobility constant. Since, for 0.001-inch Orthonol, the excess of H over

H_o at $B = 0$ is less than 0.2 for a 400-cycle sine-flux excitation, and since the maximum dB/dt is average $dB/dt \times \pi/2$, the mobility given by this interpretation is greater than 60×10^3 meters/sec-oersted.

The fact that the maximum velocity inferred by a propagation interpretation of the experiment cited by Dr. Barker is 30 times that observed on an unambiguous experiment seems to indicate that one should view with some reserve any conclusion that propagation takes place lengthwise along the tape in a wound core.

It is also interesting to consider how such an interpretation would affect the measured properties of toroidal cores. Suppose we have one core which has twice the number of wraps as another core of identical core material, mean turn diameter, strip width and thickness. Then, if the magnetization proceeds by propagation along the strip length, the velocity in the larger area of core for a given excitation frequency will be twice that for the smaller core. With the same mobility for both cores, the value of $H - H_0$ observed for the larger core will be double that for the smaller core. Again, suppose the two cores are identical in all respects except that one has twice the mean diameter of the other one. Again, the value of $H - H_0$ observed for the larger core would be double that for the smaller one if magnetization proceeded in this manner.

Since observed changes in magnetization characteristics of tape-wound cores do not follow the pattern described above, it seems clear that the reversal of magnetization in tape-wound cores does not take place by the motion of a domain wall along the length of the tape.

Alternative explanations of the experimental results cited by Dr. Barker include the simplest one that for a given current the field is greater on the inside than on the outside of the core. Secondly, the process of rewinding the core on another bobbin, with spacers between four segments of the core to accept pickup coils, introduced strains as indicated by the change in hysteresis loop shapes shown by Figs. 22(A) and (B) of the paper. If such strains were greater on the outer turns than on the inner turns, the coercive force of the outside turns would be higher than that of the inner turns. Such a strain distribution could produce the observed results shown by other portions of Fig. 22.

I wish to acknowledge the assistance of Dr. C. P. Bean, of the General Electric Research Laboratory, in the preparation of this discussion.

R. C. Barker: The discussions of Mr. Bullock and Mr. Lord are most welcome. Mr. Bullock's first comment discusses the phenomenon of amplifier triggering as it is related to core triggering, in which a minor loop of a certain height may migrate from one end of the major loop to the other. My comments on this well-known experimental fact were directed primarily toward the core behavior. The little experiment that I presented makes use of a very rudimentary circuit so as not to confuse circuit problems with core problems. The use of stress applied to the core was intended as evidence that this is indeed a core problem, and was in no way meant as a suggested remedy. I will confess, however, that the application of stress has been discussed as a potentially useful technique, but has not been developed further to my knowledge.

As Mr. Bullock points out, amplifiers having a tendency to trigger as a result of migrating hysteresis loops can often be stabilized by making the applied voltage large enough to insure that each core reaches positive saturation on its gating half-cycle. It also happens at times that certain amplifiers using these cores show some triggering while the cores themselves do not. In such cases, the causes of triggering are a bit elusive, but often they are traceable to other core properties in conjunction with particular circuit connections. Little literature on these problems is available because engineers have a natural aversion toward lengthy discussions of circuits that do not work. I am happy to read Mr. Bullock's second comment on the stressing of cores to break welds, a phenomenon which I failed to include in my discussion.

In this paper, I have purposely avoided detailed descriptions of the magnetization process, which accounts for the inference that Mr. Lord has drawn regarding the structure of domain walls in tape cores. Since the same question has been raised by others, the best reply is probably a slight enlargement on the concepts behind the notion that the flux reversal sweeps from the inner diameter of the core outward. The fundamental reason behind the assertion is that, because of the geometry of core, the inner portion is always subjected to a field higher than the outer portion, as argued in the text discussing Fig. 9. Secondly there is the unmistakable experimental fact that even at 400 cycles the flux in the inner portion of the core reverses on a time schedule that is clearly ahead of that for the outer portion of the core. Several sophisticated experiments have been designed to confirm this fact.

The experiment associated with the data of Fig. 22 was a very crude one performed several years ago and reported here largely because it is a fairly obvious experiment to perform on a single core, and can be repeated by almost anyone who wishes to invest an afternoon's time.

The fact that the schedule of flux reversal of the inner portion of the core is ahead of the schedule for the outer portion means that at any time in the proceedings one can describe the inner portion of the core as having substantially reversed and the outer portion as not yet significantly reversed. Between these two regions is what is called a *transition region*, roughly cylindrical in cross section and with a diameter that increases with time. The purpose of recent research at this laboratory has been to perform experiments relevant to this concept in order to develop the details of the structure of the transition region, its mode of motion, and their dependence upon the rate of flux reversal. The fairly obvious experimental facts that Mr. Lord cites contribute to the description of the transition region; they do not refute its existence. The notion that the transition region is a simple wall across the tape and moving lengthwise along the tape is, of course, naïve. Even the notion that the transition region is a complex domain-wall structure essentially fixed in shape but moving at a velocity dependent upon the applied filed is untenable. It would predict quite different results for experiments similar to that of Fig. 22, and would also lead to the kind of results, cited by Mr. Lord, that are not experimentally observed. It would also result in a widening of the 400-cycle loop that would be seven times as large as that of the 60-cycle loop, a fact that is found to be incorrect by reference to any commercial core catalog.

These experimental facts have been evaluated in terms of the Sixtus-Tonks equation, cited by Mr. Lord, which has been shown to be valid experimentally in the stretched wires of Sixtus and Tonks,[1] Dijkstra and Snoek,[2] and the stretched tapes of Cole discussed in the very brief letter referenced by Mr. Lord. But the quantitative and even the qualitative results of the Sixtus-Tonks experiment cannot be obtained unless the specimen is under tension.[2] As Mr. Lord points out in his last paragraph, tension in this type of material increases its coercive force. When the tension is removed, it is expected from the experiments on wires that the entire tape will reverse more or less uniformly, and that no such linear velocity will be measured. But from either electrical or magnetic considerations, the speed of the flux reversal surely depends upon the applied field. The functional relationship between this speed and the applied field is indicative of the actual domain wall area active in the reversal.[3]

The results of many experiments of the sort recently published[4] at slow flux reversals, and other to be published soon have developed the concept of the transition region as consisting of domain nucleation and growth about nucleation sites, domain-wall annihilation, and co-ordinated domain-wall growth taking part in proportions that depend upon the speed of reversal and the applied field. It is clear experimentally that at increasing reversal speed the field increases, but not in proportion to the speed. But long continuous walls that sweep out a given volume of material in a unit of time do so with much less active wall area than wall growth about a number of nucleating sites in the same volume. Thus, it is inferred that at the higher speeds the reversal is less the result of long walls moving with higher velocity, and increasingly the result of domain growth about a fairly dense distribution of nucleating sites, probably at the tape surfaces. The increased field leads naturally to the conclusion that the transition region spreads out through the core as the speed of reversal increases. A transition-region velocity along the length of the tape can be defined which is a sort of phase velocity resulting from the growth and subsequent annihilation of walls about nucleating sites, giving the appearance of a highly complicated domain-wall structure of continually changing shape, moving outward through the core, or lengthwise along the tape. The degree of domain-wall correlation brought about by magnetostatic fields between wraps is not known, and most of the other microscopic details of this picture have not been directly confirmed experimentally. But all of the microscopic experiments performed to date support this view.

I wish to acknowledge the excellent experimental work performed during the past two years by Richard M. Brownell in the pursuit of a Doctorate degree at Yale University. These experiments have made signal contributions to the state of knowledge in this field.

Pigmented Polyester Magnet Wire for High-Temperature Operation

F. A. SATTLER
NONMEMBER AIEE

L. C. SCALA
NONMEMBER AIEE

Synopsis: This work was done to develop a conductor insulation with good space factor and winding properties, capable of operating at 1,000 degrees Fahrenheit (538 degrees centigrade). A flexible, clean-burning polyester resin was used as a binder for a glass frit and a refractory in a wire enamel composition. The polyester resin contributes sufficient flexibility to the enamel to wind it into equipment. After completion of the winding operation, the organic portion of the magnet wires is burned out and the glass frit is fused to bind the refractory. The resulting insulation is not a continuous film, and air breakdown values are obtained.

POLYESTER resins based on isophthalic and terephthalic acids were investigated as binders since they burn clean without leaving a carbon residue and can be formulated to high flexibility for maximum pigment loading. A low functionality phthalic acid isomer polyester resin gave the best physical properties.

This resin, dissolved in a 1-to-1 cresol-xylene mixture, was ball-milled for 48 hours with the glass-frit refractory pigment. With the use of this resin the maximum pigment loading, with the proper retention of flexibility, was 50% pigment, 50% polyester resin solids.

Refractories

During the glass-fusing process, the refractory functions as a wire separator and partially dissolves into the glass to raise its fusion temperature. Among the many refractory materials investigated, silica (240 mesh) was selected as the best film former with the glass frit after the organic resin had been burned out and the glass fused.

Glass Frits

Since the glass frit must be fused after winding the wire into equipment, the glass had to be designed to have a fusion temperature which would not be injurious to the rest of the equipment. The glass frit must also retain sufficient insulation resistance and cut-through resistance at the operating temperature of the equipment. A minimum of glass frit which gave the proper binding action was required to eliminate cut-through during the glass-fusion operation. This was determined at 40% glass frit, 60% refractory. The first glass frit used was a 200-mesh lead borate glass with a 475 C (degrees centigrade) sag point. A formulation containing 50% polyester resin, 30% silica, and 20% glass frit was coated on no. 16 silver wire at 22 feet per minute and baked at 460 C in a 15-foot tower by the conventional dip-coating method.

Paper 59-1295, recommended by the AIEE Electrical Insulation Committee and approved by the AIEE Technical Operations Department for presentation at the AIEE–National Electrical Manufacturers Association Second National Conference on Application of Electrical Insulation, Washington, D.C., December 8–10, 1959. Manuscript submitted September 14, 1959; made available for printing January 29, 1960.

F. A. SATTLER and L. C. SCALA are with the Westinghouse Electric Corporation Research Laboratories, Pittsburgh, Pa.

The barium-modified glass frit used in the formulation described was developed in the Westinghouse Research Laboratories by Dr. C. Hirayama. The cement for the coils illustrated in Fig. 1 was developed by Dr. P. A. Tierney. D. K. McIlvaine supervised the winding of the transformers illustrated in Figs. 3 and 4.

Table III. Insulation Resistance, Megohms*

Degrees, C	Conductor No. 16 Silver	 No. 14 Nickel-Plated Copper
500	110	110
550	26	22
600	2.7	2.7
Breakdown†	300	370

* Readings taken after 10 minutes at given temperatures; coils burned out at 700 C before measuring.
† At 540 C, volts.

Appearance: smooth, hard, brittle, good adhesion.
Electric strength: 500 volts, 480 volts (wire-to-wire breakdown, standard National Electrical Manufacturers Association twist made and burned out at 650 C).
Cut-through temperature: 460 C, 440 C (500-gram load on crossed wires, temperature rise 5 C per minute from 100 C).

The burnout procedure was as follows:

	Temperature, C	
1/2 hour	350 450	with air flow
15 minutes	550 650	without air flow

Insulation resistance of the burned-out enamel was measured on standard dielectric twisted pairs using a megohm bridge at 100 volts; see Table I.

For the proper cut-through temperature and insulation resistance at 540 C, a 575 C sag point barium-modified glass frit was developed in the laboratories. This glass was incorporated into a formulation containing 50% polyester resin, 30% silica, and 20% glass frit. Coated on no. 16 American Wire Gage silver and nickel-plated copper, this enamel had the properties which are shown in Table II.

The burnout procedure was as follows:

	Temperature, C	
1/2 hour	350 450	with air flow
15 minutes	550 650 700	without air flow

Further insulation resistance and breakdown measurements were obtained on this enameled wire with parallel-wound coils, six double turns on a 3/4-inch mandrel tied with glass cord to force contact between turns; see Fig. 1. The coils were potted in a cement developed in the laboratories; it consisted of a magnesium aluminum silicate refractory bonded by a lead borate glass. The results are shown in Table III.

Parallel-wound coils of various conductors coated with the enamel just described were aged at 540 C with periodic heat cycling and insulation resistance measurements; no appreciable decrease in insulation resistance was present after 1,100 hours at 540 C; see Table IV and Fig. 2. The insulation resistance of the enameled nickel-plated copper wires, which was practically constant throughout most of the test period, increased noticeably after the seven consecutive heat cycles from room temperature to 540 C. No explanation for this phenomenon can be offered at this time. Thermal aging and cycling did not appear to have an appreciable effect on breakdown voltages at 540 C.

Metal Additives for Improved Adhesion after Burnout

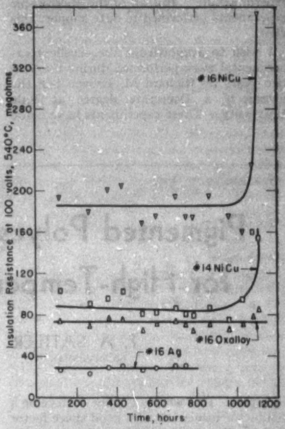

Fig. 2. Insulation resistance in megohms, 540 C versus aging time in hours at 54o C

Addition of soluble metal chelates to the enamel was studied in order to improve the vibration resistance of the residual inorganic coating after burnout. The best adhesion between the inorganic coating and the underlying conductor, particularly nickel-plated copper, was obtained when a mixture of cobalt and manganese was added to the formulation in a soluble form. The cobalt-manganese modified enameled wire gave the following properties on no. 16 nickel-plated copper wire:

Before burnout

- Build, mils, 3.2
- Quick snap, O.K.
- Three-*X* mandrel, O.K.
- Abrasion, 27, 33, 38.

After burnout

- Adhesion very good.
- Electric strength, R.T. (twisted pairs): 500 volts.
- Insulation resistance at 550 C (parallel-wound potted coil): 45 megohms.
- Electric strength at 550 C (parallel-wound potted coil): 360 volts.

Transformers were wound with the

Fig. 3. Unpotted power transformers wound with metal-modified pigmented polyester enameled wire

metal-modified pigmented polyester enameled wire at the Company's Lima Works; see Figs. 3 and 4. They passed preliminary tests at 600 F (degrees Fahrenheit) ambient after potting in an inorganic cement.

The tests consisted of potting and burning out three power transformers wound with no. 18 enameled nickel-plated copper wire in the primary and no. 14 nickel-plated copper in the secondary. These were operated at room temperature and full load to determine the current, voltage, and reactance. The temperature rise of the core was approximately 89 F. The units were then given a thermal shock test by cycling from −65 to 600 F while being energized so as to draw full load current of 50 amperes on the secondary. Five additional cycles from −65 to 690 F were given the unenergized transformers, then a final cycle from −65 to 600 F while energized. The units were then vibration tested, the conductor insulation still remaining unaltered electrically.

Fig. 4. Power transformer potted and cured at 700 C

Conclusions

A conductor insulation containing a cobalt-manganese modified flexible polyester binder pigmented with a barium-modified lead borate glass frit and a silica refractory has been developed. Transformers wound with this enameled wire and potted in an inorganic cement have shown satisfactory performance at 600 F ambient in preliminary tests.

Theory and Operation of a Cross-Field Magnetic Modulator

D. W. BOENSEL
NONMEMBER AIEE

Synopsis: The theory of operation and practical limitations of a toroidal cross-field magnetic modulator are discussed. Approximate relationships are derived for the amplitude of the fundamental component of output voltage, conversion power gain, and output impedance. Experiments on devices of this kind using two types of ferrite core material are described. The agreement between experimental results and analytical calculations is satisfactory enough to warrant the use of the derived relations in design procedures. Among other things, it has been shown that the conversion power gain is directly proportional to excitation frequency and the number of turns on the input winding, and is independent of the number of turns on the output winding. Experimental results indicate that equivalent offset currents and voltages of 1 μa (microampere) and 50 μv (microvolts) respectively, and power gains of from 20 to 30 db (decibels) can be readily obtained.

THE PROBLEM of converting low-level direct currents or direct voltages to equivalent a-c information is unquestionably one of the most widely discussed problems in the instrumentation field. Common modulation techniques use electronic, magnetic, and mechanical devices to accomplish the shift of information from $\omega=0$ to some nonzero portion of the frequency spectrum.

The common magnetic frequency shifter is the conventional second-harmonic modulator, a device which has been adequately discussed in the literature.[1–3] A different approach to the problem using another magnetic device has been suggested by Heartz and Bueltemann.[4] This new approach employs a ferromagnetic medium under the influence of perpendicularly superimposed magnetic fields. The principal advantage of such a scheme is the elimination of inductive coupling between the excitation and output, which, of course, results in a converter exhibiting extremely low zero offset.

The purpose of this report is to describe the results of an investigation pertaining to a cross-field device of this nature. The results appear to be encouraging in that such a device can be readily constructed to have no more zero offset than the conventional second-harmonic modulator and furthermore, to have appreciable conversion power gain.

Theory of Operation

Although there are many core forms which can conceivably be used to permit winding of coils which establish geometric-

A—Actual
B—Assumed

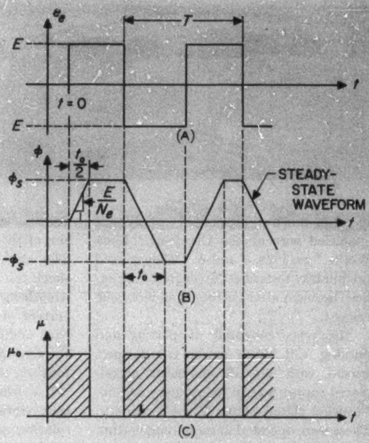

Fig. 3 (right). Waveforms pertinent to core cycling

ally orthogonal magnetic fields, the one chosen for this investigation consisted of a ferrite toroid having both annular and toroidal windings. Knowledge of the shape of the device is not particularly necessary for an explanation of its operation; however, since the experimental model took the abovementioned form, it will be expedient to explain the operation on that basis.

Preliminary Considerations

A sketch of the device is shown in Fig. 1. The core is made up of two ferrite toroids which are impact-ground to leave space for the annular winding. The surfaces of the toroids which are in intimate contact are lap-ground to reduce the air gap in the magnetic path surrounding the annular winding (henceforth referred to as the annular path). The cores are then placed securely together and toroidal windings are wound in the conventional manner.

Consider that the annular winding is used to supply a-c excitation to the core and that the core characteristic confronting this winding is similar to that shown in Fig. 2(A). The operation of the device is as follows.

Assume that the a-c excitation is sufficient to drive the core completely into saturation (points A and A' in Fig. 2(A). Since the magnetic field set up by the annular excitation is ideally parallel to the toroidal windings, the mutual inductance between annular and toroidal windings is zero and consequently, if no direct current is applied to the toroidal winding, no voltage is induced in the toroidal winding by the alternating annular current.

Based on its geometry, turns, and the core permeability, the toroidal winding has a certain inductance L_t, so that a voltage across it is of the form

$$e_t=\frac{d}{dt}(L_t i_t) \qquad (1)$$

where i_t is the current impressed on the winding by an external current source.

Each time the core is driven into and out of saturation, the darkened regions of the core characteristic in Fig. 2(A), the core permeability experiences a radical change with time. Since L_t is proportional to $\mu = d\mathbf{B}/dH$, for i_t equal to a constant current I, it is found that

$$\begin{aligned} e_t &= \frac{d}{dt}(L_t I) && (2)\\ &= IL_t'\left(\frac{d\mu}{dt}\right) \end{aligned}$$

where $L_t=\mu L_t'$. Equation 2 assumes that I is so small that it has negligible effect on the annular core characteristics, i.e., $\mu \neq f(I)$.

This cursory examination indicates the following points:

1. The magnitude of the output voltage is directly proportional to I.
2. This magnitude is proportional to the time rate of change of permeability and consequently to the excitation frequency (for a given excitation waveshape) and to the excitation amplitude (for a given frequency).
3. The fundamental frequency of the output voltage is twice that of the excitation since $d\mu/dt$ undergoes 2 cycles for every traversal of the core characteristic by the excitation.

Basic Relationships

The following discussion describes an approximate analysis which can be used to determine the output voltage, output impedance, and conversion power gain which can be expected from a given device.

Assume that the annular core characteristic has the piecewise linear form shown in Fig. 2(B), and that the excitation voltage is of the form shown in Fig. 3(A). The corresponding flux behavior shown in Fig. 3(B) follows, since, during the nonsaturated period

$$\phi=\frac{1}{N_e}\int e_e\,dt$$

and thus

$$t_0=\frac{2\phi_s N_e}{E} \qquad (3)$$

where t_0 is the time during which the core is out of saturation and N_e is the number of annular turns. The permeability time variation corresponding to this flux behavior is therefore as shown in Fig. 3(C).

Reference to equation 2 indicates that $d\mu/dt$ is the quantity which determines the alternating output of the cross-field modulator. Because of the nature of the approximation made for the **B-H** curve (the slope of **B** versus **H** is a discontinuous function), it follows that $d\mu/dt$ will always consist of an impulse train, regardless of the waveshape and amplitude of the excitation (as long as it periodically saturates the core). If the frequency spectrum of this impulse train is cal-

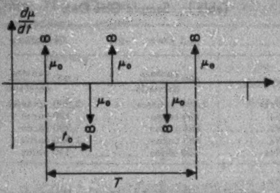

Fig. 4 (left). Impulse train in $d\mu/dt$

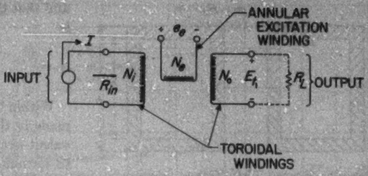

Fig. 5 (right). Circuit pertaining to calculation of conversion power gain

culated, and the magnitude of the fundamental component of the spectrum is determined, the result should give a reasonable approximation to the output from such a device using a square-loop core material. (Such an impulse train is, of course, impossible to obtain in practice. However, since a series approximation of the **B-H** curve would yield unwieldy results, the approximation given above was developed.) The impulse train of $d\mu/dt$ is shown in Fig. 4.

The coefficients in the $\mu(t)$ series are given by

$$c_k=\frac{4\mu_0t_0}{T}\left(\frac{\sin\left(2\pi k\frac{t_0}{T}\right)}{2\pi k\frac{t_0}{T}}\right) \tag{4}$$

Thus, in the $d\mu/dt$ series, the coefficients are given by

$$c_k'=\omega c_k=\frac{2\pi k}{T}c_k=\frac{8\mu_0}{T}\left[\sin\left(2\pi k\frac{t_0}{T}\right)\right] \tag{5}$$

and the amplitude of the fundamental component is

$$c_1'=\frac{8\mu_0}{T}\left[\sin\left(2\pi\frac{t_0}{T}\right)\right] \tag{6}$$

The fundamental output amplitude is, from equations 2 and 6,

$$|E_{t_1}|=\left|\frac{8\mu_0L_t'}{T}\left[\sin\left(2\pi\frac{t_0}{T}\right)\right]I\right| \tag{7}$$

The maximum value of this amplitude occurs when $t_0=T/4$ and is given by

$$|E_{t_1}'|_{\max}=\left[\frac{8\mu_0L_t'}{T}\right]|I| \tag{8}$$

For the purpose of obtaining an approximate expression for the conversion power gain of the device, it is expedient to investigate equation 7 more thoroughly. Toward this end equation 7 may be rewritten:

$$|E_t|_1=Z_{\text{eff}}|I| \tag{9}$$

where

$$Z_{\text{eff}}=|\omega_{t_1}L_{\text{eff}}|$$

$$\omega_{t_1}=\frac{2\pi}{\tau}=\frac{4\pi}{T}$$

=fundamental output frequency

$$\tau=\frac{T}{2}=\text{period of output voltage}$$

$$L_{\text{eff}}=\frac{2}{\pi}\left[\sin\left(2\pi\frac{t_0}{T}\right)\mu_0L_t'\right] \tag{10}$$

The implications of equation 9 may be interpreted by considering the circuit shown in Fig. 5. Since both input and output windings are toroidal, the flux introduced by I at the input is transferred undiminished to the output winding. In other words, the flux in the toroidal path is the same flux which would be initiated in the core if a current of $(N_t/N_0)I$ were made to flow in the output winding. (One toroidal winding excited with a control current could just as well be used, coupled to R_L through a coupling capacitor.) Thus, the amplitude of the fundamental component of output voltage (E_{t_1}) is

$$|E_{t_1}|=Z_{\text{eff}}\left|\frac{N_t}{N_o}I\right| \tag{11}$$

The effective output impedance of the device at the fundamental output frequency is

$$Z_o=Z_{\text{eff}} \tag{12}$$

so that the maximum power which can be supplied to a load, R_L, occurs when

$$R_L=Z_o=Z_{\text{eff}}=|\omega_{t_1}L_{\text{eff}}| \tag{13}$$

(This is for an untuned or purely resistive load.)

Under these conditions, the a-c load power is

$$P_o=\frac{|E_{t_1}|^2}{8\mathrm{R}_L}=\frac{Z_{\text{eff}}\left|\frac{N_t}{N_o}I\right|^2}{8} \tag{14}$$

and the input d-c power is $P_{\text{in}}=I^2R_{\text{in}}$ so that the conversion power gain of the device is

$$\mathrm{PG}_c=\frac{P_o}{P_{\text{in}}}=\frac{Z_{\text{eff}}}{8R_{\text{in}}}\left(\frac{N_t}{N_o}\right)^2$$
$$=\frac{\omega_{t_1}}{4\pi R_{\text{in}}}\left[\sin\left(2\pi\frac{t_0}{T}\right)\right]\mu_0L_t'\left(\frac{N_t}{N_o}\right)^2 \tag{15}$$

where PG_c=conversion power gain.

In the practical meter-kilogram-second system, L_t' is given by

$$L_t'=\frac{(4\pi\times10^{-7})N_o^2A_t}{l_t}$$

where A_t=cross-sectional area of the toroidal path in square meters, and l_t= mean toroidal path length in meters.

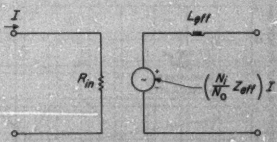
Equation 15 may now be written

$$\mathrm{PG}_c=\frac{\omega_{t_1}\mu_0A_tN_t^2\times10^{-7}\left[\sin\left(2\pi\frac{t_0}{T}\right)\right]}{l_TR_{\text{in}}} \tag{16}$$

(In this formulation μ_0=gausses/oersteds)

It is interesting to observe that in this analysis the conversion power gain is independent of the number of turns on the output winding. Obviously this does not imply that N_o may go to zero, for, if this were the case, the output voltage and consequently the load power would likewise become zero. It does indicate, however, that one may choose N_o to provide any desired output impedance level and not cause any deterioration in power gain. It is also worth while to note that although equation 16 states that the power gain is proportional to N_t^2, for a given wire size, R_{in} is also proportional to N_t, so that the power gain is actually proportional to N_t rather than N_t^2. If a fixed available winding area is assumed, however, the power gain is independent of N_t, as would be expected.

Based on the relations derived in equations 7 and 12, an equivalent circuit depicting the operation of the cross-field modulator can be developed. Such a circuit is shown in Fig. 6. It should be understood that the dependent generator



$$L_{eff}=\frac{(8\times10^{-7})N_o^2\mu_0A_t}{l_t}\left[\sin\left(2\pi\frac{t_0}{T}\right)\right]$$

$$Z_{eff}=\frac{(32\pi\times10^{-7})N_o^2A_t\mu_0}{Tl_t}\left[\sin\left(2\pi\frac{t_0}{T}\right)\right]$$

Fig. 6. Equivalent circuit for cross-field modulator

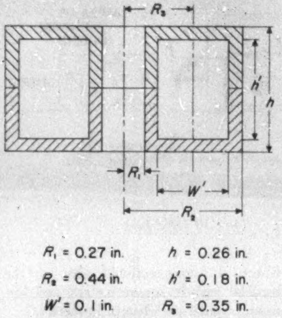


Fig. 7. Experimental core dimensions

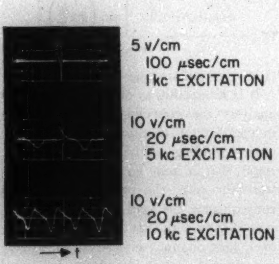

Fig. 8. Representative output waveforms

in this equivalent circuit supplies an alternating voltage having a fundamental component at twice the frequency of the excitation.

With this equivalent circuit, it is a simple matter to show that the open-circuit voltage gain A_v is

$$A_v = \frac{N_t}{N_o}\frac{Z_{eff}}{R_{in}}$$

$$= \frac{(32\pi\times 10^{-7})N_o N_t A_t \mu_0}{T l_t R_{in}}\left[\sin\left(2\pi\frac{t_0}{T}\right)\right] \tag{17}$$

and that the short-circuit current gain A_t is

$$A_t = \frac{N_t}{N_o} \tag{18}$$

Within the limits of the approximations made in the foregoing analysis, the equivalent circuit shown in Fig. 6 can be used to formulate all of the circuit properties necessary for the design of a toroidal cross-field modulator.

Experimental Results

As mentioned previously, the form of core configuration used in experiments is that shown in Fig. 1. Physical dimensions of the cores are given in Fig. 7. The following table lists the corresponding annular and toroidal winding magnetic cross sections and path lengths.

	Annular	Toroidal
Cross-section area, cm²	0.39	0.17
Mean path length, cm	1.8	5.7

Two types, type *S-1* and type *H*, of General Ceramics Corporation ferrite core material were employed in separate experiments. Pertinent core characteristics as well as winding data for the two samples are given in Table I. The values of μ_0 (not to be confused with initial permeability) indicated for these materials were found by extrapolating an average permeability from the measured core characteristics for excitation amplitudes approximating those used experimentally. These values do not correspond to those given by the manufacturer, probably because of the air gap which is present in the annular path. Unfortunately it was impossible to measure the air gap, so experimental **B-H** loops were necessarily employed in this calculation.

The experiments consisted in simply measuring the amplitude of the fundamental component of output voltage as a function of excitation frequency and input current. The load resistance necessary to reduce the amplitude of this voltage to one half its open-circuit value was also measured to obtain the output impedance as a function of frequency.

Table I. Sample Core Data

	S-1 Core	H Core
μ_0	800 $\frac{\text{gausses}}{\text{oersteds}}$	1,000 $\frac{\text{gausses}}{\text{oersteds}}$
B_{sat}	1,500 gausses	2,800 gausses
N_e	125 turns	100 turns
N_t	885 turns	1,500 turns
N_o	885 turns	1,500 turns
R_{in}	50 ohms	150 ohms

Representative output voltage waveforms under open-circuit conditions on the *S-1* core are shown in Fig. 8. The waveforms are shown for excitation frequencies of 1, 5, and 10 kc and an input current of 400 μa. It is interesting to observe that the output voltage at low frequencies is a reasonable facsimile of the impulse waveform predicted in Fig. 4. It should be noted, however, that as the frequency is increased, the lengths of the pulse generated when the core enters and leaves saturation become an appreciable portion of the total period of the output voltage. This is a result of a softening of the knee of the **B-H** curve at higher frequencies, as well as in increase in the pulse-stretching effect of distributed winding capacitance. At any rate, it is obvious that when this region of operation is reached, the analysis presented in the previous section can be expected to give only very approximate results.

The following paragraphs describe the comparison of experimental and analytical results on output voltage amplitude, output impedance, conversion power gain, and linearity.

OUTPUT VOLTAGE AMPLITUDE

The fundamental output voltage amplitude was measured with a Donner wave

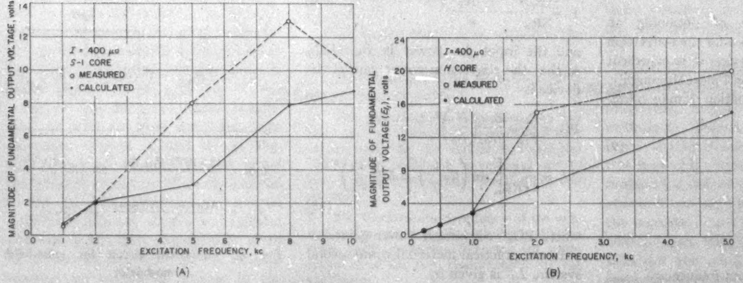

Fig. 9. Output amplitude versus excitation frequency

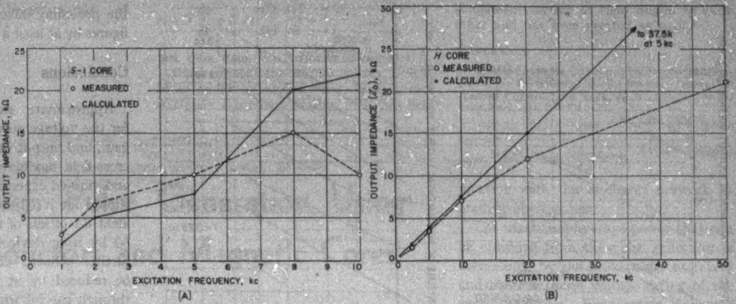
Fig. 10. Output impedance versus excitation frequency



analyzer. The results of these measurements, together with calculated values, are shown in Figs. 9(A) and 9(B). Some difficulty was encountered with the **H** core in that an extra unused toroidal winding caused the output to "ring." To damp out these oscillations, it was necessary to load the winding with a resistance approximately equal to its output impedance. Therefore, the measured voltage amplitudes were multiplied by a factor of 2, and 6 db was added to the measured conversion power figures to account for the loading on the winding.

In general, agreement of the results for frequencies below 2 kc is quite satisfactory. Even for frequencies up to 10 kc, the predicted values are off, in the worst situation, by only a factor of two. As predicted, there is a tendency for the output voltage to increase as a linear function of frequency. The reduction in this tendency at higher frequencies is obviously a result of the change in waveshape from an impulse train to a quasi-sinusoid which was observed in Fig. 8. To clarify this point, it should be observed that, whereas the amplitude of all components in an impulse train increases linearly with frequency, the amplitude in a pulse train made up of pulses having nonzero width is independent of the absolute magnitude of the fundamental frequency. Thus, as the output pulses stretch (relative to the total period) the tendency for a linear increase in amplitude with frequency diminishes.

It should be mentioned that the predicted curve in Fig. 9(A), as well as that in Fig. 10(A), is not a smooth straight line because of the variation of the term sin $2\pi t_0/T$ with frequency at constant excitation voltage amplitude. The experiments relating to Figs. 9(B) and 10(B) were performed with changes in excitation amplitude in order to maintain this term constant.

Output Impedance

The results of impedance measurements are shown in Figs. 10(A) and (B). For both types of core material, the output impedance is initially a linear function of frequency, as predicted. As the excitation frequency increases, the **B-H** loop becomes less square, so that relatively more time is spent in a region of low permeability resulting in a smaller average value of effective output inductance. This obviously results in a relationship which is somewhat less than a linear function of frequency. Over and above this is the effect of distributed capacitance, which likewise serves to reduce the output impedance below predicted values at high frequencies.

This tendency is evident in both sets of experimental data; nevertheless, the maximum error between calculated and measured impedance values occurs at a high frequency and yet amounts to a factor of only 1.8; see the results for the **H** core in Fig. 10(B) at 5 kc.

Conversion Power Gain

For most applications, one would not design a cross-field modulator to provide a specified amount of conversion power gain. Usually the quantities of interest would be the levels of output and input impedances and the voltage output per unit current input. It is generally of only academic interest that all of these quantities uniquely determine the maximum available power gain for an untuned load.

The results of these experiments and analytical calculations are shown in Fig. 11.

Although the agreement of the overall experimental and theoretical computations is somewhat less than highly satisfactory, it is nevertheless worth while to note that the low-frequency results are

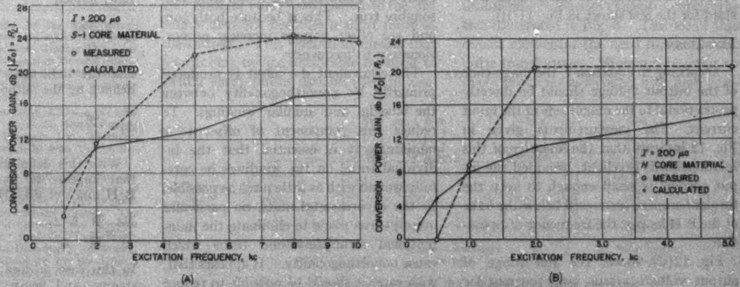


Fig. 11. Conversion power gain versus excitation frequency

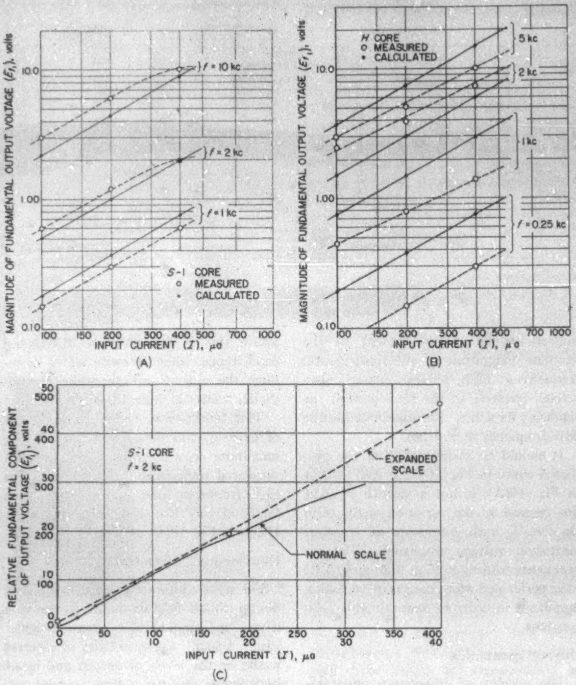

Fig. 12. Output voltage versus input current

A, B—Actual
C—Relative

usable for design procedures and those at the higher frequencies are adequate for approximate estimates.

The departure of the predicted curve of Fig. 11(A) from a smooth parabola is again caused by the variation of the sine term with frequency. As indicated previously, this term was maintained constant for the test shown in Fig. 11(B).

Linearity

According to equation 7, the magnitude of the output voltage should be directly proportional to the magnitude of the input current. The measurements given in Fig. 12 indicate that the linearity of this relationship is excellent, provided the input current is small enough to keep the toroidal ampere-turns well below the knee of the **B-H** loop at the frequency of operation.

Fig. 12(C) shows the full range of output voltage versus input current for the *S-1* core at 2 kc. The zero offset in this case is equivalent to approximately 1 μa at the input. Since the input resistance in this case is 50 ohms, the equivalent input voltage is 50 μv and the power is 5×10^{-11} watt. The expected result of equivalent input d-c offset remaining constant with frequency was found to be reasonably true. This is because both gain and a-c offset voltage increase proportionately to frequency.

The equivalent d-c offset is produced primarily by nonorthogonality between the toroidal and annular windings. To reduce this component of offset to a minimum, it is essential that the individual turns on the windings be carefully wound with as little pitch as possible. In the experimental units, no particular attempt was made to eliminate the unintentional scramble-wound turns which cause nonorthogonality. It appears that, with care, it should be possible to reduce the preceding offset voltage and current figures by at least a factor of ten.

Conclusions

Approximate analytical relationships for the voltage output, conversion power gain, and output impedance of a toroidal cross-field modulator have been derived and verified experimentally. The results show that it is possible to expect equivalent d-c offsets of the order of 1 μa and 50 μv from devices of this type. It is further believed that these figures can be reduced by at least a factor of ten through careful winding techniques.

From the standpoint of linearity, the device appears to have excellent possibilities as a d-c to a-c converter which can have power gains of the order of 20 to 30 db.

Discussion

F. J. Friedlaender (Purdue University, Lafayette, Ind.): The author presents an interesting analysis to explain the operation of a cross-field magnetic modulator. However, several questions arise with regard to some of the derivations and concepts on which the paper is based.

Equation 1 evidently expresses Faraday's Law, namely

$$e_t = \frac{d(N\phi)}{dt}$$

and the inductance L_t of equation 1 is defined by the author as

$$L_t = \frac{N\phi}{i_t}$$

With this definition, the permeability μ that appears in the expression of L_t is **B**/**H** and not $d\mathbf{B}/d\mathbf{H}$. In fact,

$$\frac{N\phi}{i_t} = \frac{\mathbf{B}}{\mathbf{H}} \frac{N^2 A_t}{l_t}$$

In this case, μ does not display a discontinuity, and hence the author's analysis and predictions no longer apply. (A differential permeability

$$\mu_{diff} = \frac{d\mathbf{B}}{d\mathbf{H}}$$

could be used; e.g.

$$e_t = N\frac{d\phi}{dt} = NA_t\frac{d\mathbf{B}}{d\mathbf{H}}\frac{d\mathbf{H}}{dt} = \frac{N^2A_t}{l_t}\mu_{diff}\frac{di}{dt}$$

but then equation 2 is not obtained.)

Furthermore, the author treats **B** and **H** as scalar quantities when, in fact, this is clearly a problem dealing with two field components acting at right angles to each other and has been treated as such.[1]

High-Power Pulse Generation Using Semiconductors and Magnetic Cores

Synopsis: A magnetic pulse generator using a controlled rectifier in the charging circuit is capable of generating high-power pulses and is suitable as a radar modulator. In the discharge network saturable inductors operate as high-power switching devices and, together with the capacitors, reduce the duration of the current pulse from a long duration at the charging circuit to a short duration at the output.

An experimental circuit demonstrates the theory. This circuit operates at a repetition rate of 5 kc and produces an average power output of 300 watts. The peak power and pulse width at the output are approximately 40 kw and 1.5 μsec (microseconds), respectively. The efficiency of the experimental circuit, not considering the bias circuit, is approximately 70%.

ADVANCES IN semiconductor devices have extended their use from the milliwatt power range to the kilowatt power range. This paper describes the application of one of the new semiconductor devices, the controlled rectifier, to radar power modulator circuits. The controlled rectifier switches power into a magnetic discharge circuit to accomplish this function. An example of the circuit configuration used is shown in Fig. 1. The circuit[1] is in some respects similar to previously developed circuits.[2,3]

The circuit operation can be explained as follows. Assume that saturable transformer P_1 is biased in negative saturation and a pulse from the trigger source turns the electronic switch on. In this manner the supply voltage E is applied as a step to the L-C (inductance capacitance)[2,3] network and the resulting voltage build-up across capacitor C_1 drives the flux in P_1 from negative to positive saturation. Saturable inductor P_1 saturates when the voltage on capacitor C_1 reaches a maximum. At this time the charging current is zero, the electronic switch opens, and capacitor C_1 discharges through the saturated inductance of P_1 to capacitor C_2. The voltage build-up on C_2 drives the flux in saturable inductor P_2, which was biased in negative saturation, from negative to positive saturation. When the voltage on capacitor C_2 reaches a maximum, saturable inductor P_2 saturates and C_2 discharges into the next section of the discharge network.

Each capacitor discharges more rapidly than it charges. In this way a relatively long pulse of energy switched into the discharge network becomes a short pulse at the output. This operation means that a switching device unsuitable by itself to switch short pulses can be used in conjunction with the discharge network to produce short pulses.

The maximum average power that can be obtained from the pulse generator is determined by the peak recurrent rating and the maximum voltage rating of the switching device. For example, if a power transistor such as the *2N-574* transistor is used, the maximum average power is approximately 50 watts. For applications such as radar modulators it is often desirable to have larger average power capabilities. The controlled rectifier offers a large increase in power handling capabilities of this type of pulse generator and this paper considers its use for such a purpose.

Circuit Configuration

Two general forms of the magnetic pulse generator exist: the shunt capacitor-series saturable inductor configuration, and the shunt saturable inductor-series capacitor configuration. An example of the shunt capacitor-series saturable inductor circuit is shown in Fig. 2. When the shunt saturable inductor-series capacitor circuit is used, the saturable inductor can be used as a combination switch and transformer. An example of this type of circuit is shown in Fig. 3.

A load, such as a magnetron in a radar application, requires a voltage in the order of several kilovolts. Thus, a pulse generator of the type shown in Fig. 2 requires a pulse transformer at the output to obtain the necessary step up in voltage. A more convenient and economic method of voltage step up is to use the shunt saturable inductor-series capacitor configuration illustrated in Fig. 3. The use of this circuit eliminates the need for an output pulse transformer. However, in order to avoid problems associated with high volt-

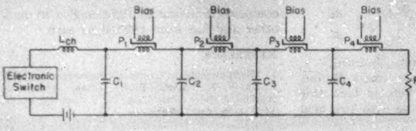

Fig. 2. Series saturable inductor circuit

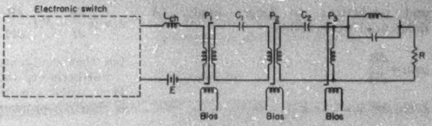

Fig. 3. Shunt saturable inductor circuit

age, it is desirable to locate most of the voltage step up in the last stage.

The best configuration as far as copper loss and load requirement are concerned is a combination of the two configurations. The shunt saturable inductor-series capacitor configuration is used in the last stage to eliminate the need for an external pulse transformer, the shunt capacitor-series saturable inductor configuration being used in the remaining stages to minimize the copper loss. A configuration of this type is used in the experimental model and is illustrated in Fig. 1.

ANALYSIS OF CIRCUIT

The charging circuit of Fig. 1 is redrawn for convenience in Fig. 4 with the first saturable inductor replaced by a switch in parallel with a constant current source. The two switches shown are assumed to operate periodically in the proper sequence as previously explained. The switch labeled S_e represents the electronic switch, and the switch labeled S_{p1} represents the first saturable inductor. The constant current source in parallel with switch S_{p1} represents the bias current, reflected in the terminals of saturable inductor P_1; magnetizing current is neglected.

It is convenient to separate the period of operation into two parts, the charging interval and the resetting interval. During the resetting interval switches S_e and S_{p1} are open and the constant bias current produces a linear voltage build-up on capacitor C_1 to reset saturable inductor P_1. It is assumed that the resetting interval has ended at $t=0$ so that capacitor C_1 is charged to a voltage $-\gamma$. At time $t=0$ switch S_e closes. The resulting voltage build-up on capacitor C_1 during the charging interval can be expressed as the sum of three voltages,

$$e_{C_1}(t)=e_1(t)+e_2(t)+e_3(t) \qquad 0<t<t_0 \qquad (1)$$

where $e_1(t)$ is the voltage build-up caused by the d-c supply, $e_2(t)$ is caused by the initial charge on capacitor C_1, and $e_3(t)$ is the voltage build-up caused by the constant bias current. These voltages can be expressed as follows:

$$e_1(t)=E(1-\cos\omega t) \qquad 0<t<t_0 \qquad (2)$$

$$e_2(t)=-\gamma\cos\omega t \qquad 0<t<t_0 \qquad (3)$$

$$e_3(t)=-\frac{I_b}{C\omega}\sin\omega t \qquad 0<t<t_0 \qquad (4)$$

where

$$\omega=\sqrt{\frac{1}{L_{ch}C_1}}$$

and the voltage on C_1 becomes

$$e_{C_1}(t)=E(1-\cos\omega t)-\gamma\cos\omega t-\frac{I_b}{C\omega}\sin\omega t \qquad 0<t<t_0 \qquad (5)$$

The total current flowing through the electronic switch and charging inductor during the charging interval can be expressed as

$$i_{ch}(t)=I_b-C_1\frac{de_{C_1}(t)}{dt} \qquad (6)$$

Differentiating and collecting terms yield

$$i_{ch}(t)=(E+\gamma)\sqrt{\frac{C_1}{L_{ch}}}\sin\omega t+I_b(1-\cos\omega t) \qquad 0<t<t_0 \qquad (7)$$

At the end of the charging interval, the charging current is zero and switch S_e opens. In this manner, the electronic switch is operated only when the current through it is zero and therefore little power is dissipated in it during the switching interval. If the time at which the current is zero is denoted as time $t=t_0$, then equation 7 yields

$$(E+\gamma)\sqrt{\frac{C_1}{L_{ch}}}\sin\omega t_0+I_b(1-\cos\omega t_0)=0 \qquad (8)$$

The waveforms of the current, capacitor voltage, and voltage across the switch S_e are shown in Fig. 5.

Another equation relating the variables of equation 8 may be obtained by considering the requirement for periodic operation of saturable inductor P_1. The volt-time integral across P_1 during the charging interval is the integral of the capacitor voltage and is given by the expression

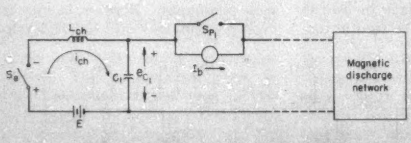

Fig. 4 (above). Equivalent circuit of the basic charging circuit and first stage of the magnetic discharge network

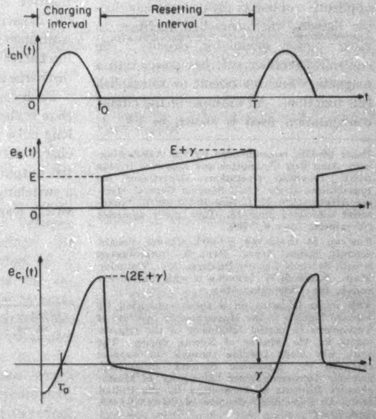

Fig. 5 (right). Waveforms of the charging current, capacitor voltage, and voltage across the switch in the charging circuit

$$\lambda_{ch}(t)=\int_0^{t_0} e_{C_1}(t)dt \qquad (9)$$

Substitution of equation 5 in equation 9, and integrating yields

$$\lambda_{ch}(t)=Et_0-\left(\frac{E+\gamma}{\omega}\right)\sin\omega t_0+\frac{I_b}{C_1\omega^2}(\cos\omega t_0-1) \qquad (10)$$

The voltage on capacitor C_1 during the resetting interval can be expressed as

$$e_{C_1}(t)=-\left(\frac{\gamma}{T-t_0}\right)(t-t_0) \qquad t_0<t<T \qquad (11)$$

The integral of the voltage across saturable inductor P_1 during the resetting interval is approximately equal to the integral of the voltage across capacitor C_1 and may be expressed as

$$\lambda_{rs}(t)=-\frac{\gamma}{T-t_0}\int_{t_0}^{T}(t-t_0)dt \qquad t_0<t<T \qquad (12)$$

It is assumed in the foregoing expression that the first loop of the magnetic discharge network is effectively decoupled from the remaining loops by the action of saturable inductor P_2, and that the impedance of P_2 is negligible compared to the other elements in the loop. After integration and simplification, equation 12 becomes

$$\lambda_{rs}(t)=-\frac{\gamma}{2}(T-t_0) \qquad (13)$$

Since the integral of the voltage across saturable inductor P_1 during one cycle of operation must be zero, the addition of equations 10 and 13 yields

$$Et_0-\left(\frac{E+\gamma}{\omega}\right)\sin\ \omega t_0+\frac{I_b}{C_1\omega^2}(\cos\omega t_0-1)-\frac{\gamma}{2}(T-t_0)=0 \qquad (14)$$

The following expression relates I_b to the previously defined parameters

$$I_b=\frac{\gamma C_1}{T-t_0} \qquad (15)$$

If equation 15 is substituted in equation 8, and the resulting equation is solved for γ, then

$$\gamma=-\frac{E\omega(T-t_0)\sin\omega t_0}{\omega(T-t_0)\sin\omega t_0+(1-\cos\omega t_0)} \qquad (16)$$

Substitution of this value of γ into equation 14 and simplifying the resulting expression yields

$$\omega t_0(1-\cos\omega t_0)+\sin\omega t_0\left[\frac{(\omega T)^2}{2}-\frac{(\omega t_0)^2}{2}\right]=0 \qquad (17)$$

This equation can be simplified if the following substitution is made:

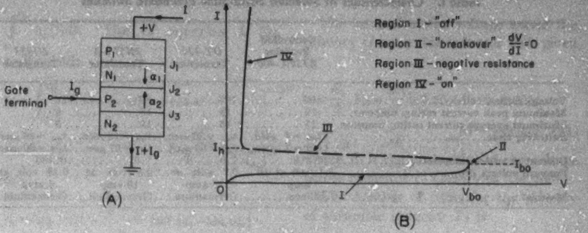

Fig. 6. P-n-p-n semiconductor

A—Schematic
B—Typical V-I characteristic

$$T=Kt_0 \qquad (18)$$

where K is the reciprocal of the duty ratio of the charging circuit. Substitution of equation 18 in equation 17 yields:

$$(1-\cos\omega t_0)+\frac{\omega t_0}{2}(K^2-1)\sin\omega t_0=0 \qquad (19)$$

By selecting appropriate values of K, equation 19 may be solved for ωt_0, which in turn can be used to obtain expressions for the various voltages and current in the charging circuit.

Controlled Rectifier as an Electronic Switch

The controlled rectifier is a p-n-p-n silicon semiconductor. It is a 3-terminal device and, in many respects, is similar in behavior to the conventional thyratron. A schematic of the p-n-p-n seniconductor device is shown in Fig. 6(A).

The junctions J_1 and J_3 are called the emitter junctions and J_2 is called the collector junction. If the gate terminal is left open-circuited, the device may be considered as a 2-terminal device of the type investigated by Moll et al.[4] A typical characteristic of such a device is shown in Fig. 6(B). If V is positive as shown in Fig. 6(A), the collector junction J_2 is reverse biased, and the emitters J_1 and J_3 are slightly forward biased. The current I which flows through the junctions is given by

$$I=IM_p\alpha_{1n}+IM_n\alpha_{3n}+I_{co} \qquad (20)$$

where α_{1n} is the fraction of the current at J_1, which is collected at J_2 as minority carrier current and α_{3n} is the fraction of the current at J_3 which is collected at J_2. The avalanche multiplication factors for holes and electrons are given by M_p and M_n respectively,[5] and I_{co} is the current that would flow through J_2 if α_{1n} and α_{3n} were zero. If the total alpha is defined as

$$\alpha_T=M_p\alpha_{1n}+M_n\alpha_{3n} \qquad (21)$$

then solution of equation 20 for I yields

$$I=\frac{I_{co}}{1-\alpha_T} \qquad (22)$$

The four principal regions of the V-I characteristic in Fig. 6(B) are explained as follows:[4]

1. At low currents, α_T is less than 1 and J_2 behaves essentially like a classical p-n junction in reverse bias. This is termed the "off" condition (high impedance region).
2. As the applied voltage is increased, avalanche multiplication at J_2 increases to a point where $\alpha_T=1$ and J_2 breaks down. This is called the "breakover" region, defined by $dV/dI=0$, where the voltage and current in 2-terminal operations have the values V_{bo} and I_{bo} respectively.
3. The device characteristic then traverses a region of negative resistance as shown by the dotted line in Fig. 6(B).
4. The low impedance region is reached when $\alpha_1+\alpha_2\geq 1$; at these low voltages M_n and M_p are essentially unity. The relation expressed in equation 22 is not valid in this region, and the device behaves as a resistor of low value. In the "on" region a certain minimum current is required to maintain the device in the low impedance state. This minimum current is designated as the holding current, I_h.

The above description relates to the controlled rectifier when no gate current is applied. If gate current is applied, the breakover voltage can be varied. The gate controls α_T, which determines the breakover voltage. It is possible to switch the device from a high impedance to a low impedance with a small gate current.

REQUIREMENTS OF THE SWITCH

Thus far in the description and analysis of the magnetic pulse generator, the elec-

tronic switch has been assumed to have ideal properties. In order to determine the suitability of the controlled rectifier as the switch, the pertinent properties of possible solid-state switches are listed in Table I.

Present-day power transistors set an upper limit on the power available from the magnetic pulse generators using a single transistor in the charging circuit. The emitter-collector voltage ratings (60 to 80 volts) and maximum collector current ratings (12 to 15 amperes) have restricted the output to a medium power range (20 to 50 watts). Since the output power depends upon the d-c supply voltage and current in the charging circuit, any increase in power must result from increasing these values. The controlled rectifier permits the use of voltages up to 400 volts and peak recurrent currents up to 30 amperes.

Another desirable property of the controlled rectifier is its ease of control. The controlled rectifier can be turned on by a small pulse of gate current, a typical requirement being 10 milliamperes at 1.5 volts. Besides the ease with which the controlled rectifier is switched into conduction, it automatically turns itself off when the current in the anode circuit is zero. This property is particularly well suited for the present application because this is the exact time that the switch should open. Whereas complex circuitry may be required to switch a transistor off when the charging current is zero, it is accomplished automatically with the controlled rectifier.

Typical turn-on and turn-off times for the controlled rectifier are 1 and 3 μsec respectively. These values are better than the typical transistor values of 12 to 40 μsec for turn-on time and 25 to 80 μsec for turn-off time. The only switching property in which the controlled rectifier is not superior to other presently available semiconductors is the voltage drop during conduction. The forward voltage drop across the controlled rectifier is typically 1 volt at 10 amperes. Typical values of transistor forward voltage drop in the corresponding current range are 0.4 to 0.7 volt.

Experimental Pulse Generator

The experimental circuit was designed to meet the following requirements:

1. average output power: 250 watts
2. pulse repetition frequency: 5 kc
3. output pulse duration: 1 μsec

The first step is the design of the charging circuit. The maximum peak recurrent rating of the controlled rectifier is 30 amperes. If the efficiency of the generator is estimated at 57%, from previous circuits, and a d-c supply voltage of 80 volts is chosen, then a first approximation to the input energy per pulse is 250/(5,000) (0.57) or 0.088 joule. The time required to transfer this energy at 80 volts with a half-sinusoid of current is $(0.088)\pi/(2)\ (30)\ (80)=58$ μsec. Thus K of equation 18 becomes $200/58=3.5$ and substituting this value into equation 19 yields

$$1-\cos\omega t_0+5.6\omega t_0\sin\omega t_0=0 \tag{23}$$

The value of ωt_0 which satisfies equation 23 is

$$\omega t_0=186.3° \tag{24}$$

Since $T=Kt_0$ and $\omega=1/\sqrt{L_{ch}C_1}$, an equation involving the charging inductance L_{ch} and capacitor C_1 can be written

$$\sqrt{L_{ch}C_1}=\frac{1}{\omega}=\frac{T}{K\theta} \tag{25}$$

where θ is the radian value of ωt_0. Substituting $K=3.5$, $\theta=3.24$ radians, and $T=200$ μsec yields

$$\sqrt{L_{ch}C_1}=\frac{T}{K\theta}=\frac{200\times10^{-6}}{3.5\left(\dfrac{186.3}{57.3}\right)}=17.6\times10^{-6} \tag{26}$$

The substitution of $\omega t_0=186.3°$ into equations 15 and 16 yields

$$\gamma=-E\frac{\omega t_0(K-1)\sin\omega t_0}{\omega t_0(K-1)(\sin\omega t_0+1)-\cos\omega t_0}$$

$$\gamma=-E\frac{\left(\dfrac{186.3}{57.3}\right)(3.5-1)\sin(186.3°)}{\left(\dfrac{186.3}{57.3}\right)(3.5-1)\sin(186.3°+1)-\cos(186.3)}=0.8E \tag{27}$$

and

$$I_b=\frac{\gamma C_1}{\omega t_0(K-1)}=0.099E\sqrt{\frac{C_1}{L_{ch}}} \tag{28}$$

γ is the initial voltage on capacitor C_1 at the beginning of the charging interval. Reference to Fig. 5 indicates that the maximum voltage appearing across the controlled rectifier is

$$V_{CR\ \max}=E+\gamma \tag{29}$$

Thus equation 29 determines the required voltage rating of the controlled rectifier. Using E equals 80 volts,

$$V_{CR\ \max}=E+\gamma=80+64=144\text{ volts} \tag{30}$$

Thus a controlled rectifier with a forward voltage rating of 150 volts was chosen for use in the experimental circuit.

Substitution of equations 27 and 28 in equation 8 results in an expression for current in the charging circuit.

$$i_{ch}(t)=1.8E\sqrt{\frac{C_1}{L_{ch}}}\sin\omega t+0.099E\sqrt{\frac{C_1}{L_{ch}}}(1-\cos\omega t) \tag{31}$$

Differentiating equation 31 and setting the resulting equation equal to zero yields

$$1.8\cos\omega t+0.099\sin\omega t=0 \tag{32}$$

Solution of equation 32 gives the time at which the current is a maximum. A value of ωt which satisfies equation 32 is

$$\omega t=93.2° \tag{33}$$

Substitution of equation 33 in equation 31 yields the following expression for the value of the charging current:

$$I_{\max}=1.9E\sqrt{\frac{C_1}{L_{ch}}} \tag{34}$$

or, solving equation 34 for $\sqrt{C_1/L_{ch}}$ gives

$$\sqrt{\frac{C_1}{L_{ch}}}=\frac{I_{\max}}{1.9E}=\frac{30}{(1.9)(80)}=0.1975 \tag{35}$$

The charging inductance L_{ch} and capacitance C_1 can be determined now from equations 26 and 35.

$$L_{ch}=89\ \mu\text{henrys} \tag{36}$$

$$C_1=3.48\ \mu\text{farads} \tag{37}$$

The average value of the charging current is given by

$$I_{ave}=\frac{1}{T}\int_0^{t_o} i_{ch}(t)dt \qquad (38)$$

Substituting equation 7 into equation 38 and performing the indicated integration yields

$$I_{ave}=\frac{1}{K\omega t_0}\left\{(E+\gamma)\sqrt{\frac{C_1}{L_{ch}}}(1-\cos\omega t_0)+ I_b(\omega t_0-\sin\omega t_0)\right\} \qquad (39)$$

Substitution of the values determined above yields

$$I_{ave}=5.45 \text{ amperes} \qquad (40)$$

Having completed the design of the charging circuit, it is now possible to proceed to the design of the magnetic discharge network. A 2-stage discharge network was chosen for the experimental pulse generator due to the simplicity of the resulting circuit. The volume per stage is given by:[1]

$$V_{ps}=\frac{\pi^2}{16}\,\frac{\mu_s}{B_s^2}\,U\left[\frac{2}{0.735\pi^2}\left(\frac{t_0}{\tau}\right)^2\right]^{1/} \qquad (41)$$

Orthonol was chosen for the magnetic material because of its square-loop properties and high saturation flux density. The saturated flux density of Orthonol is

$$B_s=1.41\times10^4 \text{ gauss} \qquad (42)$$

The saturated permeability is assumed to be

$$\mu_s=2.5\mu_0=31.7\times10^{-7}\ hy/m \qquad (43)$$

where μ_o is the permeability of free space. The peak energy per pulse stored in capacitor C_1 is $1/2C_1V_{C1p}^2$. The waveform of Fig. 5 indicates that this energy is

$$U=\frac{1}{2}C_1(2E+\gamma)^2 \text{ which equals}$$

$$\frac{1}{2}(3.48\times10^{-6})(224)^2=0.087 \text{ joule} \qquad (44)$$

Substitution of equations 42, 43, and 44 in equation 41 gives the volume per stage.

$$V_{ps}=7.96 \text{ cm}^3 \qquad (45)$$

The cores chosen for the magnetic discharge network were No. 51008-1/2*A* Orthonol cores made by Magnetics Inc. One-half-mil tape thickness was selected to keep the eddy currents small. The core dimensions are

$$V=8.1 \text{ cm}^3 \qquad (46)$$

$$A=0.65 \text{ cm}^2 \qquad (47)$$

$$\ell=12.49 \text{ cm} \qquad (48)$$

The volt-time integral appearing across saturable inductor P_1 is essentially $\int_{t_a}^{t_o} e_{c_1}(t)dt$. Use of equation 5 for $e_{C_1}(t)$ yields

$$\lambda_1=\int_{t_a}^{t_o}\left[E(1-\cos\omega t)-\gamma\cos\omega t- I_b\sqrt{\frac{L_{ch}}{C_1}}\sin\omega t\right]dt$$

or

$$\lambda_1=E(t_o-t_a)-\frac{(E+\gamma)}{\omega}[\sin\omega t_o-\sin\omega t_a]- \frac{I_b}{\omega}\sqrt{\frac{L_{ch}}{C_1}}[\cos\omega t_a-\cos\omega t_o]$$

t_a is the time at which the capacitor voltage passes through 0. Solution of equation 5 for ωt_a yields ωt_a equals 59.5°. Substitution of this value and the other known parameter values yields λ_1 equals approximately 6.0×10^{-3} volt-seconds.

The required number of turns for saturable inductor P_1 can now be calculated

$$N_1=\frac{\lambda_1}{2B_sA_1}=\frac{6.00\times10^{-3}}{2.82\times0.65\times10^{-4}}=33 \quad \text{turns} \qquad (49)$$

The first step in the design of the second stage is to calculate the saturated inductance of saturable inductor P_1 by use of equation 50.

$$L_{sn}=\mu_sN_n^2\cdot\frac{A_n}{\ell_n} \qquad (50)$$

$$L_{s1}=\mu_sN_1^2\cdot\frac{A_1}{\ell_1} =\frac{31.7\times10^{-7}\times33^2\times0.65\times10^{-4}}{12.49\times10^{-2}} =1.78\ \mu\text{henrys} \qquad (51)$$

If capacitance C_2, or its value reflected to the primary of saturable transformer P_2, is made equal to capacitor C_1, then the time required to transfer energy from C_1 to C_2 is one half the period of the resonant discharge of C_1 through C_2 and L_{s1} or

$$T_{12}=\pi\sqrt{L_{s1}\frac{C_1}{2}} =\pi\sqrt{1.78\times10^{-6}\times\frac{3.48}{2}\times10^{-6}} =5.55\ \mu\text{sec} \qquad (52)$$

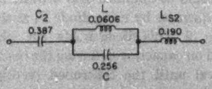

Fig. 7. Two-section Guillemin-type pulse-forming network. The element values are in henrys and farads and are normalized with respect to a load resistor of one ohm and a pulse width of one second

The integral of the voltage across the primary of saturable inductor P_2 is given by

$$\lambda_2=\frac{E_1}{2}\ T_{12}=\frac{224}{2}\times5.55\times10^{-6}=6.22\times 10^{-4} \text{ volt-sec} \qquad (53)$$

where E_1 is the peak value of the voltage across capacitor C_1 ($2E+\gamma$ or 224 volts).

The number of turns for the primary of saturable inductor P_2 is

$$N_{p2}=\frac{\lambda_2}{2B_sA_2}=\frac{6.22\times10^{-4}}{2.82\times0.65\times10^{-4}}=4 \text{ turns} \qquad (54)$$

Since two stages have been chosen for the magnetic discharge network, saturable transformer P_2 also serves as the output transformer to step up the voltage. A step-up ratio of 10 was chosen in order to to have a reasonably high output voltage and yet avoid high-voltage problems. Thus the secondary turns of saturable inductor P_2 and capacitance C_2 are given by

$$N_{s2}=40 \text{ turns} \qquad (55)$$

$$C_2=0.0348\ \mu\text{farads} \qquad (56)$$

To design the pulse-forming network, it is necessary to determine the saturated inductance of the secondary of saturable transformer P_2. Using equation 50, the saturated inductance is

$$L_{s2}=\mu_sN_{s2}^2\times \frac{A_2}{\ell_2}=\frac{31.7\times10^{-7}\times40^2\times0.65\times10^{-4}}{12.49\times10^{-2}} =2.64\ \mu\text{henrys} \qquad (57)$$

With this value known, the pulse-forming network may be designed. Fig. 7 shows a 2-section Guillemin-type network[7] used to discharge the last capacitor C_2 of the discharge network into the load. This network produces an approximate square wave of discharge current. The values shown are normalized to a load resistor of 1 ohm and a pulse width of 1 second. Because C_2 and L_{s2} are known, *L* and *C* may be determined by using the proportional values.

$$L=\frac{0.0606}{0.190}\times2.64\times10^{-6}\text{henry}=0.834\ \mu\text{henry} \qquad (58)$$

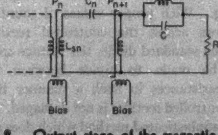

Fig. 8. Output stage of the magnetic pulse generator

$$= 0.0236\mu \text{ farad} \quad (59)$$

Fig. 8 shows the output stage of the generator. Nonlinear inductor P_{n+1} provides a low impedance path around R_L during the charging of C_n so that little power is lost in R_L during the charge. During discharge it assumes a large value of impedance.

Experimental Circuit

When the experimental pulse generator was constructed in the laboratory, various problems were encountered which are not considered in the analysis and design sections. These problems and their solutions are discussed in this section and the actual experimental circuit is presented.

One of the problems is associated with the "turn off" of the controlled rectifier. As previously mentioned, "turn off" time for the controlled rectifier is approximately 3 μsec. Even though this is a relatively fast "turn-off" time, the current in the charging circuit does reverse and reach an amplitude of about 4 amps in the negative direction before the controlled rectifier shuts off; see Fig. 10. The current drops abruptly to zero from this amplitude resulting in a large di/dt which, because of the charging inductor, produces a large spike of voltage across the controlled rectifier. This voltage can damage the controlled rectifier if it exceeds the peak inverse voltage rating of the device.

One solution to the problem is to add a conventional semiconductor diode in series with the controlled rectifier to obtain an increased PIV (variable speed) rating. With proper values of shunting resistors across the controlled rectifier and the standard diode, the voltage spike can be made to divide between the two resistances in such a manner that the controlled rectifier is not damaged. A more sophisticated method which does not require an additional rectifier is to wind the charging inductor on a magnetic core having square-loop characteristics. This core can be biased so that a positive current drives the core into its saturated region where it acts as a linear inductor, and a negative current drives the core into its unsaturated region. Since the core acts as a high impedance in its unsaturated region, it prevents the charging current from reversing significantly. Thus, little current exists when the controlled rectifier turns off, and the voltage spike across the controlled rectifier is reduced. Fig. 11 shows a photograph of the charging current when this type of charging inductor is used.

Another problem is the resetting of saturable inductor P_1. Inductor P_1 is reset by a constant bias current that produces a linear voltage build-up on capacitor C_1 in the negative direction. This voltage reaches a value γ when the core reaches negative saturation at the end of the resetting interval. Theoretically, the controlled rectifier is turned on at this time, and the charge stored on capacitor C_1 discharges through the controlled rectifier and the charging inductor and back on to C_1 in the positive direction.

However, if the circuit is operated slightly below the repetition rate it is designed for, the controlled rectifier is still off when saturable inductor P_1 reaches negative saturation and capacitor C_1 discharges through the magnetic discharge network in the negative direction. This pulse is clipped by the blocking reactor in the pulse-forming network so that some of the energy in the pulse is dissipated in the circuit. It was found that circuit operation could be obtained over a wider range of frequencies by using diode D_1 as shown in Fig. 9. This diode holds the charge stored on capacitor C_1 during the resetting interval until the controlled rectifier is turned on.

The experimental circuit with the charging inductor wound on a square loop magnetic core and a diode in the first loop of the magnetic discharge network is shown in Fig. 9. The triggering source for the controlled rectifier is a variable-frequency square-wave generator. The output is differentiated and the negative pulses clipped with a diode in order to obtain the positive pulses necessary to turn on the controlled rectifier.

Results

The results obtained from the experimental circuit are presented in this section. Waveforms of the charging current and voltage across capacitor C_1 are shown in Figs. 10, 11, and 12, respectively. These waveforms verify those predicted and have values approximately equal to the design values. The energy stored on capacitor C_1 can be calculated from Fig. 12 and is

$$U_a = \frac{1}{2} C_1 e_{C_1}{}^2_{\max} = \frac{1}{2}(3.5 \times 10^{-6})(210)^2$$
$$= 0.081 \text{ joule} \quad (60)$$

The predicted value given by equation 44 is

$$U_p = 0.087 \text{ joule}$$

so that the actual energy stored on capacitor C_1 is 0.006 joule less than the predicted value. At a frequency of 5 kc, this loss of energy corresponds to a loss in average power of 30 watts. The average power dissipated in the controlled rectifier, determined from General Electric Company data, is

$$P_{CR} = 7.9 \text{ watts} \quad (61)$$

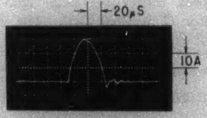

Fig. 10. Charging current when extra diode is used in series with controlled rectifier

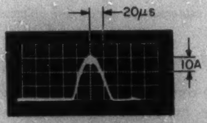

Fig. 11. Charging current using charging inductance with square-loop characteristics

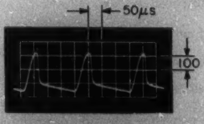

Fig. 12. Voltage across capacitor C_1

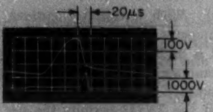

Fig. 13. Charge and discharge sequence of capacitors C_1 and C_2

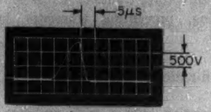

Fig. 14. Voltage across capacitor C_2

The copper loss in the charging circuit is given by:[2]

$$P_C=\frac{1}{2}(I_{\max})^2R'T_pf_r \qquad (62)$$

where

$I_{\max}$ = maximum value of the half sine wave current in amperes
R' = effective resistance in ohms
Tp = duration of the half sine wave current pulse in seconds
fr = repetition rate in cps (cycles per second)

Using the values given in Fig. 10 in equation 62, the average power loss in the charging circuit due to copper loss is

$$P_{Cm}=12.8 \text{ watts} \qquad (63)$$

The remaining loss of average power in the charging circuit is caused by core losses in inductor P_1 and capacitor losses. The core loss in inductor P_1 is

$$P_{p1}(\text{core loss})=10.1 \text{ watts} \qquad (64)$$

Fig. 13 shows the charge and discharge sequence of capacitors C_1 and C_2, and Fig. 14 shows the voltage across capacitor C_2. The energy stored on capacitor C_2 is determined from Fig. 14.

$$U_{C_2}=\frac{1}{2}\,C_2e_{C_2}{}^2{}_{\max}=\frac{1}{2}(0.062\times10^{-6})\times$$
$$(1.4\times10^{-6})(1.4\times10^3)^2=0.0606 \text{ joule} \qquad (65)$$

If the copper loss in the pulse-forming network is neglected, then the average power output at the load is

$$\overline{P}_o=f_rU_{C_2}=(5\times10^3)(0.0606)=303 \text{ watts} \qquad (66)$$

The loss in average power in transferring energy from capacitor C_1 to the load can be attributed to core, copper, and capacitor losses in the magnetic discharge network and pulse-forming network. Core losses can be estimated from experimental data take at the Brooklyn Polytechnic Institute.[3] Using the given data, the loss in average power due to the core losses of inductor P_2 and the blocking reactor P_3 are

$$P_{p2}(\text{core loss})=16.1 \text{ watts} \qquad (67)$$

$$P_{p3}(\text{core loss})=4.9 \text{ watts} \qquad (68)$$

From equation 62 the loss in average power due to copper loss in inductors P_1 and P_2 is

$$P_{p1}(\text{copper loss})=23.4 \text{ watts} \qquad (69)$$

$$P_{p2}(\text{copper loss})=9.3 \text{ watts} \qquad (70)$$

The average power dissipated in diode D_1 in the first loop of the magnetic discharge network is determined from manufacturer's data as

$$P_{D_1}=4.9 \text{ watts} \qquad (71)$$

The remaining power loss is due to losses in the capacitors.

Because no effort was made in the experimental circuit to minimize the bias currents, the effect of the bias currents is ignored in the calculation of efficiency. The measured average current in the charging circuit is

$$I_{ave}=5.35 \text{ amperes} \qquad (72)$$

An 80-volt d-c supply voltage was used so that the average power input becomes

$$P_{in}=EI_{ave}=(80)(5.35)=436 \text{ watts} \qquad (73)$$

Thus the efficiency of the magnetic pulse generator, ignoring the effect of the bias current, is

$$\eta=\frac{P_o}{P_{in}}=\frac{303}{436}=69.5\% \qquad (74)$$

The purpose of the investigation reported here was to explore a method for developing a 250-watt semiconductor magnetic pulse generator. The output power of the experimental circuit was approximately 300 watts. The large output power resulted from the use of a controlled rectifier as the electronic switch in the charging circuit. The controlled rectifier appears to be well suited for use as the electronic switch in this particular application because of its high power-handling capabilities, its ease of control, and its fast switching speed. Controlled rectifiers with voltage ratings up to 400 volts, or 250 volts higher than that used in the experimental circuit, are readily available. Thus, it appears that the output power of the type of magnetic pulse generator demonstrated in this investigation can be extended to higher values.

A Transistor-Oscillator Limit Switch for Indicating and Recording Instruments

J. T. WINTERMUTE
NONMEMBER AIEE

S. G. HAYTER
ASSOCIATE MEMBER AIEE

THE continued development of automatic controls has emphasized the need for limit switches on indicating and recording instruments which will not restrict the normal operation of the measuring unit. This control has been obtained in the past in two ways:

1. By contacts carried on the instrument pointer.
2. By employing a vane attached to the pointer to change the constants of a vacuum-tube oscillator circuit, and using the change in oscillator current to operate a relay.

Arrangement no. 1 has the disadvantage of being troubled with contact resistance unless magnetic contacts or a holding coil are used. With contacts carried on the pointer, the indication of the instrument is limited to the contact point setting. This is undesirable on recording-type instruments, where the purpose is to record the true value even when it is beyond the contact point setting.

The vane and oscillator arrangement avoids these shortcomings but introduces the element of limited life of vacuum-tube equipment. The arrangement to be described employs the vane and oscillator scheme but utilizes transistors, with their inherently longer life.

The transistor oscillator is changed from the oscillating to the nonoscillating state by the change in mutual inductance between the base and collector coils of an inductive feedback-type oscillator. This change in mutual inductance occurs when the moving element rotates a metal vane between the two closely coupled oscillator coils. When the vane is between the oscillator coils mutual inductance is decreased, oscillation stops, and the collector current drops to a low value, causing a relay to release.

A single-limit switch employs one oscillator and one set of feedback coils. A double-limit switch (a high and low limit) is achieved by employing two oscillator units.

A single-pole double-throw output relay is incorporated to provide either "make" or "break" contacts, depending on the terminals used.

Some of the major factors that had to considered in the development were sensitivity, i.e., the ability to secure control from a small motion of the moving element, self-starting of oscillation over a wide temperature range, and long life.

Oscillator Circuit Design

The oscillator employs a *2N332* silicon *n-p-n* transistor, which is a relatively low cost transistor with high storage and operating temperature limits. The oscillator circuit is a common-emitter, inductively coupled feedback type, with the base and collector coils mounted in the instrument. The *2N332* has a collector breakdown voltage of 45 volts minimum. It was desirable to keep the magnetic field set up between the collector and base coils as weak as possible, since strong fields would tend to oppose the vane motion as the vane approaches the "pull-out" position (the position where oscillation stops). With a collector current of 3 milliamperes or less, it was found that this effect is negligible even for small spring constants such as those used in small panel instruments. The high breakdown voltage of the *2N332* permits the use of a medium-sensitivity relay without resorting to large collector currents, by employing a high-resistance winding in the relay. A reverse-connected diode eliminates the induced voltage transient across the relay winding, preventing transistor breakdown.

Stabilization

Operation over a wide ambient temperature range of −20 to +50 degrees centigrade is achieved with essentially constant collector current by employing a thermistor to vary the forward bias applied to the transistor. The bias network shown in Fig. 1 consists of resistor R_1 and the shunt combination of resistor R_2 and thermistor *T*. R_1 is connected to the rectifier side of the filter resistor R_3. This results in a component being present in the bias voltage. The resulting collector voltage excursions assure self-starting at low temperatures. The operating point is selected to give class *B* operation, and with the "stiff" bias scheme shown the collector current change from the oscillating to the nonoscillating condition is very fast.

The power supply employs a constant-voltage transformer which permits reliable operation with line-voltage values from 80 to 150 volts, and provides isolation from the power line. Adjustable a-c degeneration, employing a variable iron-core inductance in the emitter lead,

J. T. WINTERMUTE and S. G. HAYTER are with the Westinghouse Electric Corporation, Newark, N. J.

The authors wish to acknowledge the early work of W. J. Schmidt, Westinghouse Meter Division, in applying transistors to the basic scheme of vane-controlled oscillators.

is used to adjust the over-all feedback. This adjustment is required to permit the use of commercial transistors with their rather large current gain spread. This also provides stabilization against change in transistor parameters with time. Shunt feedback between the collector and base could be used, but the tuned inductance method is more compact and readily locked in position, as compared with the variable resistor and blocking capacitor that would be required for shunt feedback.

Output Circuit

The present model employs a single-pole double-throw relay in the output with a contact rating of 5 amperes, 115 volts a-c noninductive load. A transistor switch or saturable reactor could be used instead, but would not give the independence of the controlled circuit that the relay provides.

Application

The transistor-oscillator limit switch was first applied to strip-chart recording instruments. The installation of oscillator coils on suitable adjustable supporting arms and a metallic vane on the moving element (Fig. 2) is feasible without upsetting the normal recorder functions. The recorder will operate over its full-scale range regardless of the limit device setting.

The small oscillator coils are rectangular in shape and are made with several hundred turns of very fine adhesive-coated wire. This type of wire is ideal for self-supporting coils and is readily cured by chemical softening of the wire coating and a subsequent short drying period. These coils are mounted in pairs in nonmetallic blocks with an open space between them. The metallic vane is so mounted on the moving element that the vane may pass freely through the gap between a pair of oscillator coils. The pen and vane move in the up-scale direction when the recorder is energized. Upon reaching a preset limit setting, the vane enters the gap between the oscillator coils and reduces the mutual inductance between the coils. The design of the vane assures continued interruption of the mutual inductance as long as the recorded value is in excess of the limit setting.

Rectangular-shaped oscillator coils are used in preference to round ones because rectangular oscillator coils will produce a greater mutual inductance change for a given angular rotation of the interrupting vane.

A step in the vane contour plus an exacting design of the oscillator coil support block and arms permits full-scale range for the limit switch settings. Recorders with two limit switches may set the switches with less than 5% of full scale between the high and low setting.

A multilead cable with a locking connecting plug at the external unit end is used for the circuits between the oscillator coils and the external oscillator unit.

Conclusions

Contact operation has been obtained from the moving element of a recorder or instrument without interference with its normal operation.

Transistors and semiconductor diodes have been used to provide long life and small over-all size.

Wire Line and Carrier Communications on the Union Pacific Railroad

C. O. JETT
MEMBER AIEE

COMMUNICATIONS in the area presently served by the Union Pacific Railroad Company preceded the Railroad by several years. The telegraph line of the Overland Telegraph Company, starting at Omaha, Nebraska, and extending westward through Salt Lake City, Utah, to San Francisco, California, was constructed in the years 1860 and 1861; while the construction of the Railroad did not start until 1864.

Inasmuch as the original telegraph line was hastily constructed, later, when it became necessary to rebuild, the line was moved onto the right-of-way of the Union Pacific Railroad and became the first wire communication facilities of the Railroad Company. Over the years more and more wire was added to the line for train dispatching, operation, and administrative purposes. Prior to 1912 only Morse telegraphy was used; however, in 1912, the first telephones were installed on the Union Pacific. The wire line plant reached its peak in miles of pole line and wire mileage in the early 1920's.

In the late 1920's voice repeaters were installed on a number of circuits to permit direct telephone communication from headquarters at Omaha to points as far west as Salt Lake City. Various types of printing telegraph machines were installed on the Union Pacific Railroad as early as 1918, and 4-channel Morkrum multiplex teleprinters were used as late as 1946, at which time all the teleprinter facilities were replaced with modern teleprinter equipment.

With the advent of carrier techniques and improved business conditions in the fall of 1937, a Western Electric type *CN-4*, 3-channel carrier system was furnished and installed by the Western Electric Company between Salt Lake City and Los Angeles, California. From this time on, the growth of business and the requirements for more and better communications necessitated rapid expansion of all forms of communications on the Union Pacific Railroad. Many single-wire Morse telegraph circuits were paired for telephone operation, voice transposed, and additional telephone instruments installed. Between a number of the more important offices, teleprinter facilities were expanded.

In 1941, just prior to the start of World War II, a Western Electric type *C-5*, 3-channel carrier system was installed between Omaha and Salt Lake City with terminals back to back at Cheyenne, Wyoming, to provide much needed additional facilities.

In rapid succession a 3-channel carrier system (Western Electric *C-5*) was installed between Salt Lake City and Portland, Oregon, and a second 3-channel system (Western Electric *C-5*) was installed between Omaha and Salt Lake City, to provide direct circuits from Omaha to Los Angeles, Salt Lake City, and Portland.

Restrictions on electronic equipment precluded any expansion of communications during World War II, except those that were mandatory for the handling of military operations. However, with cessation of hostilities, it became readily apparent that a major expansion must be made to provide administrative teleprinter facilities to consolidate the far-reaching points of the Union Pacific Railroad.

The new facilities for teleprinter service were provided by voice frequency carrier telegraph techniques. At the same time, many additional single-channel short-haul telephone carrier channels were provided on the Railroad by installing second and third story carrier systems over Western Electric's type *H-1* carrier systems which had been installed during the period 1939–1945.

Teleprinter Facilities

As mentioned previously, the Union Pacific Railroad first entered the field of voice frequency carrier telegraph facilities in 1946. In 1948, it was realized that many more channels for teleprinter service would be required than were available utilizing the conventional 170-cycle spacing for voice frequency carrier telegraph service. It was, therefore, decided to utilize equipment with 120-cycle spacing which would permit one-third more channels to be installed on a voice band. Further, a number of channels had been tried out in 1946 on what is now called "speech-plus-duplex." This technique involves removing that portion of the voice band between 1,450 and 1,900 cycles by suitable filters and installing two carrier telegraph channels within that space. The 120-cycle spaced channels then permit four carrier telegraph channels to be installed in the same space previously used by two 170-cycle carrier channels, thus doubling our teleprinter channel facilities. Today, a major portion of the Railroad's teleprinter facilities are derived by the "speech-plus-duplex" technique. There is only one location (Omaha–Salt Lake City) in which an entire voice band is utilized for voice frequency carrier telegraph service.

Several years ago, to provide additional facilities for teleprinter service, it was found that the only space available for expansion was in that band of frequencies lying above the voice range and below the "C" carrier systems, which has a frequency range of approximately 2,900–5,100 cycles. Twelve specially designed voice frequency carrier telegraph channels were then inserted into that space and today the Railroad operates 72 channels at various points in this band.

The present extent of the teleprinter service on the Union Pacific Railroad is shown by Fig. 1. It may be noted that the number of channels between various locations are not given; however, this factor is rather indefinite as channels are set up on patch basis from time to time depending upon service requirements. For locations not physically on the Union Pacific Railroad, circuits are obtained by lease from common carrier communication companies. There are a number of relay points to relay messages from one location to another. The torn-tape method is utilized to provide direct relaying without repunching a message. A typical teleprinter torn-tape relay center with six gang transmitter-distributors on the left and each cabinet on the right containing three typing reperforators is illustrated by Fig. 2.

Primary relay points are located at Omaha, Salt Lake City, Los Angeles, Portland, Chicago, and New York City. Secondary relay points are located at North Platte, Kansas City, Cheyenne, Pocatello, and Hinkle.

Typical teleprinter ending facilities are illustrated in Fig. 3.

Paper 60-815, recommended by the AIEE Wire Communication Systems Committee and approved by the AIEE Technical Operations Department for presentation at the AIEE Summer General Meeting, Atlantic City, N. J., June 19–24, 1960. Manuscript submitted December 21, 1959; made available for printing June 3, 1960.

Telephone Facilities

In 1955, after a careful review of the Railroad's existing communication facilities, it was determined that a definite requirement existed for more and better communications at many points on the Railroad. Further, it was deemed advisable to provide direct distance dial facilities throughout the entire Railroad system. Since the existing outside wire plant was fully loaded in most instances, in that it would be impossible to add additional wire without major rebuild of the pole line, it was only possible to provide this additional service by means of carrier techniques. Therefore, a major expansion into carrier facilities was started.

During the years 1955 to 1958, "C" carrier systems were installed from Omaha to Kansas City, Omaha to North Platte, North Platte to Cheyenne, Cheyenne to Green River, Green River to Ogden, Ogden to Salt Lake City, Cheyenne to Denver, Kansas City to Salina, Salina to Denver, Salt Lake City to Pocatello, Pocatello to Nampa, Nampa to Hinkle, Hinkle to Spokane, two systems Hinkle to Portland, and two systems Portland to Seattle. Further, because of the age and difficulty of obtaining maintenance material for the *C-4*, 3-channel carrier system between Salt Lake City and Los Angeles, it was replaced with a *C-5*, 3-channel carrier system extending from Salt Lake City to Los Angeles with terminals back to back at Las Vegas. Even this did not provide enough facilities. Therefore, it was necessary to enter into the high-frequency telephone carrier field.

A Western Electric *OB* system was installed from Omaha to Cheyenne and from Cheyenne to Salt Lake City. An *OC* carrier system was installed from Omaha to Cheyenne. An *OB* carrier system was installed from Salt Lake City to Pocatello, Pocatello to Nampa, and Nampa to Hinkle. Also, from Salt Lake City to Las Vegas, and Las Vegas to Los Angeles. Still not enough voice frequency channels were available for the requirements. The *OB* and *OC* carrier systems were then replaced with Lenkurt type *45-A* 12-channel open wire carrier installations. Prior to the installation of the 12-channel carrier systems, it was necessary to retranspose for 150-kc operation several pairs of wires from Omaha to Salt Lake City, Portland, and Los Angeles. Upon completion of the transposing, 12-channel carrier systems were installed as follows: One system direct Omaha to Salt Lake City with 16 repeaters. On the adjacent pair a second 12-channel system was installed with terminals back to back at Grand Island, North Platte, Cheyenne, and Green River. Also, 12-channel systems were installed between Salt Lake City and Las Vegas, and Las Vegas and Los Angeles, and another system was installed from Salt Lake City to Portland with terminals back to back at Pocatello and Nampa. The *O* carrier systems that had been removed were reinstalled to provide additional facilities between Omaha and Kansas City, and an *OB* and *OC* system from Cheyenne to Denver. Type *OB* carrier systems were also installed from Kansas City to Salina, Cheyenne to Laramie, Ogden to Salt Lake City, and from Los Angeles to San Pedro.

Fig. 4 illustrates the geographical coverage of the Railroad's present telephone communication system, and the location of the various switching offices. Today, it is possible to dial directly from one end of the Railroad to the other, and to a major portion of the intermediate telephones which are so necessary to railroad operation.

Presently, due to the shortage of competent Morse telegraph operators, the Railroad is engaged in a program of converting wire facilities on all branch lines from Morse telegraph service to telephone service. Many of these branches require ten or less telephones, permitting direct dial service through recently developed decimonic ringing techniques adapted for E and M lead control, while the remaining branches will utilize $3^{1}/_{2}$-cycle selector facilities for signaling because of the larger number of telephones involved.

The complexity and magnitude of the Union Pacific Railroad's communication system necessitate the use of commercial telephone company plant practices in the installation of equipment in the many locations where such facilities are required. Fig. 5, showing the communication office at Omaha, illustrates typical practices.

Due to the long association of the Union Pacific Railroad's communications department with the Western Union Tele-

Fig. 4. Union Pacific Railroad telephone channel facilities

graph Company, many Western Union practices have been continued, especially with respect to testing and patching the open wire plant. A typical Railroad testing and patching switchboard installation is shown in Fig. 6.

Data Facilities

In 1956 the Railroad entered into a program to expedite movement of trains and the handling of identifying correspondence by employing techniques called electronic data processing methods, or, in simple language, "machine accounting." Equipment manufactured by IBM (International Business Machines Corporation) was utilized. Originally, data were transmitted on teleprinter channels and

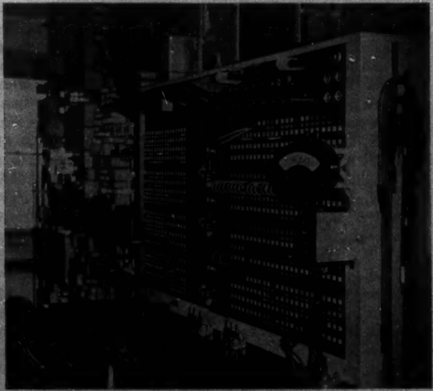

Fig. 5 (left). Typical communication equipment rack

Fig. 6 (above). Typical wire testing and patching facility on a railroad communication system

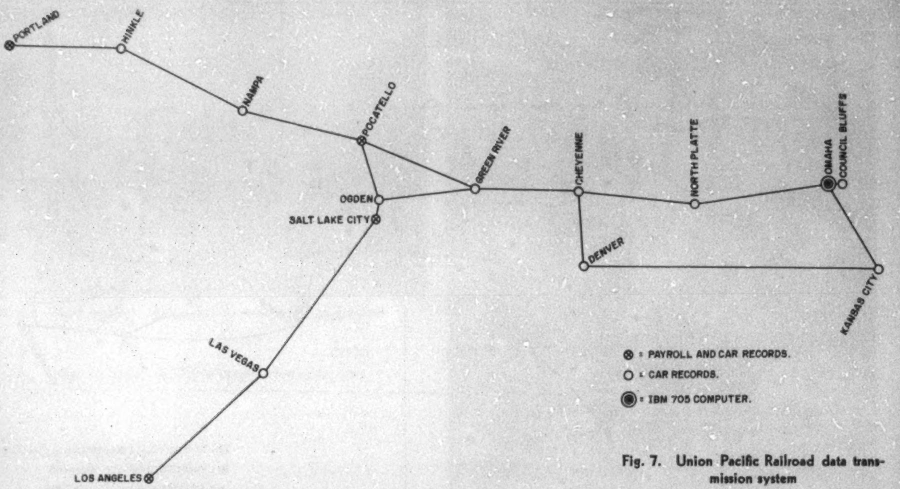

Fig. 7. Union Pacific Railroad data transmission system

converted from card to tape and tape to card on a local basis, but this procedure was cumbersome, wasteful of manpower, and much too slow.

The program of data transmission was speeded up in 1957 by the elimination of the intermediate process of card to tape and tape to card by utilizing the transceiver manufactured by IBM, which transmitted a card from one transceiver to a similar transceiver at the distant end on 100-wpm teleprinter channels. After approximately a year's experience with this type of equipment, it was realized that it, too, was inadequate for the assigned task, and that it would be necessary to use higher speeds which necessitate using the voice frequency type transceiver, on a 4-wire basis, whereby four transceiver channels can be derived from one voice frequency telephone channel, resulting in the doubling of the number of cards per minute transmitted and received by each transceiver circuit.

Early in 1958, a comprehensive data system was established over the entire Railroad to feed data from the various originating points to the IBM Model *705* computer located at Omaha, for car record operation between the various reporting offices. This system is shown in Fig. 7.

Today, two types of data are being handled on the present facilities. One type is the car record, which is the operational record of all freight cars moving throughout the Union Pacific system, and to connecting railroads. The second type of data transmitted is pay roll accounting, in which the pay roll records of the employees of the Railroad are channeled daily to the computer in Omaha, where the pay roll record is kept and the checks prepared for payment on a semimonthly basis.

Specialized Facilities

Only in railroad operation is it necessary for one person to direct and control an entire facility covering, in many instances, several hundred acres. This is the condition that exists in railroad yards. To expedite the movement of trains and the switching of cars through the various terminals, it has been necessary to establish large intercommunicating and paging facilities whereby the supervisor can contact and direct many different persons, diesel switching crews and repair forces. This is accomplished by means of strategically located paging speakers and 2-way talk-back speakers which permit an employee to signal his supervisor, or the supervisor to speak to personnel even when they are several hundred feet distant from the speaker. Each of these yard intercommunicating systems is custom engineered to provide the best coverage in view of the service requirements. This service in the yards is generally provided through buried multiconductor telephone cables comparable in many cases to the telephone exchange plant in villages and small towns. Yards frequently have 15 to 25 paging speakers and as many as 100 2-way talk-back speakers, all under control of one supervisor. A similar problem exists in the modern terminal freight house with incoming and outbound freight and transshipment of freight from one car to another, in that the entire operation must be under the direct control of one individual. The problem most generally is solved with a system somewhat smaller than that utilized for yard operations.

Future

Presently, there is no further room for expansion on the wire line communications plant and yet the requirements exist for more facilities for voice communications, teleprinter channels, and for the transmission of data of many types and from many places on the Union Pacific into Omaha. The cost to expand the wire communications plant would be prohibitive. The Railroad, therefore, is entering into a program of installing a microwave radio communication system. Presently under construction is a system from Omaha to Laramie, and the section from Laramie to Salt Lake City is now in the planning stage. It is hoped that the communications facilities so derived by microwave techniques will be adequate for a number of years.

Presently over the major portion of the Railroad two pole lines exist. One pole line is used by the signal department to control the operation of signals and in certain areas to provide centralized train control, while the other pole line is used by the communications department to provide the communication facilities. For the past several years, when it has been necessary to rebuild or replace either of these pole lines, a concerted effort has been made to consolidate, where feasible, the two pole lines into one line. Progress has not been too rapid, frequently due to the large number of wires of the two departments. It is believed that the incorporation of microwave radio facilities into the Railroad's communication plant will permit the elimination of considerable pole line mileage by reducing the number of wires needed by the communications department, which will then permit one pole line to serve both departments.

It is possible that a certain number of carrier systems will be retired because the service they are performing can be more easily performed by microwave techniques, but due to the scarcity of population in the area served by the Union Pacific Railroad, there is limited availability of commercial facilities along the Railroad's right-of-way. It is mandatory that the Railroad be able to get in touch with many of its employees living at isolated areas along the right-of-way in the event of emergencies and other conditions requiring their services on an unscheduled basis, and it is only through Railroad communication facilities that this personnel can be contacted.

The E6 Telephone Repeater Background, Description, and Theory of Operation

IN 1948 the Western Electric Company introduced a 2-way telephone voice repeater which operated in a radically different manner than had previous 2-way telephone repeaters. The new repeater employed the negative impedance principle, meaning that it was essentially a 2-terminal device intended to be inserted in series with a telephone circuit. Previous voice repeaters were 4-terminal units made up of combinations of 1-way amplifiers and hybrid coil circuits connected to provide 2-way transmission. The popularity of the new repeater stemmed from its low cost and from the fact that it could pass d-c supervisory currents and dial pulse signals without need for special bypass equipment.

The first of the series, the *E1*,[1] and the later *E2* were inserted in series with the line pair and they introduced a negative resistance which increased the voice currents at both the receiving and sending ends of the connection. The former action was desirable since it increased the received signal, but the latter caused echo if the repeater was used on connections with appreciable transmission time delay. The large impedance discontinuity introduced by the repeater limited the operating net loss of the circuit to avoid singing when the circuit was in the idle condition and caused poor frequency response when the circuit was in use.

Another negative impedance device, the *E3* repeater, was developed to be used specifically in combination with the series repeater. It was connected across the cable pair, not in series with it. The combination series-shunt *E13* or *E23* repeater could be adjusted to provide a much better impedance match to the line pair, thus reducing reflection and echoes and permitting operation of the circuits at lower net loss.

The manufacture and use of *E*-type repeaters was confined to a few thousand a year for several years after their introduction in 1948. However, with the need for improvement in transmission of circuits in metropolitan areas, the number installed mushroomed rapidly. By early 1959 more than one million units of the *E1*, *E2*, and *E3* had been built and installed in the Bell System.

The maintenance experience on these repeaters over a 10-year period has been very favorable. Few of the repeaters have failed, and routine maintenance is limited to a semiannual or annual check of the electron tube cathode activity. Such checks are easily and quickly made. The stability of gain and gain-frequency characteristics has been good. What, then, are the characteristics that would be desired in a new repeater?

Transistorization of the *E2* and *E3* is one obvious step. The *E23* repeater uses two dual electron tubes, requiring a total of 7 watts of 48- and 130-volt supply. Transistorization cuts the power to less than 2 watts using only a 48-volt supply, which is common to most telephone offices. It may provide freedom from replacement of the active elements.

The changeover from an electron tube circuit to transistor circuits is not difficult. Such circuits have been described in an article by Linvill[2] published in 1953. Experimental models, which could use the identical network strappings or repeater adjustment as the *E2* and *E3* converters, have been built. However, one drawback of the present *E13* and *E23* repeaters is the method of adjustment of the repeater, both to match line impedance and to provide the desired gain over an adequate frequency band. Once the repeater has been adjusted to work with a given line it has proved to maintain its adjustment very well, but the initial procedure is time consuming and it must be repeated if the repeater gain is to be changed because of reassignment of the cable facilities. A new repeater should therefore minimize the adjustment procedure.

Operation and Gain Adjustment of E23 Repeater

A brief description of the method of operation and adjustment of the *E23* re-

---

Paper 60-814, recommended by the AIEE Wire Communication Systems Committee and approved by the AIEE Technical Operations Department for presentation at the AIEE Summer General Meeting, Atlantic City, N. J., June 19–24, 1960. Manuscript submitted March 24, 1960; made available for printing May 4, 1960.

E. J. Doyle and T. J. Talley are with the American Telephone and Telegraph Company, New York, N. Y.; Lester Hochgraf is with the Bell Telephone Laboratories, Murray Hill, N. J.; and L. Pedersen and J. O. Smethurst are with the Bell Telephone Laboratories, North Andover, Mass.

Important contributions to the development of the line-building-out network were made by Miss R. L. Huxtable, American Telephone and Telegraph Company, and by J. L. Garrison and R. W. DeMonte of the Bell Telephone Laboratories; to the development of the converters and test sets by A. L. Bonner and W. J. Kopp of the Bell Telephone Laboratories. Figs. 31 and 32 are reproduced by courtesy of J. W. Topping of the New Jersey Bell Telephone Company.

Fig. 1. Schematic diagram of E2 repeater

peater will serve to point out the functions of various parts of the negative impedance circuit and the repeater-adjustment problem. This brief exposition will preface the description of the operation of the *E6* repeater.

A schematic diagram of the *E2* series repeater is reproduced in Fig. 1 from the article by Merrill, Rose, and Smethurst.[3] Note the passive elements which are shown on the top of the diagram above the dashed line. This is the variable network or adjustable portion of the series repeater. Impedance of this network is transformed to a negative value by the tube converter in the amplifier unit. The line terminals, which serve as both input and output terminals, are connected to the cable pair through the input transformer shown at the bottom of the diagram. In most applications the repeater is used on coil-loaded cable pairs between two central offices. The gain-adjusting network shown in Fig. 1 is for one particular value of gain with the repeater connected to two *H-88* loaded cable pairs which have 0.5 length end sections; i.e., the nearest loading coils are 3,000 feet away from the repeater.

The negative impedance and gain inserted in the line are not varied by changing the conversion ratio of the amplifier portion, but by changing the magnitude of the positive impedance of the variable network. The line impedance to which the repeater should be adjusted is shown in Fig. 2(A) for both 19- and 22-gage *H-88* loaded cable pairs with 0.5 length end sections at the repeater.

End section lengths different from the above are taken care of by varying some of the capacitance components in the network, or by building out short-length end sections (less than 3,000 feet) with the capacitors labeled *B01*, *B02*, or *B03*, shown near the lower part of Fig. 1. This complexity of adjustment is necessary because the impedance of loaded cable pairs is a complex function of frequency over the voice band; it also varies with the length of end section as shown in Fig. 2(B). Similar adjustments are required in the *E3* repeater network.

Each different gain setting of the repeater requires changing the values of most, if not of all, components in both *E2* and *E3* networks. The desired configuration and component values are obtained by strapping wire connections and soldering them to terminals on the sides of the *E2* and *E3* units. The 39 network-adjusting terminals of an *E2* repeater connect to 12 fixed resistors, 11 capacitors, and 3 tapped inductors. Similarly, in an *E3* unit there is a nearly equal number of network components.

A test set has been devised to speed the strapping adjustment prior to permanently wiring and soldering a repeater network, but the procedure is time consuming and inflexible. The strapping procedure requires much time during intial installation or during the subsequent eassignment of an *E2* or *E23* repeater.

Considerable engineering time has also been spent on working out the best network strappings for a given repeater gain and cable loading. Because of this work, and because of the field work required to change to a different gain value, these data have been issued only in 0.5-db (decibel) gain steps for series repeaters used alone, and in approximately 0.8-db steps for *E23* repeaters.

Method of Operation of E6 Repeater

It has been recognized for some time that the method employed in the *E2* and *E3* repeaters, of providing a large number of network elements and using relatively few components for any particular installation, is wasteful of apparatus and engineering, and of installation time. Evidence from the field indicates that only a few typical network arrangements of the many configurations possible are used in a majority of cases. To confirm these conclusions, a survey was made to determine the types of exchange-area facilities in common usage. From analysis of the data it was discovered that about 85% of all trunks were *H-88* loaded cable circuits in either 19-, 22-, or 24-gage cable.

Vol.
Pt. 1

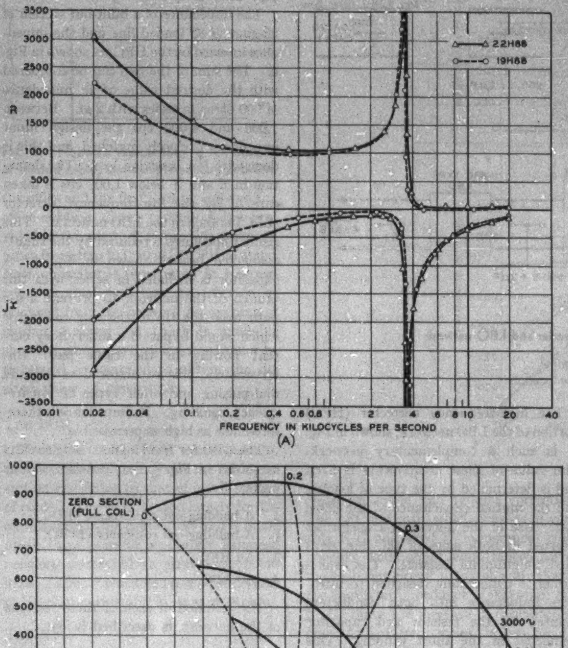

Fig. 2. Characteristic impedances of H-88 cable pairs

A—Of 19 and 22 gage terminated at mid-section
B—Of 24 gage for various end sections

Furthermore, *H-88* loading is the only widely used arrangement recommended for future additions to the exchange-area plant. As a result of this investigation it was decided to develop a new repeater for *H-88* loaded cable circuits and to let future demands determine the necessity for other types of networks.

The field of use of the *E6* repeater is similar to that of the *E23* in short-haul trunks and special-service lines wherever moderate gains suffice. Its freedom from 130-volt power needs, however, suits it ideally to many situations where provision of power for *E23* repeaters would have been too costly. It will be widely used in trunks between offices in the same exchange area: local-to-local, local-to-tandem, and local-to-toll.

In the *E6* repeater the functions of impedance matching and gain production have been separated. Instead of matching the repeater to the line, the line is matched to the repeater. This may seem trivial but it results in a repeater which is easier to adjust and which has better transmission performance. The impedance transformation is made by a passive network called the line-building-out network (LBO), which is connected between the loaded line and the gain unit as shown in Figs. 3(A) and (B). This network transforms the impedance presented by the loaded pair for different end section lengths and wire gages to a constant value which, in the case of *H-88* loading, is made equivalent to an impedance of 900 ohms in series with 2 μf (microfarads). This impedance at the line terminals having been obtained, the complex gain network of the *E2* and *E3* repeaters can be replaced by a much simpler structure. The adjustable gain network is reduced to an adjustable resistor which is relatively easy to change.

Figs. 3(A) and (B) show the schematic connection of an *E6* repeater to lines at a circuit terminal and also at an intermediate office. The LBO network is always connected between the gain unit and cable pairs. One LBO is required for a terminal repeater and two for an intermediate repeater. On the office side of a terminal repeater a dummy LBO furnishes the connections between the converter and the line contacts on the plug.

LBO Network

The input impedance of an *H-88* loaded cable pair was shown as a function of frequency in Fig. 2(A) and as a function of both frequency and end section length in Fig. 2(B). A function of one part of the *E6* LBO network is to build

out or extend the cable end section to give the same impedance as that of a full-length end section (6,000 feet for *H* loading). This is done with shunt capacitors and series resistors shown on the left side of Fig. 4.

The impedance of a full-length end section of loaded cable at frequencies above about 1,000 cps (cycles per second) resembles the impedance of a constant-*K* low-pass filter. This impedance can be simulated closely by the network shown on the left side of Fig. 5. It is possible to design a complementary network that can be inserted in series with the full-length end section impedance to achieve a nearly constant input resistance over a wide frequency band. This type of network is shown on the right side of Fig. 5.

The high-frequency corrector (HFC) portion of the LBO network, shown in Fig. 4, is such a complementary network. The value of these components is fixed and is determined by the type of loading and the mutual capacitance of the cable pair. Use of the 3-winding transformer inserted in both sides of the line gives good longitudinal balance. The transformer is deliberately designed to introduce inductance into both conductors shunted by the resistor and capacitor connected in the third winding. This part of the LBO network presents a nearly constant resistive impedance to the gain unit at frequencies above the cable cutoff frequency where the full-section cable pair impedance becomes very low. The reactance of this portion of the network corrects the reactance of the cable pair impedance at, and just below, the loaded pair cutoff frequency.

The impedance of a built-out section of 22-gage *H-88* loaded line and the impedance inserted by the HFC are shown in Fig. 6. The sum of the two can be compared with the desired value of an impedance of 900 ohms in series with 2 μf. Between 1,000 and 4,000 cps the design input impedance is closely matched, and this is done with low insertion loss. The deviation in *R* and *X* below 1,000 cps is taken care of by the low-frequency corrector (LFC) branch of the LBO network. This rising impedance is reduced by the shunt-connected branch shown in Fig. 4. A capacitor is included in series with this branch of the network to prevent a d-c path from the tip to the ring conductor which would bypass d-c supervisory current flowing in the cable pair. Unfortunately, this capacitor does degrade dial-pulsing and other types of low-frequency signaling. Its impedance is therefore made as high as permissible.

The LBO for *H-88* loaded cable circuits as shown in Fig. 4 thus consists of four parts:

1. A building-out capacitance (BOC).
2. A building-out resistance (BOR).
3. An HFC.
4. An LFC.

The function of each of these sections of the network is described below.

THE BOC

The BOC network is connected across the cable pair, at the repeatered point, for building out the cable end section capacitance to that of a full section of cable. It can compensate for irregularities between

the office and the first loading coil and for office cabling. Seven capacitors are provided in the network to provide a capacitance from zero to 0.10 μf in 0.001-μf steps. Each capacitor is terminated in a screw-type terminal and may be inserted or removed from the network by opening or closing a screw. A chart is available showing which particular screws must be tightened or loosened to obtain the desired value of capacitance.

The BOR

The BOR resistors are connected into the network for building out the cable end section resistance to that of a full section of cable. The BOR is used largely for 22- and 24-gage cable conductors and is made up of three pairs of accurately balanced resistors connected to screw-type terminals. The six resistors have a total value of 196 ohms adjustable in steps of 28 ohms.

The HFC

The HFC network inserts series impedance to make the cable, as built out to a full section by the BOC and BOR, look like a constant resistance through and beyond cutoff. In balanced circuits two precise series networks would be required to preserve the line balance for longitudinal currents. Through the use of transformer techniques, a high degree of balance is secured by a single *R-C* (resistance-capacitance) network. Such an arrangement results in reduced size of components by appropriate application of the impedance transformation available in the design of a 3-winding transformer. Since the same value of series impedance is required for all gages of cable of a given capacitance and loading, no adjustment for gage is provided in the HFC network.

The LFC

The impedance characteristic resulting from the addition of BOC, BOR, and HFC is one that approaches a constant resistance above frequencies of 1,000 cps. However, at frequencies lower than 1,000 cps the resistance and capacitive-reactance terms of the cable impedance increase in value and require correction. The LFC network, which consists of variable R-C and fixed *L* (inductance) components, adds shunt admittances across the built-out circuit to match more closely the converter impedance of 900 ohms and 2 μf. Since the increase in cable impedance, at low frequencies, is less for 19-gage than for 22- and 24-gage cable, the 19-gage corrector has the highest impedance and the smallest effect. Three adjustments are provided in the LFC network to assure the optimum adjustments for 19-, 22-, and 24-gage pairs.

When the LBO is associated with intermediate repeaters, less than full LF correction is applied because of the adverse effects of two networks on both signaling

and transmission loss. Since maximum return losses are not usually needed at intermediate locations, a somewhat lower correction factor can be employed in these cases than is required for terminal repeaters. Two additional adjustments have been included in the LBO to select the optimum adjustments of the LFC for terminal or intermediate use.

Performance

Fig. 7 shows typical return loss in 19-, 22-, and 24-gage uniformly loaded cables for an adjusted LBO network. These are for the echo range, 500- to 2,500-cps sweep, and also for a 2,000- to 3,000-cps sweep. Note the degradation in return loss when the end section length exceeds 5,800 feet. At this length the BOC in the network has been reduced to zero μf, and no adjustment range remains.

These return losses were measured against an impedance of 900 ohms in series with 2 μf. This is the impedance that matches the average impedance of subscriber loops and to which hybrid networks are built in an office of a 900-ohm nominal impedance. This impedance provides low reflection between a 4-wire terminating set and a trunk equipped with an *E6* terminal repeater, or between the repeater and most subscriber loops. Thus low reflection is obtained either with the repeater located at the point of connection to an intertoll trunk or with the repeater located at the end office.

Gain-Unit or Converter Circuits

The gain unit is the active or amplifier portion of the repeater. It corresponds to a 4-terminal gain pad adjustable to an image impedance of 900 ohms in series with 2 μf and from zero to 13 db in gain. As with the *E23* repeater, the gain unit consists of a series-connected and a shunt-connected converter in a bridged-T connection. A common coupling transformer

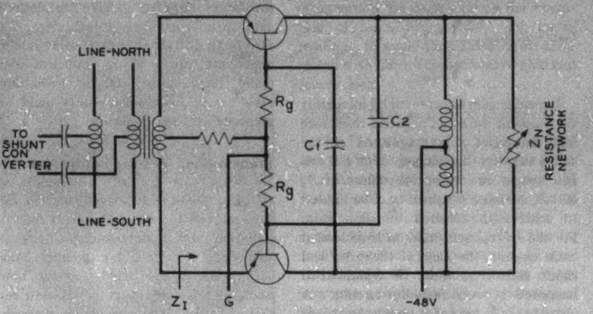

Fig. 9. Simplified schematic of series negative resistance converter circuit

having an impedance ratio of 1 to 9, is used for joining the series and shunt elements together to form a 4-terminal network. The negative series impedance is introduced into the line by a pair of balanced windings on the line transformer and the shunt admittance is bridged across the mid-points of the two line windings. A schematic circuit of the gain units of the *E6* repeater is shown in the diagram of Fig. 8.

The negative impedance series converter is a 4-terminal network consisting of a transistorized positive-feedback amplifier, designed to be open-circuit stable, and a variable resistance network.

A simplified schematic of the series negative converter is shown in Fig. 9. The series-connected converter is a 4-terminal circuit whose impedance at the "input" terminal *T1* is the negative of the value of adjustable resistance connected in the network. This type of circuit using transistors has been described by Linvill.[3]

When C_1 and C_2, the feedback capacitors, are made large and have low impedance relative to R_1, the ratio of E_1 to I_1, which is the input impedance, is given by

$$\frac{E_1}{I_1}=(1\text{-}2\alpha)Z_{\text{net}}+2r_{\text{emit}}+(1-\alpha)2r_{\text{base}}$$

The resistance of r_{emit} is a few ohms at the emitter current value used and the ratio of Z_{net} to r_{base} is such as to make the third term a few per cent. Ordinarily the transistor α is about 0.97, so that the input impedance is nearly equal to $-Z_{\text{net}}$. Since the α's of good transistors may vary, the negative impedance or conversion ratio is dependent upon the proper selection of transistors. In typical units, which have initial α's between 0.95 and 1.0, the 5% spread between units would result in a 12% change in the ratio of Z_{in} to Z_{net}. Possible aging of the transistors would further degrade the performance, and this extent of variation is intolerable when the design requirements allow a maximum deviation in gain of only ±0.2 db for each converter.

The compound transistor circuit suggested by Darlington[4] and shown in Fig. 10 provides a method of improving the performance of the converter unit. In this array a second transistor is added to each half of the push-pull circuit, shown in Fig. 9, collecting the current loss in the base of the original transistor and returning it back to the collector. In effect these two transistors with relatively poor α's form a compound unit with an α of essentially unity. In this case α compound, α_c, is equal to $\alpha_c=1-(1-\alpha_1)(1-\alpha_2)$, where α_1 and α_2 are the α's of the individual units. For example, new transistors with α's between 0.94 and 1.0 will result in an α_c between 0.996 and 1.0 to stabilize the conversion factor. As a result, the initial and aging requirements for the transistors can be relaxed and the uniformity of repeaters made dependent upon the precision of other passive components.

The shunt converter is similar to the series converter except that the circuit functions are reversed. The negative impedance is derived at the collectors rather than at the emitters of the transistors. In addition, a phase-shifter network has been included in the positive feedback path to control the impedance of the combined series and shunt converters. This network makes the repeater impedance appear to be 900 ohms in series with 2 μf to balance the LBO network.

Transformers *T1*, *T2*, and *T3* are used to couple the series and shunt negative impedances to the cable pair. They remove d-c supervisory voltages from the series and shunt converters, and permit d-c pulsing on the cable circuit. The transformer *T1* functions as a bridged-T structure with both the image impedance and gain controlled by varying the values of the series arm Z_A and the shunt arm Z_B.

If the image impedance of the repeater is made equal to the image impedance of the line, as modified by the LBO network, no reflections will occur. The circuit gives gain in both directions of transmission.

In the *E6* repeater the series converter Z_A inserts a negative resistance of $-R$ into the line with no phase shift. The shunt converter Z_B, which includes a phase-shifting network shown schematically in Fig. 11, presents a shunt impedance of $Z\underline{/180-\theta}$.

An important feature of this method of operation is that the desired magnitudes and phase angle of the repeater can be obtained by using only resistor elements in the gain-adjusting networks. The insertion gain of the combination repeater, when facing its image impedance on both sides, is

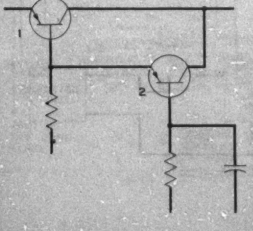

Fig. 10 (left). Compound transistor arrangement used in E6 gain unit

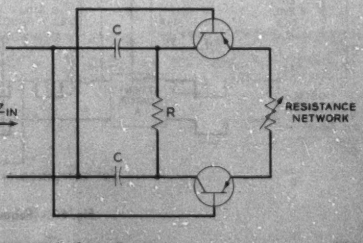

Fig. 11 (right). Simplified schematic of phase shifter in E6 shunt converter

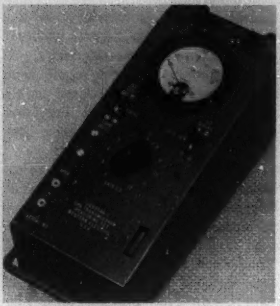

Fig. 12. The 54A transmission measuring set

$$\text{Gain} = 20\log_{10}\frac{1+\sqrt{\dfrac{Z_A}{4Z_B}}}{1-\sqrt{\dfrac{Z_A}{4Z_B}}}$$

Repeater gain is increased by increasing the value of the series negative resistance and decreasing the magnitude of the shunt negative impedance. For a specified image impedance, the values of Z_A and Z_B are fixed and must be co-ordinated to achieve the desired insertion gain. For the *E6* repeater, used on *H-88* loaded cable circuits, the gains of the series and shunt converters must be equal when measured between 900-ohm circuits. A chart has been prepared giving the values of the series and shunt converter network resistances required to give the desired gain, in approximately 0.1-db steps, for zero to 13 db. If circuits of other image impedance are ever in sufficient demand, for example, 600- or 1,350-ohm cable circuits, additional charts could be prepared for these facilities.

Transmission Testing Equipment

One of the aims for developing the *E6* repeater was to reduce the costs for installation and maintenance. Considerable simplification and economies have been realized by designing three new pieces of test equipment for the new repeaters. The *54A* transmission measuring set is used to determine the gain of

the series and shunt converters, individually or combined, to insure that the proper impedance relationships have been set up to obtain high return losses between the converters and LBO networks. A companion unit, the *54B* test stand, provides a convenient device for holding the repeaters in an upright position for gain adjustments; it includes test jacks and keys for establishing connections to make return-loss measurements. The third unit, coded as the *54C* return-loss measuring set, is arranged to measure the return losses of the cable circuits, the cable circuit plus LBO, and the cable circuit plus LBO plus converters against a termination of 900 ohms and 2 μf, when optimum performance is required of the *E6* repeater. All three sets are designed for simplicity of operation, by co-ordinating the operation of keys, attenuators, and meter readings, to avoid the human errors associated with the measurements of gain and return loss.

THE 54A TRANSMISSION MEASURING SET

The *54A* set is used to adjust the gain and the image impedance of the converter or gain-unit section of the *E6* repeater. It is a portable transistorized device, shown in Fig. 12, which is used not only for initial repeater adjustments, but also for making periodic measurements of gain and signal-level carrying capacity of the converters to detect any deterioration of the transistors. All keys and switches are arranged so that measurements can be made quickly, to reduce repeater out-of-service time.

The transmission set consists of a 1,000-cps oscillator, two attenuators, a detector, and a meter circuit, designed to measure the gain of the series and shunt converter circuits between precise 900-ohm impedances. By measuring the insertion gain of series and shunt converters separately, and then adjusting these gains for equality, an image impedance of 900 ohms plus 2 μf is obtained for the combined unit.

The oscillator consists of an *R-C* type of bridge circuit, using two transistors, with the output level stabilized by including a small tungsten filament lamp in one arm of the bridge. A third power transistor, with a 12-db local negative feedback, acts as a buffer stage to furnish a +13 dbm output power for measuring purposes. The output impedance is adjusted, at the factory, to be within 900± 3 ohms.

The detector is a transformer-coupled, push-pull, class *B* transistorized amplifier with the indicating meter inserted into the common battery lead. The meter movement is reverse-biased, to provide a linear scale feature, and a readable scale range of 3 db is used for gain measurements. The meter face plate is calibrated to read zero at mid-scale for an input signal of +3 dbm, and covers a range of ±1.5 db in 0.1-db steps. Approximately 40 db of negative feedback is used to stabilize transistors and guarantee meter accuracy. Internal compensation is included in the set to correct for changes in transistor characteristics with temperature. Since the over-all accuracy must be better than 0.05 db to give reliable readings of 0.1 db, an internal calibration circuit is provided to take care of small deviations in the oscillator and detector output levels. The power supply, obtained from the central office 48-volt battery, is stabilized by means of a Zener diode regulator. The input impedance is adjusted to be 900±3 ohms at 1,000 cps.

A switching circuit and two built-in attenuators are used to measure gain and overload of the *E6* converters. Fig. 13 shows the connections used in calibrating the *54A* set and in measuring gain and overload with it. Repeater gains between zero and 13 db can be measured. For any gain the switching circuit will insert sufficient attenuation ahead of the converters to read an output of +3 db referred to one milliwatt. Upon operation of the load-measuring key, the input attenuator is

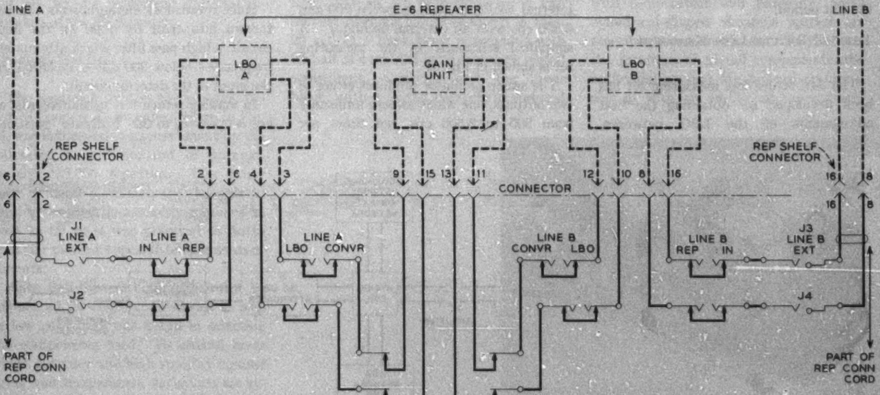

Fig. 15. Test connections provided by 54B stand

transferred to the output circuit for applying a high-level signal to the converters. With good transistors, the gain should not change more than the amount prescribed in the operating instructions. Larger reductions in gain indicate transistor impairment and probable cause for replacement of the devices.

The 54B Test Stand

The *E6* repeater cannot be adjusted on the relay-rack mounting shelf because, in this position, the adjusting screws for the LBO and converter networks are inaccessible. The *54B* test stand, shown in Fig. 14, has been developed to hold the repeater in place, to power it for installation and maintenance tests, and to provide convenient connections to various points for return-loss and trouble-location tests. The test stand consists of a rotating platform, turnable through 180 degrees; one position provides access to the converter unit adjusting screws, and the opposite side provides access to the LBO network adjusting screws. A test cord, plugged into the repeater-shelf connector jack, extends the line connections to the *54B* set. Forty-eight-volt power for operating the repeater is obtained from a socket provided on the relay-rack power distribution panel, and multiple outlets are available in the test stand for providing power to operate the *54A* and *54C* equipments. Fig. 15 shows the location in the circuit of the jacks provided for testing purposes.

A holding coil circuit is provided which gives a d-c path from conductor to conductor, on either side of the repeater. This prevents a previously dialed-up test termination from being released during the test period.

The 54C Return-Loss Measuring Set

The *54C* return-loss measuring set has been developed for obtaining the best adjustments of the LBO networks. Much of the improved performance of the *E6* repeater depends upon the optimum settings of these networks. Limited experience on several field trials indicates that the cable records do not always contain precise knowledge of the end section resistance and capacitance. The records appear to underestimate the capacitance of the end section by amounts which range from several hundred to 1,500 feet in length.

Adjustments made with the aid of the *54C* set compensate for the true end section resistance and capacitance and make it possible to secure better return loss for mixed gages and deviations in cable characteristics in the end sections. It is designed to give an integrated measure of return loss of the LBO network, repeater, and cable against a standard termination in the echo and singing bands. While its primary purpose is to determine the most favorable settings for the network adjustments, it can be employed to give a quantitative measure of swept band return loss. Ultimately, it may find broader applications in making similar adjustments of impedance compensators and precision networks associated with 2-wire toll-connecting trunks and for cable acceptance tests. Jacks are provided so that an external oscillator may be used with the hybrid coil and detector portions of the set.

The *54C* set, shown in Fig. 16, is a return-loss measuring device consisting of a sweep oscillator, a detector and a meter, a single-coil hybrid, and a compromise network of 900 ohms in series with 2.16 μf. Return losses from -13 to $+45$ db can be measured over the frequency band from 500 to 2,500 cps with the internal oscillator, and between 200 and 3,300 cps with an external oscillator. A simplified schematic of the measuring set is shown in Fig. 17.

The sweep oscillator produces either of two outputs, one which sweeps uniformly from 500 to 2,500 cps, ten times per second, and the other which sweeps from 2,000 to 3,000 cps at the same rate. The output signals are amplified by a 2-stage transistorized circuit to produce the desired sweep frequency test power.

The 2,000- to 3,000-cps sweep is used for adjusting the BOC of the LBO network which is most critical at the higher audio frequencies. The 500- to 2,500-cps sweep is used to adjust the BOR and LFC portions of the LBO network.

The hybrid coil is a 600- to 10-ohm ratio transformer which will hold calibration throughout the range of return-loss values measured. Terminals are available on all four sides of the hybrid coil for connection to external test equipment, such as a single-frequency oscillator, to detectors and to networks. The transformer is not designed to permit direct current to flow through the line windings. The internal 900-ohm plus 2-μf network has no d-c path and therefore can have a signal voltage present across the cable pair without having direct current flow through the hybrid coil.

The detector is a 4-stage transistorized amplifier and rectifier whose output is fed into a d-c meter. Approximately 45 db of negative feedback is used to stabilize the transistors and to improve the linearity of rectifier and meter. An input attenuator, calibrated in 10-db steps, is used to keep readings on the meter scale. The meter is shunted by a capacitor which integrates the received power throughout each 1/10-second sweep to produce a steady meter reading. Response of the detector is approximately linear to changes in the level of the input signal, and it measures the average return loss of the frequency band being swept.

Since return-loss measurements can be thrown into error by noise on the line circuit, a high-pass filter which attenuates frequencies below 200 cps is included in the input of the detector circuit.

In making return-loss measurements, a key is operated to the "calibrate" position

and the output of the sweep oscillator is adjusted for a zero-db reading on the meter scale. Restoring the key to the "measure" position and adding or removing loss from the input attenuator to bring the meter reading on scale will give the return loss as the difference between two readings. Attenuator and meter readings in red indicate negative return losses; black readings are used for positive return losses.

The *54C* is powered from the 48-volt office battery obtained from the power-distribution panel or from a multipled outlet in the *54B* test stand. Fig. 18 shows a typical arrangement of the *54A*, *54B*, and *54C* sets for measuring gain and return loss of the *E6* repeaters.

Physical Design

The approach used in the physical design of the new *E6* repeater, shown in Fig. 19, was influenced to a great extent by the estimated annual demand of approximately 125,000 repeaters. This fairly large demand permitted the designer to consider automatic assembly methods at least as far as it was practical to do so with our present types of telephone components.

Since Bell System equipment must be engineered for continuous service as well as low cost, care was taken in selecting the components used. In critical areas where accuracy and high stability against aging and temperature variations are required, small wire-wound resistors with 1/2% and 1.0% tolerances are specified. In other cases, it was satisfactory to use deposited-carbon types, mostly with 1.0%, but some with as high as 5.0%, tolerances.

Metallized mylar capacitors were selected because of their accuracy, small size, and low cost. The line coil is a new design precision transformer with provisions for adjustment of both inductance and d-c resistance to close limits.

The transistors employed are of the Western Electric Company alloy p-n-p germanium type.

The method selected for mounting this variety of components is the so-called matrix structure or sandwich type. The structures of the converter and the LBO network are each made up of two molded phenolic blocks as shown in Figs. 20 and 21. Each block is provided with its half of a molded cavity for each pigtail component. Consider first the lower block: with a pigtail component inserted in its proper cavity, the one lead wire is extended through a hole in the bottom of the cavity and then through a printed wiring board which is attached to the bottom side of the block. When all pigtail components have been placed in this manner, the second or top block is fitted to complete the sandwich structure. The top block, molded with the proper cavities, is also equipped with a printed wiring board which will receive the second lead wire of the pigtail components. When the matching halves of the phenolic block are put together, they form a closed housing for the pigtail components.

To compensate for dimensional changes with temperature and humidity, small cylindrical-shaped neoprene spacers are placed between the blocks. To facilitate the insertion of pigtail components, the individual cavities are tapered or funnel shaped with an additional tapered sec-

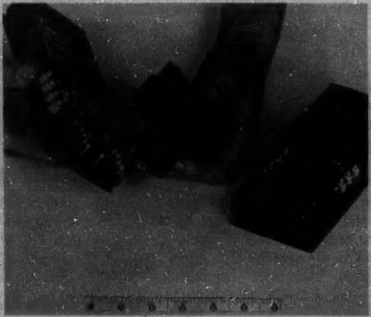

Fig. 20. Converter assembly

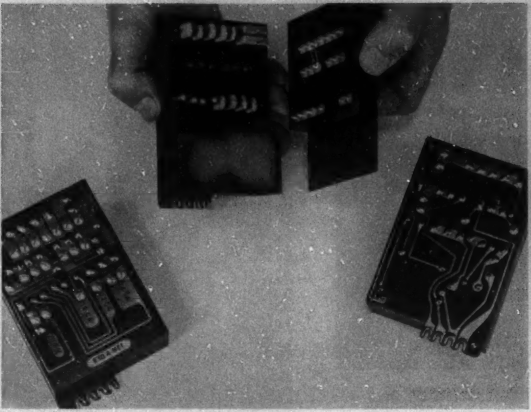

Fig. 21. LBO network

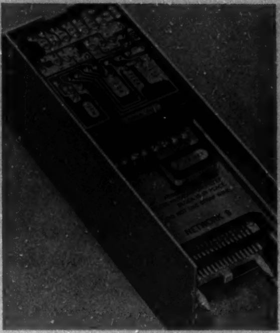

Fig. 23. The E6 repeater for terminal use

tion at the base to guide the pigtail lead wire through to the printed wiring board. The pigtail leads are precut to proper length and no clinching is performed for connections to the printed conductor. All connections are dip soldered.

Components, other than pigtail types, such as transformers and inductors, are assembled in open cavities that are entirely part of the bottom block without a matching top section. Following test and adjustment of these components, the cavities are filled with a microcrystalline wax and protected with a metal plate in the case of the converter and with a printed wiring board for the LBO network. The transistors are an exception to the cavity method of mounting because of the problem of heat transfer, and to facilitate replacement. The shelf arrangement on the lower block of the converter provides a mounting surface for the transistors, as shown in Fig. 20.

Each adjusting screw in the converter and LBO networks is provided with a captive washer which bridges or opens a gap between two printed wiring conductors. To insure reliable contacts the captive washers are gold plated and the printed conductors have a hot tinned finish. To guard against vibration, a nylon nut, located in the molded cavity of the top phenolic block, is used for the adjusting screw.

When the converter and the associated LBO networks have been assembled in their matrix structures, the electric connections between the two are made by means of screws. The comblike protrusion in the phenolic block on one end of the LBO network, shown in Fig. 21, consists of four open-end brass grommets, soldered to the printed wiring and arranged to receive the screws that go into tapped metal bushings located on the converter. The bushings have a terminal arrangement that permits soldering connections to the printed wiring.

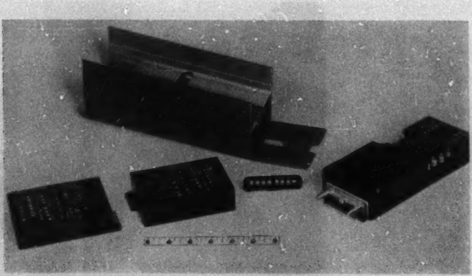

Fig. 22. Aluminum housing and networks

The printed wiring boards used in this assembly are made from a paper-base phenolic, grade *XXXP*, 1/32 inch thick and clad with 2-ounce copper on one side. The conductor width is 1/16 inch and a minimum spacing of 0.050 inch between adjacent conductors has been specified. To maintain a higher order of insulation resistance, two spray coats of clear lacquer are applied to the exposed board surfaces following final assembly.

The *E6* repeater is a plug-in unit and all external connections are made by means of a newly designed plug and connector. The connector has 16 dual-contact forked terminals spaced 1/8 inch apart in a molded block. The assembly is such that a floating action of each terminal is obtained. The terminal is made from phosphor bronze and is gold plated on the contact end. The wiring end is arranged for solderless wrapped connections. The over-all length of the connector is slightly less than 3 inches.

The plug has 16 gold-plated phosphor bronze contacts molded in a strip. These contacts engage the forks of the associated connector. The terminal ends of the contacts are arranged to be dip soldered to one of the printed wiring boards of the converter. In addition, provision is made for securing the plug with two screws to a separate guidance detail. This detail, which is an aluminum die casting, is designed to relieve the plug and connector of strain. When the repeater unit is plugged in on its mounting shelf, the tapered prongs of the guidance detail align the plug and the connector prior to engagement. A spring catch on the shelf engages one of the guidance prongs and locks the repeater in place.

The converter and the associated LBO

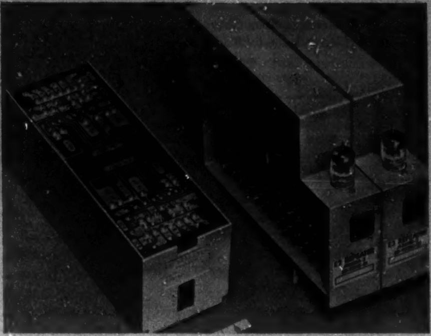

Fig. 25 (right). Comparison of E6 repeater with E2 and E3 repeaters

networks must, of course, be assembled into one complete working repeater unit. For this purpose an aluminum housing was designed; see Fig. 22. This consists of an H-shaped extrusion, smooth surfaces on the outside but provided with rails on the inner surfaces, and equipped with a small hinged door at one end. These rails match grooves in the phenolic blocks of the converter and LBO networks. The converter slides into position in the housing below the center rib, with the 16-contact plug facing the open end, or rear, of the unit.

The first LBO network slides into the housing above the center rib end from the front-door side. The second LBO network (assuming an intermediate repeater) slides into the housing above the center rib but from the opposite end. At approximately the middle of the housing there is a cutout in the center rib. Through this cutout the electric connections between the LBO networks and the converter are made by means of screws. When these connections are made, with the use of a molded spacer or filler block that drops into the center rib cutout, all the required parts making up a repeater unit are then interconnected and locked in place within the housing. For a terminal application of the repeater only one LBO network is required. In this case it is necessary to use a dummy network in place of the second LBO network, as shown in Fig. 23. Electrically, this dummy unit simply provides a wiring path from one side of the converter to one of the line connections.

The over-all dimensions of a complete repeater unit are $9^{19}/_{32}$ by $3^{3}/_{8}$ by $3^{9}/_{16}$ inches, and the weight of an intermediate repeater is $4^{1}/_{4}$ pounds.

In service the *E6* repeater unit is supported on shelves mounted on relay racks. The shelves are aluminum die castings made in two sizes, one for 19-inch racks holding five repeaters, and one for 23-inch racks holding six repeaters. These shelves, one of which is shown in Fig. 24, are so designed that the repeater is guided into position to engage the connector. The repeater is then automatically locked in place as described previously. As shown in Fig. 19, monitoring jacks of the installed repeater are accessible through a cutout in the door of the repeater housing. The jacks are actually mounted on the printed wiring boards of the converter. When it is desired to remove the repeater from service, the hinged door of the housing is opened and this automatically disengages the plug from the connector. The repeater unit may then be easily removed from the mounting shelf. The door action referred to here is obtained by a built-in cam in the hinged portion of the die-cast door.

A variety of relay-rack arrangements is available in order to satisfy various operating conditions. These details are beyond the scope of this paper; it is of interest to note, however, that the new design requires only half the space of the *E2-E3* electron-tube repeater. For a comparison, see Fig. 25.

Engineering

The fundamental difference between *E23* and the *E6* repeaters means that different techniques are used in the latter's application to the telephone plant. Both the design of an *E6*-repeatered circuit and its subsequent in-service line-up are different from the design and line-up of its predecessor.

The job of the circuit designer in using an *E6* repeater is twofold. He must first determine the effect the repeater will have on the circuit: the amount of available gain, the effect on signaling ranges, crosstalk and overload considerations, and the like. In short, he must determine if the repeater will do for the circuit what needs to be done. Second, he must determine the information the installation man will need to do an efficient line-up job. This in general involves giving the installer instructions for initial repeater adjustments so he will have a starting point for his line-up procedures.

One advantage of the *E6* repeater over the *E23* is that as an intermediate repeater it can be used between different types of facilities without sacrificing performance. For example, an *H-88* high-capacitance LBO network transforms line impedance to 900 ohms in series with 2 μf; a *D-88* high-capacitance network transforms an appreciably different line impedance to the same 900 ohms in series with 2 μf. The image impedance of the gain unit therefore can match the line in both directions. It should not be inferred, however, that the impedance of any type of cable facility can practicably be transformed to 900 ohms in series with 2 μf, but only line impedance not greatly different from 900 ohms. And only when line impedances on both sides of intermediate repeaters are transformed to the same value can the repeater match them both.

FACTORS CONTROLLING TOP GAIN

In the design of an *E6* repeatered circuit the allowable gain available from the repeater depends upon the return loss at the critical frequency, as seen by the repeater in both directions. These return losses are measures of reflections from the ends of the facility, structural imperfections, and irregularities in the intervening cable facilities, all referred to the location of the repeater. This is in line with conventional *E*-repeater design techniques where the repeater gain is

limited by the need to avoid singing and near-singing.

The terminal return losses used at the end of a trunk depend upon whether or not idle-circuit terminations or gain disablers are used. If they are not, a zero-db return loss (total reflection) is used since the circuit is open in the idle condition. If they are, a terminal return loss of 4.5 db is assumed at the originating end.

The structural return loss of the intervening cable facility depends upon the capacitance deviations in the cable itself, the inductance deviations in the loading coils, and the regularity of the load spacing. Preferably, the structural return losses used in designing an *E6* repeatered line would be measured values obtained in connection with cable completion tests. The use of such values permits obtaining the maximum possible gain from the repeater. In the absence of such data, estimates can be based on typical deviations of capacitance and inductance and on known load-spacing deviations.

It should be noted that the charts of allowable gain are based on return losses at the critical frequency, since the gain is limited by singing. The echo return losses used for terminal-link calculations in the Nationwide Switching Plan are not the same values, and they will lead, if used for this purpose, to improper repeater gains.

The terminal return losses are referred to the repeater location by adding twice the intervening loss. Of course, any lumped irregularity, such as a junction of two dissimilar facilities, a load-spacing irregularity of a piece of equipment, is also referred to the repeater. The various return losses are then combined on a power basis to obtain the return loss to be used in determining repeater gain.

One divergence in method arises here, because of the differences between the *E23* and the *E6* repeaters. The return losses upon which the repeater gains are based are those referred to the terminal of the *gain unit* through the LBO networks. Therefore, the losses of the LBO's are added to those of the cable facilities in referring the return losses. The losses of the LBO's, of course, depend upon how much building out they contain.

SETTINGS OF LBO NETWORKS

The LBO networks are designed to build out the impedance of the cable facility to 900 ohms in series with 2 μf so that it matches the repeater. As shown in Fig. 4, the LBO consists of an adjustable R and C line build-out, a fixed, HFC, and an adjustable LFC.

Adjustment of the R and C line build-out, of course, is related to length and gage of the cable end section to be built out. For engineering purposes, tables such as Tables I and II relate the length and resistance of the cable end section to the proper values of BOC and BOR.

The LFC is adjustable for gage only: 19, 22, or 24. For mixed gages adjustment is best made by trial during the line-up. For the rather usual case where finer-gage cable adjacent to the repeater does not extend out of the end section, guides are available with which the designer can specify approximate adjustments as line-up starting points.

The loss of the LBO is the sum of two parts: 0.3 to 0.5 db for the LFC, depending on gage; and the loss of a length of cable (simulated by the LBO) needed to build out the actual end section plus office cabling to 5,800 feet. Loss per unit length of the *loaded facility* is used in computing this latter part.

GAIN SELECTION

The allowable gain of the gain unit is shown on the chart in Fig. 26 as a function of the critical-frequency return losses referred to the repeater. Since this chart gives allowable gain of the gain unit by itself, the losses of the LBO networks must be included in determining the over-all losses of a circuit.

This limitation of gain given in the

allowable-gain chart is designed to provide adequate margin, in the order of 8 db in the average situation, against repeater-singing in service. This may seem excessive but it should be remembered that return losses representative of a group of circuits were used in the calculations, and that therefore many circuits will have margins considerably less than this.

The allowable gains of the *E6* repeater are higher than those of the *E23* for equal return-loss values by one db or more. High cable structural return losses are necessary to develop this additional gain. Representative structural return losses of at least 20 and preferably over 25 db at the critical frequency are necessary to exploit fully the additional gain capabilities of the *E6* repeater.

Crosstalk is generally a controlling factor only where the repeater is used at the end of a circuit, at which point the disturbing talker levels are high and the customer experiencing the crosstalk may be located quite close to the repeater. For the typical *22H-88* facility, maximum gains in the gain unit of about 7 db are recommended in the terminal situation. Intermediate repeater gains may of course be higher and are generally controlled by stability. Crosstalk coupling in the old nonstaggered twist cables, put in use around 1920 and before, is likely to be so high that repeaters with such cables are not recommended.

Effects on Signaling

The effect of the *E6* repeater on signaling must also be considered in the design of the circuit. The repeater not only passes but amplifies audio-frequency signals, such as single and multifrequency. It does, however, adversely affect the various low-frequency signals in different ways.

D-c supervision and 20-cycle ringing can be passed through the repeater without need for bypassing, subject, however, to the maximum loop-current limitation of 60 milliamperes. The increase in loop resistance caused by inserting the repeater depends upon whether it is a terminal or intermediate repeater, as well as upon the amount of building out used in the LBO network. An idea of the range of reductions involved may be gleaned from Table III which gives minimum and maximum effects.

In addition to the above loop-resistance effects, the shunt converter of the *E6* repeater bridges a capacitance across the pair. This has a distorting effect on pulse signals. The effect is quite complex and depends upon the length and resistance of the cable pairs and the type of central office and signaling systems used, as well as upon the adjustment of the relays in the signaling system.

Table III. Range Effects on Loop Signaling E6 Repeaters

	Loop Resistance, Ohms	
	Minimum Terminal E6, No Building-Out	Maximum Intermediate E6, Maximum Building-Out (Both Sides)
Supervision	65	482
20 cycles	400	792

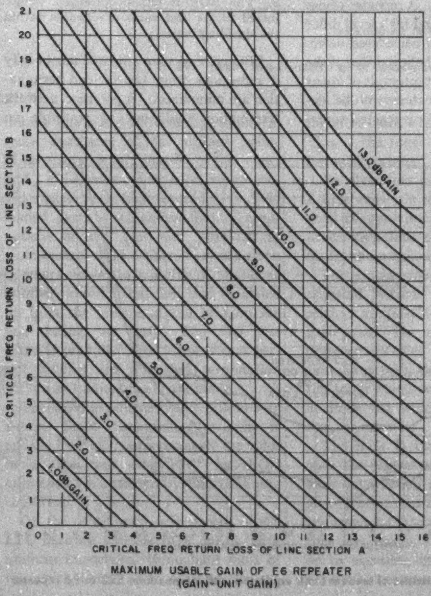

Fig. 26 (left). Maximum usable gain of E6 repeater (gain-unit gain)

In general, the distortion caused by the *E6* repeater is within operating margins for dial pulsing and revertive pulsing into crossbar offices and for panel-call-indicating (PCI) signals. Operation of certain revertive pulsing into panel offices and certain types of dial pulsing into step-by-step offices is adversely affected by the use of an *E6* repeater. The effect of the *E6* on pulsing has been summarized for the design engineer on a group of charts, which indicate certain restrictions that pulsing circuits impose on its use.

Example of Design

Let us take a typical example of an *E6*-repeatered trunk and go through a design calculation. Assume an 8-mile direct trunk using *24H-88* facilities as shown in Fig. 27. The trunk connects two offices with a signaling range of 2,400-ohm loop resistance. A terminal *E6* repeater is used. The representative stuctural return loss at the critical frequency has been found to be 26 db. No gain disablers or idle-circuit terminations are used.

The setting of the LBO are as follows: The 2,800-foot cable end section has a loop resistance of 145 ohms. From Table I the proper building-out resistor is found to be 84 ohms, obtained by screwing down the no. 1 screws. From Table II for a 2,800-foot end section of 24 gage, the proper BOC is found to be 0.043 obtained by turning down screws *A*, *C*, *E*, and *F*. The loss of the LBO is that of 5,800−2,800=3,000 feet of *24H-88* plus 0.5 db or 0.7+0.5=1.2 db.

The next step is to determine the return loss at the repeater. The terminal return loss is referred through the cable and LBO losses. The structural return loss is referred merely through

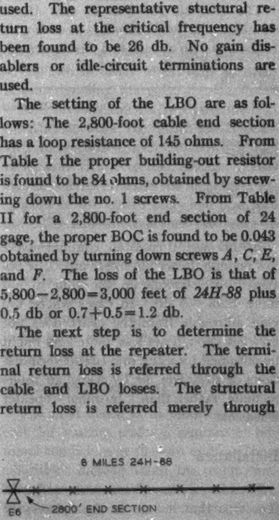

Fig. 27 (right). Typical example

the LBO loss. Both are then combined on a power basis.

$$\left.\begin{array}{l}\text{Terminal RL}\ .0+2(9.8)+2(1.2)\\ \qquad\qquad =22.0\\ \text{Structural RL}\ 26+2(1.2)\\ \qquad\qquad =28.4\end{array}\right\}=21\ \text{db}$$

where RL = return loss.

The central office side of the repeater, of course, presents a zero-db return loss, since no disabler or idle-circuit termination is assumed. The chart of maximum usable gains shows a gain-unit gain of 8.5 db for return losses of 21 db and zero db. Since this is a terminal repeater, crosstalk would normally limit this gain to about 7 db, although with modern unit-type 24-gage cable, the crosstalk characteristics might possibly permit the 8.5 db. Assume conservative designing, and use 7 db of gain.

For the benefit of the line-up man, 7 db of gain is specified, and if desired the proper screws to turn down can also be specified from a chart (in this case screws *C*, *E*, *J* and *2*, *4*, *5*, *7*, *8*).

Checking the signaling situation, add the loop resistance of the cable to the repeater resistance.

	Ohms
Cable, 8.0 miles, 24 gage	2,190
Gain unit of repeater	40
Building-out network (25 and 84)	109
Total	2,339

This meets the 2,400-ohm signaling range of the office.

The over-all net loss of this trunk should also include office loss at each end. If about 0.5 db at each end were assumed the over-all net loss would be as follows:

	Decibels
Cable facilities	9.8
Office loss	1.0
LBO	1.2
Total	12.0
Gain-unit gain	−7.0
Net loss	5.0

In this case, if crosstalk couplings were low enough, lower net losses might be obtained by stepping up the gain to not more than 8.5 db. In cases where top gain allowable from the chart does not give low enough net loss, more gain might be obtained by using idle-circuit terminations or disablers, or by using an intermediate, rather than a terminal, repeater if feasible.

Installation

Thus far, we have been concerned with the steps that led up to the delivery of the *E6* repeater at the place where it will be used. We known how it should perform in any given circuit; now, how will it deliver the expected performance?

Choice of LBO

A specific type of LBO network is needed for each type of cable loading. Initially, LBO networks are being produced for *H-88*-loaded and certain *D-88*-loaded facilities.

Adjustment of Gain and Image Impedance

Tables are available showing the screw adjustments needed to provide various gains. After the adjustments are made in accordance with the engineered gains, the gains of series and shunt elements of the gain unit are measured separately with the aid of the *54A* and *54B* sets as a check of image impedance. The image impedance of the two units together is correct if the gain of the series unit by itself equals the gain of the shunt unit by itself.

After the series converter and shunt-converter gains have been measured, and if necessary readjusted, the gain of the gain unit as a whole is measured and recorded on the front of the repeater as a reference from which drift can be computed.

Gain at higher than normal input level is measured using the *54A* set as a check of transistor condition. A repeater whose gains at normal level and high level differ by more than 0.4 db is considered defective. At present, it is believed that if the overload test is made at intervals of about a year, defective repeaters will be detected before they can have reacted appreciably on service. Experience may modify the present view of a desirable test interval.

Since the LBO network accomplishes the impedance match between cable facilities and the gain unit, its optimum adjustment is the essence of the high-grade performance of the *E6* repeater. Ideally, each LBO should be adjusted individually to the cable pair to which it is assigned. Practically, all LBO's in a group may be adjusted alike, with small sacrifice in performance if the group of facilities to which they are assigned is uniform and free from troubles.

The optimum adjustment of LBO networks is accomplished with the *54C* return-loss measuring set. This set consists of a sweep generator, a hybrid arrangement permitting direct optimizing of return loss, a transistorized detector, and controls. It is powered by 48-volt central office battery, but also uses 60-cycle power to control output frequencies through synchronous drive. Fig. 16 shows the sweep return-loss measuring set.

To start, the LBO networks are set at close to optimum adjustment, from knowledge of the type of facility and end section. Next, three separate adjustments are made in the following order:

1. The BOC is optimized.
2. The best LFC network is selected.
3. The BOR is either optimized or adjusted to the best value practicable within the signaling limits.

LBO networks are adjusted most easily if reflections from the far-end termination are minimized. A precision network termination built out to resemble an

14	20.3	17.0	22.0	18.0

Fig. 29. Return loss characteristic of tandem trunk equipped with intermediate E23 or E6 repeater

infinite line would be ideal, but would require assistance at the distant point. If necessary, a termination of 900 ohms and 2 μf in series can be used, which provides moderately high return loss to *H-88* loaded pairs of 0.5 end section. Terminations of this kind are provided in most central offices, where they are given numbers similar to subscribers' telephone numbers in order that they may be dialed up from the other end and held on the line during the tests. The *54B* test stand is provided with features that permit holding up a dialed termination while LBO adjustments are made.

The BOC is adjusted with a 2- to 3-kc sweep. Since the singing margin is usually least at the upper end of the voice band, the best sensitivity for BOC adjustment is obtained by thus confining the sweep.

On the other hand, adjustment of the LFC network and the BOR are of fairly uniform importance throughout most of the voice band. The adjustments are therefore made with a 0.5- to 2.5-kc sweep. This is the range in which echo return loss is important.

To save time in optimizing, the BOC is first varied in steps of about 0.004 μf until an approximate maximum is reached. Finer variations may then be made to attain the maximum.

For single-gage trunks, the LFC is adjusted without test, since standard settings are provided for 19-, 22-, and 24-gage pairs. For mixed gages, the circuit designer specifies a setting from rules that have been determined empirically; the tester starts with this setting, but if he finds one which gives higher return loss, he uses it.

The BOR is then adjusted. Starting with the suggested resistance, the tester finds out whether a lower or higher value gives greater return loss. He always uses the resistor that provides the highest return loss except when an upper limit is set by signaling limitations. In case two different resistance settings give the same high return loss, he uses the lower of the two in order to provide all practicable signaling margin.

After all adjustments have been made in the LBO network, the return loss is measured and recorded, both with 0.5- to 2.5-kc sweep and with 2- to 3-kc sweep. These measurements indicate the structural excellence of the loaded pairs and how well the LBO network matches the pairs to the gain unit. They are useful for reference in case of cable trouble.

If the repeater is an intermediate one, the LBO network on the other side of the repeater must be adjusted. This is done in the same way as the first, but entirely independently.

Monitoring Check and Test Call

The final check is to monitor the circuit for singing under a number of terminal conditions at the two ends. These conditions include about the worst combinations that could occur at any time. If no singing occurs under any of these conditions, then it probably will not occur in the idle condition, during dialing, in switching, or in service. If singing does occur in any of the test conditions, the gain must be reduced until the trouble can be cleared.

All that now remains is to remove the patched connections to test gear, to plug the repeater into the shelf, to have the circuit put in service, and to make a test call.

Results Obtained with E6 Repeater

Where the cable quality, i.e., the structural regularity, is good, circuits equipped with *E6* repeaters can be operated at lower net loss and with better return loss than with the complex adjustable network of the *E23* repeaters. This improved performance is attributed to:

1. Better match between the line impedance and *E6* repeater.
2. The adjustable building-out portion of the LBO network.
3. Finer adjustment steps provided in the gain unit.

Fig. 28 shows the net loss of a trunk equipped with an *E23* and with an *E6* intermediate repeater. With the *E6* repeater the circuit can be operated at 1.7 db lower net loss. Fig. 29 shows return losses measured on the same trunk. Note that despite the lower loss operation the return loss is generally higher than for the *E23*-equipped trunk. The *E6* is therefore providing a better circuit than could have been obtained with the older repeaters.

As is customary in the Bell System, extensive field trials of the new design have been undertaken. The circuitry has been on trial in Atlanta, Ga., for nearly 3 years. In addition, a large number of preproduction models of the new repeater are now in actual use on commercial circuits in a number of locations across the country.

Providing 150-Megacycle Telephone Service to North Carolina's Ocracoke Island

M. B. McMILLAN
MEMBER AIEE

EXTENDING along the east coast of North Carolina from Manteo in the north to Atlantic in the south lies a chain of islands known as the Outer Banks. Within this chain are Hatteras, Ocracoke, and Portsmouth. It is with the island of Ocracoke that this paper is concerned.

The island of Ocracoke is approximately 16 miles long and has an average width of less than one mile. On the north, it is bounded by Pamlico Sound and Hatteras Inlet; on the east, by the Atlantic Ocean; on the south, by ocean and sound; and on the west, by the sound only. The island may be reached from the north by automobile over paved roads on Hatteras and Ocracoke Islands and by State-operated ferries across Oregon and Hatteras Inlets. Mail boat service operating daily between Atlantic and Ocracoke offer passenger service from the south, and private plane service is available from several mainland cities. The island is inhabited by approximately 850 residents, the greater number of whom live in Ocracoke Village at the southern end of the island. The village is adjacent to the inlet and is built around a salt-water lake. The pursuits of the sea occupy most of the island's 850 population.

The only communications prior to 1955 were the the United States Coast Guard facilities at Ocracoke Village. These facilities offered the islanders limited communications in cases of emergency. In 1955, telephone service was requested for Ocracoke Island. The nearest telephone exchange to the island is the unattended dial office at Engelhard, N.C., approximately 28 air-line miles distant, and the nearest serving toll center is located in Washington, N. C., approximately 97 air-line miles distant; see Fig. 1.

Surveys of the families and business establishments on the island indicated that facilities which would provide a total of three communications channels for off-the-island communications and that a 100-line dial office located at Ocracoke Village should be sufficient to satisfy demands for service. Comparative cost studies were made utilizing: 1. radio facilities between Ocracoke and Washington, 2. radio facilities between Ocracoke and Engelhard and

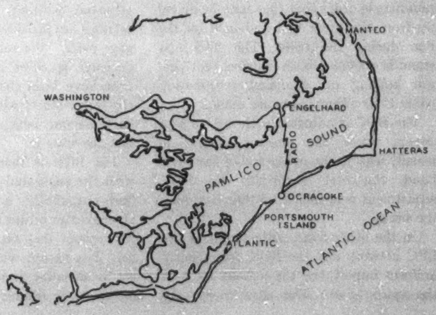

Fig. 1. Map showing location of Ocracoke Island, N. C.

Paper 60-793, recommended by the AIEE Radio Communication Systems Committee and approved by the AIEE Technical Operations Department for presentation at the AIEE Summer General Meeting, Atlantic City, N. J., June 19–24, 1960. Manuscript submitted March 21, 1960; made available for printing April 26, 1960.

M. B. McMillan is with the Carolina Telephone and Telegraph Company, Tarboro, N. C.

Fig. 2. Radio transmitter-receiver bay

carrier superimposed on existing wire line facilities between Engelhard and Washington, and 3. submarine cable between Ocracoke and Engelhard and carrier superimposed on existing wire line facilities between Engelhard and Washington. This study indicated that the three trunks between the proposed Ocracoke central office and the serving toll center at Washington could be most economically provided by the use of multiplexed radio between Ocracoke and Engelhard, and by carrier superimposed on existing wire line facilities between Engelhard and Washington.

The desire to keep the antenna height to a minimum and the expected reflection effects on the 28-mile overwater path made the 152–162-mc (megacycle) frequencies the most attractive. After a survey of existing stations operating in the area in the 152- to 162-mc frequencies, a frequency of 152.57 mc was selected for Ocracoke and a frequency of 157.83 mc for Engelhard.

The wire line section between Engelhard and Washington, having previously been transposed for carrier operation, offered a very economical layout for a carrier system. A conventional 4-channel compandored open-wire carrier system was established in this section with terminals at Washington and Engelhard and with an intermediate repeater located at Belhaven, N. C. A room was constructed in the rear of the hotel to house the 100-line dial office and the multiplexed radio equipment. The local cable plant was constructed on the island, radio and wire line facilities were connected, and on June 15, 1956, telephone service was established to Ocracoke Island.

Radio Equipment

Packaged station combinations modified for extended bandwidth, as shown in Fig. 2, operating in the 150-mc frequency range, were used for the radio facilities. This combination included a transmitter, a receiver, and a carrier-operated relay, tropicalization-treated and mounted in an indoor cabinet. The base-band frequency response of 0.2 to 11.2 kc allows for the multiplexing of a voice-frequency channel and two single side-band suppressed carrier channels, together with three associated signaling channels. The broad-banding of this equipment, which had previously been available on a single-channel basis, was accomplished through modification. The modification provides a frequency-modulation characteristic, extended bandwidth, the elimination of the peak deviation limiter, and the addition of feedback in the base-band amplifier. The units are phase-modulated, have a 50-watt radio-frequency output, input and output impedances of 600 ohms, and continuous input and output level control. For continuous duplex operation, the operating frequencies of the transmitter and receiver are separated by 5 mc. Actual operating frequencies as well as transmitted levels are shown in Fig. 3.

Antennas

Each radio terminal utilizes one corner reflector with special iridite treatment. The antennas have an approximate gain of 7.5 decibels compared to a dipole with a front-to-back ratio of about 15 decibels. The Engelhard reflector is mounted on a

150-inch guyed tower as shown in Fig. 4. The Ocracoke Island reflector is mounted on a 65-inch pole. Reinforced guying is used for protection against the hurricane-force winds, often present along the coast. The vertically polarized antenna is connected to two cavity resonator filters with *RG-8U* transmission line. The cavity resonator filters suppress transmitter extra-band radiation and avoid receiver desensitization, which permits simultaneous transmission and reception on the common antenna. The cavity resonators are mounted on a special rack attached to the wall and are connected to the radio terminals with type *S-450* transmission lines.

Radio Multiplex Equipment

Telephone carrier channels, as shown in Fig. 5, provide for application of three telephone message channels to the broadband radio facilities. The system consists of one voice frequency, two carrier-derived channels, and three signaling channels. The voice-frequency channel occupies a band of frequencies between 200 and 3,000 cycles per second. Two additional amplitude-modulated single-side-band suppressed carrier channels are derived by modulation of voice frequencies of 300 to 2,700 cycles per second. Channel 2 transmits and receives on the upper side band of 3.5 kc and channel 3 transmits and receives on the lower side band of 11.5 kc, as shown in Fig. 6. The block diagram of three channels of the radio carrier system, including compandors and voice-frequency terminating units, are shown in Fig. 3. Signaling for dialing and supervision on the three channels are transmitted and received at carrier frequencies of 7.5, 7.0, and 8.0 kc for channels 1, 2, and 3 respectively. Each channel utilizes a compandor unit to provide an effective increase in signal-to-noise ratio.

Radio System Alarms and Controls

The alarms and controls of the radio system appear as both audible and visual alarms on the Washington, N.C., central office switchboard with instructions to authorized personnel for their interpretation and operation. A red pilot light indicates when the carrier is on or off. Red light on indicates that the carrier is on, while red light off indicates that the carrier is off. In addition to this visual alarm, an audible alarm will sound to indicate that the carrier is off.

The method used to turn the transmitter carriers on and off is as follows: The contacts of a switch located on the Washington switchboard are extended over an open-wire carrier-signaling facility to Engelhard. These facilities are used to operate a relay which will turn the Engelhard transmitter carrier on. When the Engelhard transmitter is on, its carrier will operate a relay associated with the Ocracoke receiver. The contacts of the Ocracoke carrier-operated relay are connected to the keying circuit of the Ocracoke transmitter. When the carrier of the Ocracoke transmitter is on, a relay in the Engelhard receiver will operate which will activate a signal light on the operator's position in Washington. An additional open-wire carrier signaling facility is utilized between Washington and Engelhard for control and supervision of the Engelhard transmitter and receiver, thereby giving complete system control from the Washington control point. The carrier system is so arranged that failure of the open-wire facility on which the carrier system is superimposed will result in a shutdown of the radio system.

Fig. 5. Radio multiplex equipment bay

Dial Central Office

The new office located at Ocracoke Village is a step-by-step community dial central office with a capacity of 200 individual lines. The office is arranged for normal 2-letter 5-digit dialing and is identified as WAverly 8. While local calls are made on the 2-letter 5-digit basis, incoming and outgoing calls to distant points must be routed through the Washington central office. Island subscribers may reach the Washington operator by dialing 0.

Power

The basic power for the radio-carrier system is single phase, 115 volts a-c, 60 cycles. The village of Ocracoke generates its own power, using diesel-driven generator facilities. The power plant was installed during World War II by the U.S. Navy to provide power for Navy installations on the island. The facilities were obtained by the islanders after the war and expanded to serve the village.

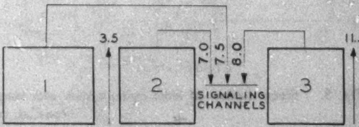

Fig. 6. Radio multiplex channel allocations

A privately owned ground return power system serves the town of Engelhard. This system operates without a neutral conductor and uses the earth for the return path. Emergency a-c power for the Engelhard office is provided by diesel-driven automatically controlled alternators with a single-phase 60-cycle output of 7.5 kw at 240/120 volts a-c. In the event of a power failure, the generator will start automatically and will continue to operate until the power is restored.

Conclusions

The use of the radio-carrier system in conjunction with the open-wire carrier system and the dial office has provided the isolated community on Ocracoke Island with a modern, reliable telephone service. The acceptance of this service by the islanders is evidenced by the fact that 50 additional lines have been installed since the initial installation was made.

THE General Telephone Company of California is presently the largest operating company within the General Telephone System. Its major operating territories embrace the Los Angeles metropolitan area and include important exchange areas situated in other sections of central and southern California. For many years, this company has standardized on the use of step-by-step switching equipment manufactured by the Automatic Electric Company. Included in our operating areas at this time are 37 exchanges which are served by a total of 70 step-by-step central offices. These offices vary in size from small terminal per-line installations of 200 lines to large multiunit offices of 43,000 terminals.

Central office switching equipment for the many exchanges furnishing service to subscribers was engineered and installed by this company. Company engineering to meet switching equipment needs was established in order to insure that our individual requirements with respect to traffic, special switching apparatus and community growth changes, however unique, were met with minimum delay. It was felt that a more complete and thorough job of engineering could be achieved at lower cost and on shorter time intervals by our own engineers than would be possible by using conventional factory engineering services.

The period of accelerated growth experienced by the company since World War II made substantial changes in earlier engineering methods imperative. As reflected in Fig. 1, the General Telephone Company of California is presently serving in excess of 1,000,000 stations. This quantity represents an increase of approximately 540% since 1945, and was accomplished by the establishment of many new central offices as well as numerous additions to existing offices to meet the service demand.

During the early part of this era, detailed equipment lists and specifications for switching equipment were prepared by hand. Written data from an engineer were transcribed to typewritten sheets for subsequent delivery to the supplier. As the need for switching equipment grew, it became evident that equipment engineering personnel would have to be augmented by a significant number to meet the then current and predicted future growth needs. Appropriate mechanization studies instituted at this time were culminated by a change from the manual system to an IBM (International Business Machines Corporation) machine process in December 1956. Through the use of this new process, our company was able to meet its obligation of effectively providing for central office equipment growth requirements. At the same time, it was possible to accomplish this task with fewer engineers than would have been required under the previous method of operation. Not only were the engineering processes made measurably more economical, but greater job uniformity and a significant reduction in engineering and clerical errors resulted.

Manually Prepared Equipment Lists

Subsequent to the receipt of proper authority for engineering additions to automatic telephone switching systems, or new systems, the detail engineer reviewed the project traffic order to determine equipment types, quantities, layout, trunking, power, and all related requirements. The engineer's first order of business was to start immediately an equipment order for the factory, to minimize any delay in receipt of equipment due to manufacturing processes. Before actually preparing this order, however, the engineer was obliged to research applicable circuit and assembly drawings, closed work orders and allied records to insure that the items of equipment required for the job were compatible and would function in the desired manner as elements of a complete switching system.

In the course of this research, it was possible for inaccuracies to be introduced. Piecepart numbers designating the variety of components making up a given job were lengthy and, as such, enhanced the possibility of numerical transpositions. Needless to say, transpositions at this point, or later in the typing operation, if they were sent to the factory undetected, resulted in unnecessary correspondence to resolve the problem thus created. This, of course, assumes that either the factory or the engineer subsequently became aware of the discrepancy. When such was not the case, the obvious event would occur; the wrong equipment item would ultimately be received. It is interesting to note at this point that numerical transpositions in a piecepart number often represent a valid part number, further

Paper 60-778, recommended by the AIEE Communication Switching Systems Committee and approved by the AIEE Technical Operations Department for presentation at the AIEE Summer General Meeting, Atlantic City, N. J., June 19–24, 1960. Manuscript submitted November 2, 1959; made available for printing March 28, 1960.

M. E. Hacker and C. M. Davis are with the General Telephone Company of California, Santa Monica, Calif.

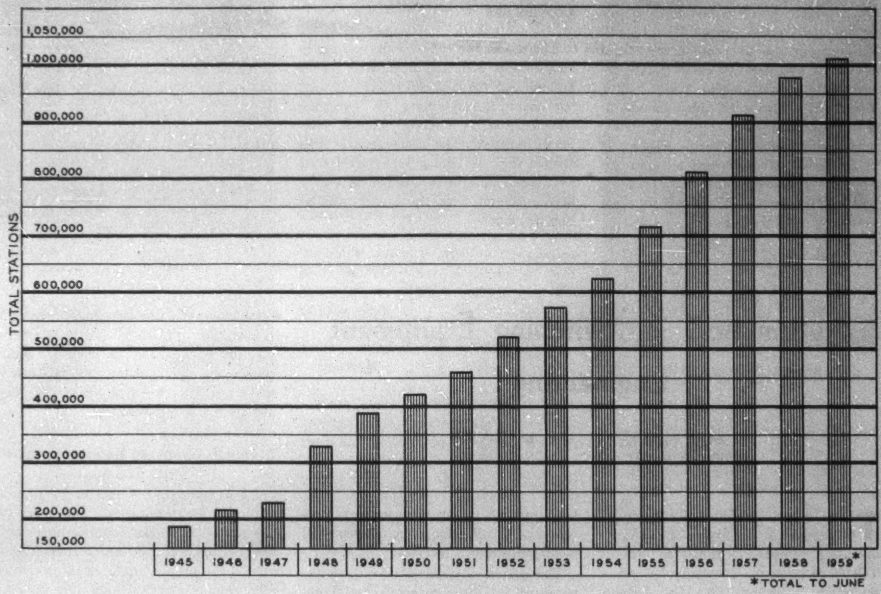

Fig. 1. Graph of station growth since World War II

complicating any error detection procedure.

METHOD OF PREPARATION

When sufficient data had been accumulated for the project, the engineer would originate a handwritten order preparatory to typing. This order was prepared on a special group of forms containing all necessary facts pertinent to the engineering project at hand. As noted in Fig. 2, a switch count summary was originated to reflect the general types and quantities of switching equipment required for the job. Specific details covering each individual item to be ordered from the factory were then written on other forms; see Fig. 3.

Following a general description of the use of the equipment listed in Fig. 3, the engineer would continue by listing the item number, quantity required, manufacturer's part number, and a brief word description of the first item of equipment required for the job. Where applicable, circuit or assembly numbers were included in the description to minimize manufacturing errors. Thereafter, subsequent items were listed in a similar manner. As noted in the figure, all equipment required for the job was grouped as a matter of convenience. Thus, for the project of Fig. 3, distributing frame equipment became group 1; trunk board equipment, group 2; etc. Through this procedure, manufacturing as well as engineering processes were greatly facilitated.

In conjunction with this operation, the detail engineer was required to obtain current equipment prices in order to allow a reasonably accurate estimate to be made relative to the items to be purchased. These cost figures were not to be included on the factory equipment list, but were accumulated primarily for work order and budget purposes to cover the installation of the switching equipment.

PREPARATION TIME AND REPRODUCTION CONSIDERATIONS

The amount of time required for the preparation of an equipment order on the basis just described varied in proportion to the complexity and size of a given switching system. Accordingly, situations requiring the provision of directors, automatic toll ticketing, and related switching apparatus involved considerably more detail engineering time for the preparation of an equipment list than did a job associated with the establishment of, or an addition to, a small local step-by-step central office. For these reasons, equipment lists for the factory might consist of as few as one or two pages or as many as 80 or more. Engineering time for the completion of a handwritten list could therefore vary from a matter of hours to as much as 6 to 8 weeks and, on occasion, even longer.

Throughout this period of manual preparation of the equipment list, the problem of transcription or clerical errors was ever present. Diligent effort on the part of the detail engineer, the typist, and supervisory personnel reduced to a practical minimum, but could not entirely eliminate, the difficulties attributed to this source. During this era, a constant stream of correspondence between the factory and the company strove to rectify the various errors detected and to clarify any deviations from standard factory ordering procedures.

It should be mentioned at this point that other clerical activities concerned with the typing of the completed pencil equipment list also contributed to the general problems associated with the manually prepared equipment list engineering method. Due to the number of copies required of each list, the legibility of some carbon copies of each sheet was impaired. Additionally, since this equipment list subsequently became a part of an installer's specification, it was necessary to type the same list twice; once to order the equipment and a second time months later when the installer's instructions were prepared for distribution. Aside from the handicap of semi-illegible copies, the necessity of typing each equipment list twice unnecessarily increased engineering costs.

Summary

From the foregoing general description, it is apparent that the typing routine, along with numerous other procedures, required attention in order to place equipment engineering on a more efficient basis as the company grew. The monotonous, routine task of transcribing ordering information and shop notes on the more lengthy equipment lists accounted for our initial interest in mechanizing such work. Removing this tedious clerical type of work from the shoulders of the detail engineer would free him, in a minimum time, to accept new engineering projects. Toward this end, studies were made to determine the feasibility of utilizing automatic business machines for the production of complete equipment specifications. The details of this effort are outlined in the paragraphs to follow.

Machine-Prepared Equipment Lists

Investigations leading to the use of automatic business machines for the production of switching apparatus equipment lists were based primarily on three major objectives, as follows:

1. To increase the productivity of the detail engineer.
2. To reduce the need for additional clerical and engineering personnel during a period of accelerated company growth.
3. To minimize the "human errors" present in the manually prepared equipment list system.

Prior to the actual implementation of such a program, it was necessary to devise a standard, uniform method with which to identify the myriad components comprising an automatic telephone system. Therefore, to make the preparation of equipment lists with IBM equipment a practical reality, such items as linefinders, selectors, connectors, director equipment, earthquake bracing, terminal blocks, cable, and miscellaneous mounting hardware had to be provided with their own unique identification numbers.

Subsequent to the compilation of a complete listing of all required equipment items, the systematic development of a flexible identification scheme was approached on the basis of segregating the basic switching system elements into fundamental "building blocks of equipment." Thus, from such building blocks an engineer would find it possible to order complete or partial switching systems merely by specifying only those items required for a given project. Accordingly, a numerical coding system was evolved to identify all items in each building block or order specification as they came to be known. From these listings, the detail engineer would be able to convey conveniently to an IBM key punch operator both equipment-type and quantity information from which appropriate control cards could be prepared.

To insure that the over-all objectives of machine-prepared equipment lists would be satisfied to the greatest extent possible, close co-ordination of various developmental activities was maintained between our company and the switching equipment manufacturer. At the inception of our initial studies, certain factory procedures

Fig. 4. Partial list of Automatic Electric Company job specifications

were reviewed to determine that the proposed IBM program would conform to manufacturing needs wherever possible. At the same time, an existing factory "job specification" identification system was adopted for use by our company in setting up and maintaining an effective machine ordering process. Fig. 4 reveals a partial list of these job specifications.

It might be helpful at this point to differentiate between "order" and "job specifications." Simply stated, an "order spec" is, as its name implies, a means for the engineer to order the equipment required to satisfy the needs of his engineering project. A given project may require the use of one or several order specs, depending upon the complexity of the system. A completed order spec is sent to the IBM group for machine production of a final equipment order for the factory. The resulting order is then known as an "equipment list" and is ready to be forwarded to the factory together with an appropriate purchase order. The equipment list consists of one or more job specs which conform exactly to factory spec numbers. In other words, order specs, which are used by the telephone company engineer are converted by the IBM process into job specs as required by the factory in their manufacturing procedures.

Upon the inauguration of our IBM program, routines were established to control all equipment-ordering activities utilizing the IBM process. This included the addition of new order specs when required, inserting new items into existing specs and revising equipment groupings for greater efficiency where necessary. In this manner, the detail engineer was assured of having up-to-date standard equipment items from which to design efficient telephone switching systems.

NEED FOR ORDER SPECIFICATIONS

Order specs were created primarily to facilitate the application of business machine processes to the needs of switching equipment engineering. Indeed, they were to become the basic ingredient in the ordering process, and as such every effort was made to furnish them in a form which was as complete and flexible as conditions would permit. Any feature which was considered to be of value in reducing the actual time required by an engineer to prepare a complete order was included. As implied by Fig. 4, a definite need for order specs existed because factory job specs included, in most cases, far too great a variety of switching apparatus under one specification number. A single IBM order spec based on a given job spec would have contained so many pages that it would have been of little practical value to either the detail engineer or IBM key punch operator.

To derive the greatest benefits from the IBM process, therefore, arrangements were made to provide a more detailed breakdown of the equipment manufacturer's job specifications. Fig. 5 illus-

Fig. 5. Partial index of General Telephone Company order specifications

trates a portion of the order specs which were established to meet our engineering needs from the factory job specs. In the course of planning for a practical system of ordering information, it became clear that in some cases even further subdivision was required for the convenience of the detail engineer. An example of this may be seen in Fig. 5, where selector equipment is concerned. A single order spec for this equipment would have consisted of approximately 84 pages. By assigning order specs 202, 203, and 204 according to specific types of selectors, a single, large specification was avoided as described below:

Specification No.	Title	No. of Pages
202	Selector equipment, first, fifth, and toll route	43
203	Toll transmission selector equipment	18
204	Toll intermediate selector equipment	23

Depending upon the specific needs of an engineering project, selectors will be ordered under one or more of these specifications. For this reason an engineer need concern himself only with such spec sheets as are directly applicable to his project. This clearly avoids the necessity of searching through irrelevant data and accounts for a significant saving in the detail engineer's productive effort. This concept was extended to include all comparable equipment types which, by virtue of either complexity or numerous physical arrangements, dictated the need for a further reduction to basic elements to conform to the objectives of the IBM program.

Order Specification Coding System

It is beyond the scope of this paper to present a complete description of the order spec coding system. However, through the paragraphs to follow, and the accompanying figures, a general understanding will be gained of the more important system features. As will be readily understood, the mechanized approach to preparing complete telephone switching equipment lists was no less demanding than that of the manually prepared equipment lists. Indeed, in the face of a machine incapable of judgment, performance directives had to be explicit and accurate if the end product were to emerge in an acceptable and usable form.

As was the case with the manual sys-

tem, automated equipment lists required appropriate item, group, quantity, piece-part number, description, and similar information. At the same time, a straightforward stationery form was required to facilitate its completion by the detail engineer. Referring to Figs. 6 and 7, it will be seen that all of the above requirements were satisfactorily met through a coding system and form arrangement which became standard for all order specs. At present, there are 108 order specs available for equipment engineering purposes with a combined total of approximately 1,258 pages. These specifications encompass some 20,000 individual equipment items and, in addition, provide for the acquisition of specialized items where required by a need unique to a given engineering project.

Fig. 5 illustrates the 3-digit code system utilized in the order spec assignment scheme. Additionally, this figure contains a listing of the ten code number blocks into which various equipment engineering functions are divided. It will be noted that ample provision has been made for the expansion of the IBM program to include any future engineering requirement which lends itself to the adaptation of automatic business machine processes.

Group 1 of each order spec was reserved for an index of the various groups which were to make up an individual specification. This index served to aid engineering processes since, if the engineer required but a few items in a particular specification, rapid access to the items of interest was assured. Subsequent groups were listed in a numerical sequence to the maximum required by each basic specification. Each group within an order spec will become an "item" in the final equipment list.

The item number was perhaps the most significant coding unit developed for the order spec system. Basically it consists of a 5-digit-plus-decimal-point code and serves a wide variety of purposes. Its primary objective is to identify each of the various lines on an order spec. In addition, it satisfies several other equally important requirements. Aside from the item or spec line number itself, the 5-digit-plus-decimal-point code provides for the identification of the supplier from whom an item will be purchased, identi-

fies all installer's, engineer's and shop notes in a uniform manner, and signals the IBM machine whenever tabulation is required to accumulate totals of similar types of equipment such as nuts, bolts, washers, etc. Substantial experience in using the various order specs has proved that adequate study and planning during the formative stages of our IBM program has resulted in an item-coding scheme which inherently contains the maximum in utility and flexibility.

Mentioned briefly in the manually prepared equipment list description were two other items related to arithmetic computations; these were the switch count summary and the addition of estimated equipment costs. As might be expected, the IBM equipment utilized for the production of switching equipment lists is ideally suited for these operations. These data are conveniently available as by-products of the IBM process and they effectively remove additional clerical activity from the duties of the detail engineer. Routines are provided whereby up-to-date cost information is regularly inserted into the master IBM card file for each order spec.

As each order spec was completed, during the developmental phases of the mechanization program, it was thoroughly checked and subsequently transferred, line by line, to a master IBM card file. From this master group of cards, printed copies of each order spec were then available upon which could be entered data pertinent to an engineering project. The properly notated form was then converted by a key punch operator into control cards which were subsequently used by a tabulating machine operator to pull the required groups of cards within an order spec from within the master card file.

The cards thus selected are then reproduced with the copies serving as a basis for processing the current engineering job. Through the use of a master deck of IBM cards for each order spec, the amount of key punching is kept to a minimum, since the master deck is reassembled into its original form after duplicate cards are prepared for each job.

Upon the completion of the various card-sorting, deleting, arithmetic and other machine functions involving the duplicate cards, a final printed equipment list is available for the factory. At this point any number of copies of the equipment list may be obtained with each copy as equally distinct as the original. This feature alone represents another significant advantage over the manually prepared equipment list method.

Fig. 9. Typical equipment list detail sheets

While necessarily brief, the above description suggests the achievement of the desired goals established at the beginning of the investigations concerning the use of business machines to relieve the detail engineer of unnecessary clerical activities. The order spec system is the key to this success, and studies continue for improved methods of more fully utilizing the various features available in the IBM equipment. Figs. 6 through 9 depict a before and after situation concerning a typical order for switching equipment. Figs. 6 and 7 represent a completed order spec as the IBM key punch operator receives it, and Figs. 8 and 9 are examples of a completed equipment list as received by the factory for manufacturing purposes. The estimated cost column in Figs. 6 and 7 has been left blank, although in an actual list it would be filled in by the IBM process.

Another item covered under the manual preparation method involved specifications for the equipment installer's use. By design, the complete standardization of the mechanized ordering process allows the use of the same job spec, which is forwarded to the factory, as the basis of an installers specification. With the addition of the relatively few instructions peculiar to an individual job, a complete specification is then available which covers all phases of the installation of the switching system equipment.

Conclusions

Our company, as a segment of the independent telephone industry, recognized the various problems to be faced during the postwar years. With local communities growing "by leaps and bounds" it became abundantly clear that a change was necessary in our equipment engineering methods to keep pace with the ever-increasing demand for telephone switching facilities. An exploratory program utilizing automatic business machines for the production of certain switching equipment engineering requirements was instituted. The success and subsequent effect of this

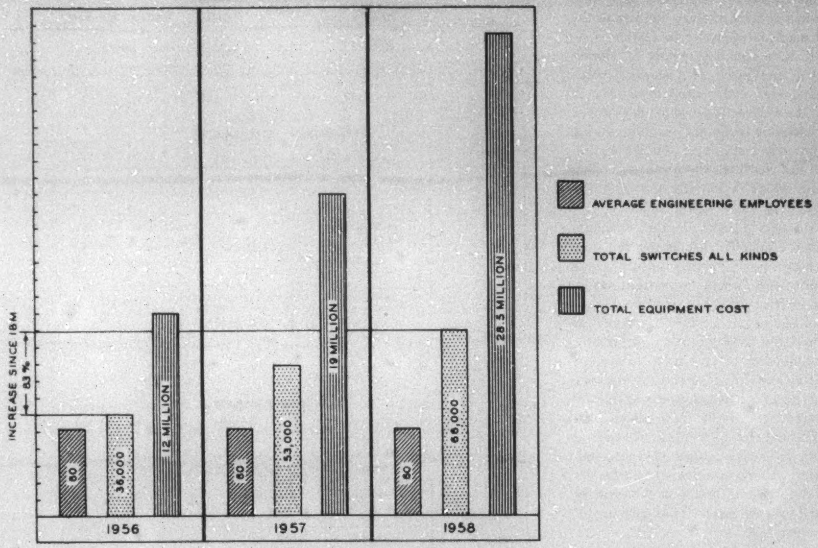

Fig. 10. Graph of switches versus manpower

program on our equipment engineering activities is reflected in Fig. 10 where the switch requirements for recent years are plotted against the number of detail engineers required to handle the work load adequately. It is evident from this chart that the efficiency of the detail engineers was increased substantially by the mechanization of the ordering process. Not only were greater numbers of engineering projects completed during a given length of time, but it was possible by the adoption of the IBM process to attain this goal with little increase in the total complement of engineering personnel.

Our mechanization program has accomplished the three primary objectives outlined earlier in this paper. Through the use of automatic business machines we have increased the production capability of each engineer, minimized the need to hire additional engineering employees during a period of rapid growth, and achieved a remarkable reduction of all types of "errors" on switching equipment lists.

It is interesting to note also that certain other less tangible benefits have been forthcoming with the change to machine-prepared equipment lists. One advantage was in the form of improved job interest on the part of the individual engineer. With the great bulk of the routine clerical type of activity removed from his responsibility, the detail engineer could devote a greater portion of his time to the more interesting phases of switching system design. Not only was the morale of the individual improved in this case, but the telephone company benefited by an improvement in the quality of the projects being completed. When considered collectively, the several advantages accruing from the use of automatic business machines as a tool for equipment engineering purposes actually exceed those originally contemplated.

The present IBM system for equipment-ordering purposes represents but one facet of a long-range plan, which implies further important business machine uses in the future. An example of this is found in current studies which concern themselves with the adaptation of engineering reference drawings to IBM equipment. Because of the nature of our present manually prepared card index for reference drawings, it is not possible to furnish copies to the detail engineer. It is anticipated that a "mechanized" approach to this need will allow the publication of master and supplemental indexes to meet any engineering reference requirement. Convenient access to engineering drawings, either by equipment type, operating features, or drawing number, will contribute to a further increase in the efficiency of our equipment engineering force.

Our equipment engineering automation efforts utilized IBM punched card equipment merely as a matter of convenience, since a substantial installation of this equipment existed within the company. It is recognized that any number of equally effective machine processes could doubtless produce the same results and, perhaps, do so in a more efficient manner.

Needless to say, opportunities exist for the application of mechanized processes ahead of as well as behind the one described in this paper. It is entirely within the realm of possibility for the present typewritten traffic specification to be reduced to punched card data which, together with appropriate directives, could result in a more fully integrated equipment engineering operation. Along the same line, the output of our present system might be advantageously modified to furnish punched cards or tape to the manufacturer in lieu of the present printed specification. Such a procedure would allow the Automatic Electric Company to use this data directly for manufacturing processes and avoid the need to translate a verbal equipment list into a machine input form at the factory.

Voice Immunity of Tone Operated Switching Centers

J. H. GUENTHER
NONMEMBER AIEE

J. SHIRMAN
ASSOCIATE MEMBER AIEE

TONE operation of electronic switching centers is the natural outgrowth of 4-wire operation of communication systems using a radio link. The radio circuit may be anywhere between the subscriber and the switching center or between switching centers.

Once the decision to use tone operated devices had been reached, the next major decision was to determine what part of the spectrum should be utilized for the control tones. For ease of design the obvious answer would be to use a frequency band for control which is separate from the information frequency band. A little reflection shows the fallacy of this thinking. The bandwidth requirement becomes out of proportion to its use. The switching function operates during such a small period of the total circuit holding time that to utilize an expanded bandwidth solely for this function is wasteful in an already crowded frequency spectrum. A separate signal band is also expensive from a components point of view as separating filters and signaling circuitry are needed at every switching stage.

For these reasons in-band supervisory and keying tones which are within the frequency spectrum required for the transmission of intelligence were chosen as the mode of operation. The use of in-band tones presented one major problem. How to prevent voice energy from operating the switching circuits?

In a telephone system all switching functions except release are normally performed before the flow of any information. This leads to an obvious solution to the problem; that is, provide a lock out of the telephone transmitter during switching. This is partially done on present impulse dials and is also partially done on push-button tone generators associated with the tone operated telephone. To accomplish this the transmitter is disconnected from the line during the time the tone button is operated, much the same way the impulse dial back contacts disconnect the transmitter during the dial cycle. This operation prevents voice frequencies from being present on the line at the same time that legitimate supervisory and keying tones are present. However, this does not prevent voice frequencies from operating the control tone detectors between control tone pulses or during the conversation time.

A possible method to accomplish immunity against voice operation would be to provide at every telephone two additional tone buttons. One would signal end of dialing, and would cause the tone detectors at the switchboard to lock out before the telephone is connected to the line. The other button would signify end of call and would unlock detectors before completion of the call. This method is not acceptable for two reasons. First is the high cost involved. Any cost added to the telephone set proper is of course multiplied by the number of telephones used. The second reason is the unaccustomed operation required. Additional operations required of the subscriber would result in increased false calls and condemnation of the switching system. The most acceptable solution to the problem is to provide voice immunity in the tone detection circuits at the switching center.

The system here described was designed under Signal Corps Contract No. *DA-36-039-SC-72356* and *DA-36-039-SC-72790* for the Army field switchboard. Operating specifications were set by the over-all switching requirements of the system. The specifications of importance in the design of the digit detection and voice guard are as follows:

1. Tones and voice signals may be received at the switchboard at any level from 0 dbm (power in decibels referred to 1 milliwatt) to −30 dbm, depending upon the condition of the phone and the connecting line length. These signals must be correctly detected under all the standard environmental conditions of temperature, battery, component parameter changes, etc.

2. Signal detection must take place when the duration of the signal tones is as short as 50 ms (milliseconds) and as long as several seconds; however, a break of up to 8 ms such as may be experienced by radio fade or contact bounce of keysenders must not record multiple digits.

3. These signals must be received and detected in the presence of 10 db (decibels) S/N with the further requirement that normal voice tones shall not produce false signaling.

Further specifications for the operation of this particular switching system reserved the frequency spectrum below 1,500 cps (cycles per second) for other digital processes. This necessitated setting the tone frequencies at the upper portion of the spectrum. Specifically, eight tones from 1,700 cps to 2,900 cps at 200-cps intervals were selected for control purposes.

Laboratory investigation along with research into the available literature led to the decision that each supervisory and keying signal should be composed of a 2-frequency tone. Accordingly, all supervisory functions except "seize" are performed by a 2-frequency compound tone. It was considered unnecessary to protect against false seize initiated by voice due to the nature of telephone operation, that is, the instant the phone is taken off the hook seize tone is sent out. Any voice tones that could simulate seize will have no effect because that tone is present anyway. As soon as seize tone is detected and dial tone is returned by the switching

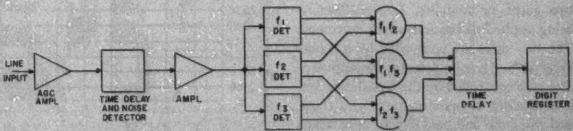

Fig. 1. Block diagram of basic digit detection circuit

Paper 60-820, recommended by the AIEE Communication Switching Systems Committee and approved by the AIEE Technical Operations Department for presentation at the AIEE Summer General Meeting, Atlantic City, N. J., June 19–24, 1960. Manuscript submitted March 17, 1960; made available for printing April 27, 1960.

J. H. GUENTHER and J. SHIRMAN are with the Stromberg-Carlson Company, Rochester, N. Y.

The authors acknowledge the many contributions made by the engineers of the Telecommunication Department, Stromberg-Carlson Company. Acknowledgments are also extended to the members of the Switching Branch, Data Processing Division, Communications Department, U. S. Armed Services Research an dDevelopment Laboratories, for their assistance during the development phases of this project.

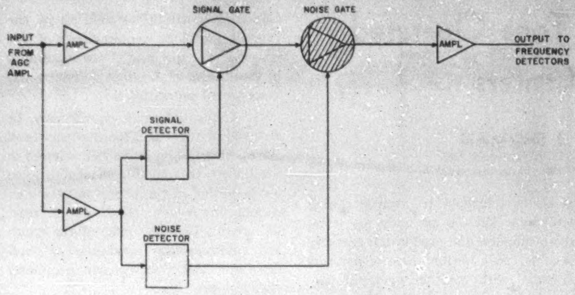

Fig. 2. Block diagram of noise detector circuit

center the seize detectors are removed from the circuit and any further seize tone on that line will have no effect on the seize detectors. The signal detection circuits were designed for voice immunity simultaneously with the design for operational requirements.

Fig. 1 is a logic block diagram of the basic signal detection circuits. For clarity only 3-frequency detectors are shown.[1-3] Signal reception and detection is accomplished by amplifying the line input with an automatic-gain-control (AGC) amplifier which produces an output of 0 dbm for any input signal level in the range of 0 dbm to −30 dbm; and by then detecting the individual control tones by single-frequency-pass-filters followed by storage circuits. Voice guard action is provided by time delay and noise detection circuits.

Before designing the time delay and noise detection circuits it was necessary to determine the frequency components and their relative strength and duration in the noise spectrum. In this connection two types of noise must be considered; white noise such as might be encountered in a high gain radio link, and voice during signaling. White noise and voice do not have the same energy distribution with frequency.

As white noise has a relatively even distribution of energy over the entire frequency spectrum a circuit for rejecting white noise is easily accomplished. Fig. 2 shows such a circuit. The signal from the AGC amplifier is made to pass through two gates, or switches, in series before being applied to the frequency detectors. The two gates are controlled by a signal detector and a noise detector respectively. The gate controlled by the signal detector is equivalent to open contacts of a relay and will close and pass signals only when the signal detector operates. The gate controlled by the noise detector is just the opposite, that is, equivalent to closed contacts of a relay and opens to prevent an output when the noise detector operates.

Due to the even energy-frequency character of white noise such a circuit is relatively simple in design. The signal detector is comprised of a bandpass filter, tuned to pass the signal frequencies of 1,700 through 2,900 cycles. This filter is followed by a trigger circuit which produces a d-c output when energized with a pulsed input. Thus the presence of any frequency or frequencies in the signal band will operate the signal gate.

The noise detector is similar but opposite in action. A band reject filter, designed to complement the signal filter, will pass any or all frequencies which fall outside the signal band. This filter is followed by another trigger circuit which produces a d-c output of opposite polarity. This d-c signal will be removed in the presence of noise energy and thus inhibit signals from passing through the noise gate.

By adjusting input attenuators in the signal and noise detectors it is possible to make the noise gate operate at a 10 db S/N. For this part of the specification "noise" is defined as "white noise."

Because of the operating characteristics of the AGC amplifier it is necessary to provide a time delay of approximately 10 ms (milliseconds) minimum before either the noise detector or signal detector operates. This minimum time allows the output of the AGC amplifier to stabilize. The first few cycles of AGC output are highly distorted and, if allowed to pass on to the detector circuits, the distortion products would operate the noise gate circuit and inhibit the signal.

This basic circuit fulfills the requirement of detection in the presence of 10 db S/N, but further modification of design was necessary to provide for voice immunity. Before designing for voice immunity it was necessary to establish the energy distribution versus frequency of the voice. Reference 1 provided valuable information about the average voice characteristics. Fig. 3 is a sound spectrogram of the words "speech we may see," reproduced by permission of the publisher and authors of "Visible Speech," by Potter, Kopp, and Green.[1] This sound spectrogram has time as a horizontal axis, frequency as a vertical axis, and intensity recorded as density, using a 300-cycle bandwidth analyzer. This is representative of voice characteristics.

Analysis of the instantaneous speech sounds reveals differences which are contrary to the generally accepted ideas of speech energy distribution. Classical curves showing speech energy distribution against frequency are based on long-time averages, and indicate maximum power output in the vicinity of 400 cps with very little average power in the 1,700- to 2,800-cycle range. However, analysis of sound spectrogram patterns for various English words and phrases show many areas of high intensity sound in the 1,700 to 2,900 cps band for considerable time durations; that is considerable compared with a maximum 50-ms detection time. Sounds such as ch, th, ss, and ee have energy peaks which appear almost entirely within the 1,700–2,900-cps signaling band. These sounds are responsible for talkdown of the basic circuit as described and necessitated a design approach to eliminate, or at least reduce, their effect.

Referring again to Fig. 1, special time delay circuits were designed into two different areas of the circuit to provide this voice immunity. Fig. 4 shows the

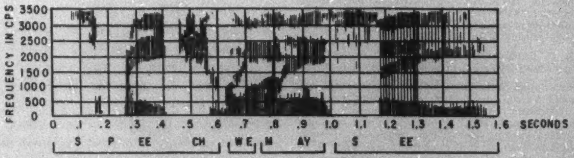

Fig. 3. Sound spectrogram of the words "speech we may see"

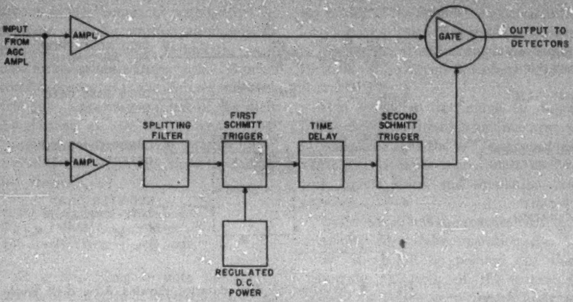

Fig. 4. Block diagram of control detector

block arrangement of the control circuit for either signal or noise gate. The output of the AGC amplifier is separated in the splitting filter and applied to a first Schmitt trigger circuit. The purpose of this trigger circuit is to provide constant amplitude pulses to the time delay circuit. Battery variations are removed by the regulator circuit which changes the battery variation from approximately 20% to 2%. The time delay circuit provides for a controlled delay for the operation of the second Schmitt trigger and for a fast release at the end of the signal. This is especially important in the noise detector as a pulse of noise should not block the detector for an indefinite length of time.

Fig. 5 shows the basic arrangement of the time delay circuit with the important voltage waveforms. The input d-c pulses *A*, are constant amplitude pulses supplied from the first Schmitt trigger of Fig. 4 and are applied to capacitor *C*1 which charges negative through *R*1 and *CR*1. The discharge path is primarily through *R*2, which is much smaller than *R*3, and *CR*1 being a high impedance for the discharge current. This charge and discharge action produces the waveform *B* when a pulse of audio input is applied to the circuit. As *R*3 is a large resistor the charging of *C*2 produces a linear waveform as shown at *C*. At the end of the pulse of audio, *C*1 discharges rapidly through *R*2 while *C*2 discharges slowly through *R*2 and *R*3 in series. The input impedance of *Q*2 is high compared with *R*2 plus *R*3 and can be neglected. When the charge on *C*1 falls below the charge on *C*2, diode *CR*2 conducts and both *C*1 and *C*2 finish discharging rapidly through *R*2.

The firing level of the second Schmitt trigger of Fig. 4 is adjusted to provide the desired operate time delay and release time delay as shown on curve *C* of Fig. 5. The output pulse of the Schmitt trigger operates the signal gate as explained previously.

Referring again to Fig. 2, the signal detector is designed to pass only frequencies in the band of 1,700 to 2,900 cps and the noise detector is designed to reject the signal band and pass all other frequencies. The firing level of the noise detector Schmitt trigger circuit is set to operate if white noise, restricted in bandwidth to 300 to 3,500 cps, exceeds a ratio of 10 db as compared to the signal operating level of the signal detector. The time delays of the noise circuit are adjusted to operate faster and release later than the signal circuit time delays. This method of operation, while not completely foolproof, provides a high degree of voice guard immunity. Referring again to Fig. 3, even though energy distribution of many common sounds contains peaks within the 1,700- to 2,900-cps signaling band, these energy peaks must now contain 10 db more energy than the combined out-of-band frequencies.

However, there are speech sounds which will always pass through this vice guard gate. Again, referring to Fig. 3, it is seen that for intervals of 50 ms there are common word sounds whose energy peaks are completely within the signal band, especially when the energy below 300 cps is removed. This is true especially of the common sounds such as ch, th, ss, and ee. These voice sounds are effectively removed by the combination of multiple frequency tones and the second time delay circuit as shown in Fig. 1. This time delay circuit is similar to that described in Fig. 5 having a controlled operating delay and fast release. The operation of this part of the circuit requires that two frequencies which identify a digit must be present simultaneously for a fixed time duration to be registered as a digit in the following circuits.

Fig. 6 is from a photograph showing the delay times of operation of the noise guard circuit. The curves are identified as follows:

1 AGC amplifier output. Input is compound tone composed of 2,300 and 2,500 cps of equal amplitude.
2 Trigger voltage that opens the signal pass gate.
3. AND-gated outputs from the 2,300 and 2,500-cps signal detectors.
4. Trigger voltage that operates the register digit gate.

The delay and release times of the gate control circuits were adjusted on a compromise basis as the different performance requirements demand different time delays for optimum performance. These requirements break down as follows:

1. *Signal detection*—50-ms pulse minimum, requires operate delay time of 50 ms maximum, requires release time short to reset circuits for next digit as soon as possible.
2. *Voice rejection*—requires operate time delay as long as possible; a long release time delay also helps.
3. *8-ms break in signal pulse*—no effect on operate time, requires relatively long release time.

To provide optimum operation, the delay of the first gate control circuit has been adjusted to 20 ms under conditions that are normal. The rise time delay in the narrow bandpass detection filters is 8 ms and the delay of the register storage control has been adjusted to 14 ms. Under nominal conditions, therefore, the detection of a digit is accomplished in 42 ms. The release times reset the circuit

in 25 ms, thus allowing for a rapid detection of the next digit.

These delay times were measured under varying conditions of temperature, beta, and battery as required by the Signal Corps specifications. Measurements were made with varying combinations of the three parameters over the following ranges:

Temperature............................ ..20 F (degrees Fahrenheit) to 135 F
Beta.........................40 to 100
Battery....±10.0 VDC to ±14.5 VDC

Varying beta and/or battery under any fixed temperature conditions had a relatively negligible effect on the time delays in the circuit. Extreme variations of these two parameters produced a total over-all change in the detection and release time of approximately 5 ms.

Temperature, however, has a more pronounced effect on the time delays. At high temperatures the operate time of the two gates reduces to 10 and 7 ms, respectively, with the over-all operate delay time reducing from 42 ms to 25 ms. The operative time of the narrow-band-pass filters remains relatively constant, all the changes taking place in the voice guard and register storage time delay circuits. At the low extreme of temperature the operate delay time of the gates increases to 25 ms and 17 ms, respectively, allowing an over-all storage delay time of 50 ms.

Tests have also been made, under all the above environmental conditions, showing the action of the delay circuits when the input pulse is broken for 8 ms. Fig. 7 is from a photograph showing a break in the input pulse. Even though the third trace shows a break in the digit detector output, the gate control has operated only once and therefore only one digit is registered. The 8-ms break was moved throughout the 50-ms signal period. When the 8-ms break occurs within the first 20 ms of the signal, the effect is to increase the delay time for the operation of the digit storage gate. When the 8-ms break occurs during the latter 10 ms of the signal, the effect is to reduce the recovery time.

As digit reception and detection are required from telephones at various distances from the switchboard, an artificial line was constructed to simulate various lengths of telephone lines. Fig. 8 shows the attenuation characteristics of this line.

The operation of the AGC amplifier and all the time delay circuits depend upon the power in the compound digit tone, and not upon the level of any individual frequency. The frequency detectors, however, must each detect their frequency from the compound tone. As seen from Fig. 8, each detector must operate over a level range of 9 db. To accomplish this, each narrow-band-pass filter is followed by a Schmitt trigger circuit adjusted to operate over a level range of 9 db. To stay within the 9-db range produced by the attenuation characteristics of the line with frequency, it was necessary to specify that a compound tone produced by the telephone always be of such a character that the higher frequency component be either equal to or higher in level than the lower frequency component. The telephone digit sender meets these specifications and all tests were satisfactory.

Voice guard action was checked by counting digit simulations per speech hour. To obtain consistent results throughout the design and testing of the circuit, a standard voice test tape was made. This was a 30-minute tape recorded with various male and female voices. English of various accents and

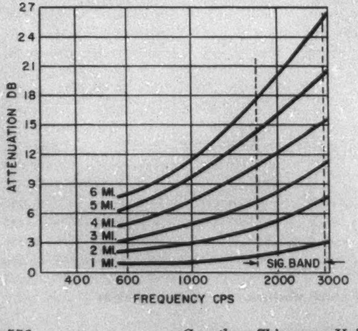

Fig. 8 (left). Attenuation characteristics of artificial line

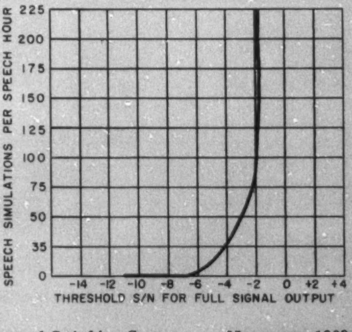

Fig. 9 (right). Speech simulations versus signal to noise ratio setting several foreign languages were used. To simulate actual operation as closely as possible, high fidelity techniques were used for recording and playback. A pulse counter connected to the digit register control gave an accurate count of the digit simulations caused by speech. Final results of voice simulation measured over the environmental range show the following results:

at 20 F = 0 digits/speech hour
76 F = 4 digits/speech hour
135 F = 16 digits/speech hour

It is interesting to note that under the same extremes of environmental conditions, the S/N of the circuit varies from 10 db to 5 db due to changes in sensitivity of the Schmitt trigger circuits. This same variation of speech simulations is observed at room temperature when the S/N of the circuit is varied. This is shown in Fig. 9.

At a sensitivity setting of 10 db or better, S/N, the circuit is immune against normal voice. As the S/N is reduced the noise gate becomes increasingly ineffective against voice, and simulations rise rapidly.

While the circuit approaches complete immunity from false operation due to voice, it should be pointed out that deliberate talkdown of the circuit is possible, although very difficult. Reference to the voice spectrograms in "Visible Speech" shows the proof of this. With practice, sustained compound sounds representing any digit may be produced by the human voice. When the input signal contains digit tones which are 10 db stronger than all extraneous tones, by definition the circuit must register a digit, whether the tones are produced by a digit sender or not.

Production Design Considerations in Television Chassis Sweep Interference Reduction

G. W. CARSON
ASSOCIATE MEMBER AIEE

PRESENT-DAY television (TV) receivers utilize circuits that generate an appreciable amount of radio-frequency power. These signals exhibit the same characteristics as those which would be present if they came from a miniature transmitter, and they are capable of causing interference with other radio receiving devices.

Signal-generating devices are known to generate harmonic signals in addition to a signal of the desired frequency. The high-level pulse generator of the horizontal deflection circuit of TV receivers is such a device. This deflection circuit generates a fundamental pulse at 15,750 cycles per second, plus a multitude of harmonics. The harmonics are objectionable in that they extend through the amplitude-modulation broadcast band (550 to 1,600 kc) and into other much higher service frequencies.

With the advent of numerous radio and communication services throughout the radio spectrum, the problem of mutual radiation interference becomes ever more complex. Extensive research and experimental work has been conducted by committees of the Institute of Radio Engineers (IRE) in conjunction with the various industries. As a result, the IRE Committee on Radio Interference has formulated standards which define methods of measurement of spurious radiation. This work guided the FCC (Federal Communications Commission) in establishing limits and standards that the industry must endeavor to meet for efficient utilization of the already crowded radio spectrum. The present discussion of horizontal-sweep radiation reduction in TV chassis is concerned with the factors which are important to the engineer engaged in TV receiver design.

Initially, the assumption is made that the standard test setup is available; see Fig. 1. The IRE Standard[1] specifies:

1. An isolating input coupling pad matching the typical 300-ohm receiver-tuner input impedance; see Fig. 2.
2. A low-pass power-line filter network (*1805*); see Fig. 3.
3. The primary 60-cycle a-c power-supply voltage maintained at 117 volts ±2%.
4. The field strength meter adjusted so as to present a nominal 50-ohm input impedance. The function switch of this meter is set to field intensity, continuous wave, or carrier position for measurements.
5. The shielded screen enclosure at least 7 feet high, by 7 by 10 feet inside dimensions, with the test chassis a minimum of 30 inches from the walls of the shielded enclsure and 30 inches from the shielded floor structure.

The FCC and the IRE representatives from the radio and TV manufacturers

G. W. Carson is with the Zenith Radio Corporation, Chicago, Ill.

The author especially wishes to express his thanks to N. W. Aram, A. Cotsworth, and R. O. Gray, all of the Zenith Radio Corporation, who contributed helpful suggestions for this paper.

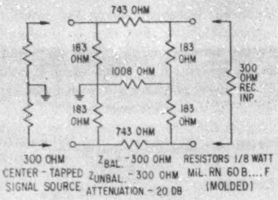

Fig. 2. Standard antenna-coupling pad of a 20-decibel attenuation and a 300-ohm impedance

are in agreement on the power-line-conducted measurement technique. In particular, it is felt that when no frequency component of the line-conducted voltage on either side of the power line is in excess of 100 microvolts, the direct field radiation to other TV and radio services is not likely to cause objectionable interference. This is contrasted with previous procedures which required free-field loop measurements in isolated interference-free locations remote from the city.

Extensive research and measurements among various TV receiver manufacturers have reduced the deviations between test setups, made according to Fig. 1 to a point of acceptable agreement. Correctly designed screen rooms and equipment are mandatory for obtaining reproducible data. The Stoddart Aircraft Radio Company, Inc., *NM20B* radio-interference and field intensity meter has been found satisfactory for these measurements, although other units of comparable quality are available.

A coaxial switching assembly has been very useful in maintaining the terminal impedance of the unused measuring points; see Fig. 4. A standard signal generator should be available as shown in Fig. 1, to cross-check the accuracy of measurements at regular intervals. This is necessary because of the idiosyncrasies of even the better field intensity meters.

Analyzing the TV chassis reveals two prime causes of horizontal sweep harmonic interference: the electrostatic field of voltage and the magnetic field of currents. The plate circuit of the horizontal pulse tube develops a peak pulse of 3.5 to 5.5 kv. This circuit contains extremely high current and voltage components at the 15,750-cycle horizontal-sweep frequency, and substantial amounts at harmonics of this frequency. Random-dressed wires that are very close physically to this circuit will therefore exhibit excessive interference levels.

Troublesome chassis designs in the past have permitted the chassis base to perform as an antenna. A measurable loop voltage in these cases existed between the chassis and the screen room or adjacent grounded system. The amount of this effect is influenced by the antenna input coupling impedance, the chassis and circuit capacitances, and the inductive coupling to the a-c power cord. Two basic design configurations connect the line power to the tube heaters and the rectifier *B* supply. In the one, transformers couple the proper voltages and currents to the tube heaters and rectifier circuit; in the other, the heater filaments are connected in a series sequence directly across the power line, as are the selenium or silicon rectifiers.

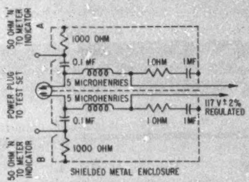

Fig. 3. Standard power line impedance filter (1805)

By virtue of the inherent isolation of the power transformer secondaries from the line in the first case, the capacitive and inductive harmonic interference is held to a minimum. Series-filament chassis with selenium or silicon rectifier power supplies present a difficult problem because of the direct electric connection to the power line cord. With this design, it is imperative that low-harmonic voltage appear between the chassis and ground. Basic circuit design and chassis layout must be well chosen to minimize these undesired harmonic voltages on the chassis. When cabinet design provides a metallic enclosure or cabinet, this directly reduces the objectionable harmonics. Wooden cabinets or any of the synthetic substitutes do not shield the sweep harmonics. An attenuation of several decibels is attained because of the shielding effect of a metal cabinet.

Spurious sweep radiation can best be minimized in original TV receiver design if the contributing factors are recognized and kept in mind during layout of the original circuit.

One of the prime evils is excessive lead length in sweep circuits. Leads carrying harmonic sweep frequencies will couple spurious frequencies to other chassis wiring if located within fractions of an inch. A most critical lead is the top plate connection to the horizontal-sweep tube. This tube should be placed as close as possible to the sweep transformer, which is normally in a shielded enclosure. The shield cage should be well grounded electrically whether screws or twist lugs are used. Inadequate grounding of the shielded sweep cage gives rise to large harmonic sweep interference currents at the high-impedance mounting point where it is attached to the chassis.

The sweep circuit (tubes and transformer) should be isolated physically from the rest of the chassis components to minimize coupling to other circuits and to avoid common ground coupling as well as direct electrostatic coupling.

Circulating ground currents are best minimized by short ground leads. Avoid the common ground connection from a cathode terminal to a filament terminal and then to ground. This introduces the peak saw-tooth current from the horizontal tube into the primary filament wiring by virtue of common impedance. This, in turn, couples and radiates to other wiring and eventually the interference is conducted to the power line.

Surprising reductions are effected by attention to the total physical area of the sweep circuitry and to the wire lead lengths. Parts should be located adjacent to the circuit concerned. The total area of the entire circuit should be as small as possible. In addition to reduced radiation from short leads, circulating ground currents are thereby reduced. This minimizes common coupling to nearby components.

The electrolytic capacitor of the power supply filter is very important in the series filament selenium-rectifier receiver design. This component should maintain low impedance to the saw-tooth current flowing in the horizontal-sweep tube circuitry. The multiple-section electrolytic capacitor should be checked for low-coupled impedance at the sweep harmonic frequencies in the broadcast band. The filter capacitor should be physically close to the sweep circuits to maintain short lead lengths. These leads radiate appre-

Fig. 4. Coaxial constant-impedance switching assembly

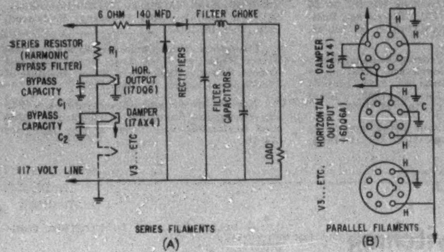

Fig. 5. **Preferred filament-wiring configurations**

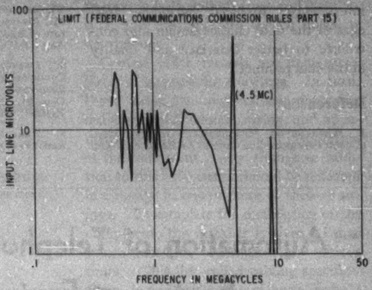

Fig. 7. **Conducted power-line emission of sweep harmonics of receiver complying with FCC requirements**

ciable harmonics and couple undesired signals directly into unrelated circuits.

Assuming that nominal effort is made to keep the wiring short and dressed away from other circuits, the deflection yoke and its connecting wires have not contributed appreciably toward excessive sweep harmonics.

Transformerless series-filament receiver design presents one problem because of the heater-cathode capacitance of the damper control tube. The sweep voltages and harmonics are directly coupled to the a-c power line through this capacitance via the series-filament wiring. Appreciable reductions in sweep harmonic line conductance are effected by the arrangement of the tube filament sequence wiring. Fig. 5 is the preferred arrangement of, first, a series dropping line resistance *R*1; second, the horizontal output tube filament; and third the damper filament.

The added series impedance gained by this arrangement reduces the harmonic voltages coupled to the filament from the damper cathode because of the heater-cathode capacity and the pulse existing in the cathode circuit.

Additional bypass capacitance (*C*1 and *C*2) from the filament circuit to ground was required in one such case to bring the sweep harmonics within the required measurement. It may appear that these horizontal sweep filaments could be placed at the bottom end of the filament string. This is ruled out because of other problems encountered if the low-level or high-frequency amplifying tubes (radio-frequency tuner or intermediate frequency) do not have the filament adjacent to the cold or "grounded" side of the series-filament 117-volt string.

It is preferable in any design to use only the one required connecting wire to each of the filament solder terminals at the damper tube socket. Likewise, only one lead should connect for the respective *B*+ circuit, as shown for the parallel-filament case in Fig. 5(B). If tube socket terminals are used indiscriminately as convenient tie points, appreciably more harmonic currents will be introduced into related circuit wiring.

The ground lead from the filament transformer should be short and away from horizontal circuits. Also, the primary a-c wires should be isolated from the horizontal circuits.

Since the Underwriters Laboratories, Inc., have increased the limit on total maximum high-voltage circuit capacitance to 3,000 micromicrofarads, this can be utilized to great advantage by increasing the bulb-coating capacitance. The rectified voltage from the horizontal-pulse transformer flows in this capacitance. Thus, more capacitance and better grounding aid substantially in reducing the high-level harmonic voltages.

To take advantage of this greater allowed capacitance, the outside graphite bulb coating was extended to the outer rim of the picture tube. The graphite coating, was grounded by the mounting strap used to secure the tube to the chassis, giving a low-resistance d-c connection to the chassis ground. Equally important is a low-impedance ground path offered by a wide metal strap to the alternating voltages in the circuit. This improvement in reducing the grounding resistance and impedance of the picture-tube bulb coating has been accomplished in Zenith television receivers with a reduction in cost; see Fig. 6. Fig. 7 shows the measured conducted power line emission.

It is axiomatic that there exist no one or two simple corrections that will remove the problem of undesired sweep harmonic interference. The solution is primarily good basic initial design in all the related parts, with the consistent aim of minimum harmonic-sweep interference.

Minor circuit modifications can increase the measured harmonics at one frequency due to in-phase addition of these voltages. It frequently happens that one troublesome circuit must be modified to accomplish, say, a 6-decibel reduction in the harmonic measurements before other relatively minor changes will give the last decibel or so needed to attain the desired low level of harmonic

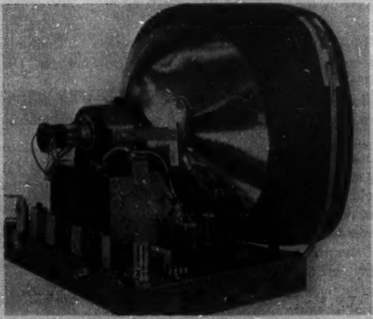

Fig. 6. **Zenith TV chassis illustrating ground-strap connection to external graphite electrode of picture tube**

interference. Reduced harmonic voltages in the final chassis design also contribute to better interlace and quality in the final product.

Automation of Telephone Switching Equipment Engineering

L. W. BLUMER
NONMEMBER AIEE

G. E. REIFENSTUHL
NONMEMBER AIEE

N. E. LIST
NONMEMBER AIEE

THE TELEPHONE industry is beginning to use computers to engineer new telephone switching equipment and additions to it. Most of this equipment which sets up calls among subscribers is located in central offices. An examination of the factors involved in manually engineering this equipment will help to explain why Bell Telephone Company engineers feel computers will make engineering faster, cheaper, and more accurate.

What Is Involved in Engineering of Switching Equipment?

Engineers must first determine which type of central office switching equipment is to be installed. Office size, trunking to other offices, service objectives, maintenance costs, expected growth rate, economics, and many other factors bear on this decision.

Assume for illustration that crossbar dial equipment is chosen to replace an existing manual office. The number of subscribers at "cutover" time must be estimated. Calling rate and call duration time must be computed on the basis of locally collected data and the projections made from them. Consideration of these factors, capacities of various equipment required and service objectives, etc., fix the minimum size of the switching system.

Economics of providing building space and equipment for growth help fix the maximum office size provided initially.

In order to price out the job, the engineer must know engineering, equipment, and installation costs. He must determine the time intervals required for each to establish a schedule for the job.

The engineer must consider the variables covered above and many others which interrelate with them. He must make a series of decisions based on these factors. For large dial jobs he usually writes an outline specification. He makes cost estimates and obtains management authorization for the undertaking.

For the job just described the Bell Telephone Company engineer then places an order with the Western Electric Company to detail engineer, manufacture, and install the equipment.

His outline specification, order, and job drawings specify:

1. Where, when and what equipment is to be installed.
2. Floor plan layout.
3. Trunking patterns, assignment of trunks to switching equipment.
4. Equipment features.
5. Anticipated growth patterns.

The Western Electric engineer's subsequent job in preparing detailed specifications and job drawings is covered later.

Why Consider Computers?

"Manual" engineering takes considerable time. Engineering rates loaded for supervision, clerical and drafting assistance, floor space, etc. have risen over the years.

Time and costs involved often preclude consideration of all desirable alternatives. Computers are fast. They could permit checking reasonable alternatives quickly.

Many elements, such as conversion of calling rate and call duration data into equipment quantities, are highly repetitive computations. Computers are designed for this work. Engineering talent could better be used to program computers.

Humans thrive on innovations. Engineers excel. But this sometimes adversely affects job uniformity. Computers do not innovate.

Faced with the same choice of alternatives at different times, humans are not consistent. Computers are.

Engineering rules must be learned and remembered. Although they must be taught in very simple steps, computers learn, remember, and apply what they know much better than humans. So they offer the advantages of accuracy and consistency to engineering.

Summed up: Because of experience with computers and knowledge of their capabilities, Bell engineers feel they will offer cost reduction, interval reduction, standardization, uniformity, and other advantages to equipment engineering.

Will Computers Be Feasible for Engineering?

Yes. Bell Telephone Company engineers have this evidence:

1. Rapidly expanding use of computers to write detailed central office equipment engineering specifications at Western Electric. About 15% of all job specifications written there are now produced by computer. Details are given in the section on Automation of Western Electric Equipment Engineering.

2. Computer preparation of detailed specifications for large business customer dial switching systems. These data will be discussed in the section on Computer Processed Short Order Plan for Dial PBX's.

3. Telephone company feasibility studies. Gross savings in engineering

Automation of Western Electric Equipment Engineering

Bell Telephone Companies prepare outline specifications on central office equipment which is to be detail engineered, furnished, and installed by the Western Electric Company. This section discusses some of the techniques which have been developed for the production of detailed engineering information by a large scale electronic computer used for many other purposes.

The Western Electric equipment engineer performs three basic functions in his detailed analysis of the telephone company specifications. The automated procedure must provide information for these functions in printed form for further manual processing or in the form of cards or tape for further machine processing. These functions are as follows:

Information for manufacture
Information for installation
Maintenance of central office records

These functions are performed by engineers at two locations on both manual and dial switching equipments. Toll dial switching equipment is engineered in Newark, N. J. Regular central office dial switching equipment is engineered in Chicago, Ill. At the present time much of the engineering in Chicago is concerned with the system known as No. 5 crossbar. This system makes use of crossbar switches and relay common control circuitry to provide talking paths among subscribers. The techniques described in this section have been generally applied to this system. Some attempts have been made toward applying them to step-by-step, No. 1 crossbar, and crossbar tandem dial systems. However, these systems are older. They are not as adaptable to engineering automation techniques as the more standardized No. 5 crossbar system.

In the manual engineering of a No. 5 crossbar order, manufacturing information is provided by a series of specifications. In general these specifications cover a type of frame or unit, and contain a summary of materials required. The major equipments are ordered as lists on manufacturing drawings. These lists have been provided for the various standard operations which the equipment has been arranged to perform. Combinations of types and quantities of equipment provide central office installations capable of fulfilling almost any traffic requirement. Another portion of these specifications includes a listing of the drawings to be used in both manufacture and installation, and contains any special notes or instructions.

Central office records are kept on a series of engineering drawings. In turn, these show the various manufacturing drawings, with figures, wiring, and apparatus used in production and installation of the equipment. Any change or addition to this equipment should be reflected in a change in one or more of these drawings. To complete the installation of the equipment, the installer is given a list of interconnections between the various units. This list, called cabling specifications, includes number of runs, switchboard cable code, length of run, and termination on the units.

It can be seen from the foregoing description that certain information will appear in a number of forms throughout the order. So certain basic decisions will logically lead to a need for detail information in many places. As an example of this statement, assume two frames (0 and 1) are being added, with an option A on Frame 0 and an option B on Frame 1. Since these frames will be ordered by a series of manufacturing drawings, it can be determined what these drawing numbers should be and may add or delete certain drawings on the basis of option A or B. The summary of materials will require lists for the manufacture of the basic frames and Frame 0 will require a list for option A while Frame 1 will require a

The codes are used as follows:
Line Destination—Number of cards required for this line
Line Count—Number of lines being printed. Provides count for page and title routine
Printer Control—Controls operation of the printer. A zero provides double space, a one a new page, etc.
Line Number—Provides a means of sequence checking
Use Code—Used to control further processing on the basis of whether this line is always required, or needs modification, etc.
Drum Section—If line required modification, machine instructions will be found within this drum section
Position in Section—The instructions start at this tenth of the 200-character section

different list for option B. These options will be reflected in the central office record drawings. The options may appear as differences in cabling between these frames and other units. Production of detailed information from relatively few basic engineering decisions makes computer production of these details practical.

Early investigation indicated that even a large scale computer would not have the memory capacity required to write a complete specification. This led to a line-by-line approach to specification writing. This concept is shown in Fig. 1.

The first step in preparing a specification for production by this method is an analysis of the various equipment engineering decisions which may affect the specification. After this analysis has been completed a master specification containing lines for all anticipated conditions is prepared. This will later be placed on tape and becomes the input specification tape of Fig. 1. During the writing of the master specification, notes are made of the engineering decisions which must be made for each job. These notes are made into a questionnaire which will be used to produce the job input punched cards. The lines within the master specifications can be divided into three general types: 1. lines which are always required and will not be modified by the job; 2. lines which are always required but will require modification per job information; 3. lines which may or may not be required and may require modification based on the option used on the job. The machine instructions which produce the decisions on each line are contained on the program tape.

A general machine routine has been written which reads the specification tape into memory one line at a time. Each line carries a 13-character code which is used to control further processing. A sample of a line with its associated coding is shown in Fig. 2.

The machine instructions which are contained on drum sections (line subroutines) may contain only a few simple instructions. Or they may be complex looping routines which provide many output lines for every input line. The line shown in Fig. 2 would have a test for zero quantity (this frame is not always provided), transfer to read in a new line if zero quantity, or place quantity in the** position of line if not zero and transfer to an output printing routine. A flow chart for this subroutine is shown in Fig. 3.

Many cables are required once per frame type. The line routine for such a condition would be transferred to the general printing routine, but would then be transferred back to the same line instead of bringing in a new one. This line would be modified to raise the frame number, and then printed again. A count would control the number of times this was done, and a new line would be brought in when all cables had been written.

Every line would be read and processed against the order cards for the specification. Upon completion of the specification, a new set of order cards would be read into memory. The lines for this specification type would be found and processed one at a time. When all order cards have been processed, the general routine will rewind the tapes and type out a message for the machine operator.

Describing the process requires considerable time. However, an average specification can be machine processed in a minute to a minute and a half.

Computer Processed Short Order Plan for Dial PBX's

A trial of computer-engineered "short orders" for 740E dial Private Branch Exchanges (PBX's) has been been successfully completed. Full-scale use of the new ordering plan for the PBX's is about to begin in the Bell Telephone Companies. These relatively small customer switching equipment units normally serve from 40 to 80 lines.

This new ordering plan involves preparing detailed specifications by computer in Chicago.

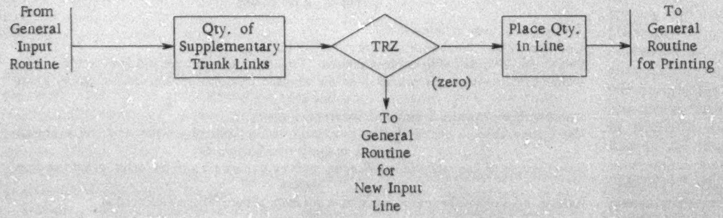
* Distribution made over 5 frames.

An order originates in a Bell Telephone Company with preparation of a 3-page form and requisition sheet. The engineer simply fills in blanks or encircles options. Thus, he orders in outline form, not in technical description, the number and types of switches, the switchboard, etc.

As many copies as required are made by any quick reproduction method available in the telephone company. Copies are used as needed locally. Others are sent to appropriate distribution, installation, and manufacturing organizations of the Western Electric Company.

At Chicago, a deck of punched cards is prepared from the quick order form. These cards, master specification tape, and a program tape are loaded into the computer. The output is a complete detailed specification which combines the following:



From General Input Routine
Qty. of Supplementary Trunk Links
TRZ
(zero)
Place Qty. in Line
To General Routine for Printing
To General Routine for New Input Line

Fig. 3. Subroutine

1. The general job summary.
2. Material list, edited by sources.
3. Cabling specification.
4. Job drawings in tabular form.

Copies of the completed specification are used by the manufacturing organization in filling the order. Others are used by the installer and the distribution people for billing and other uses. Of course, copies go to the telephone company.

The advantages of this quick order plan are:

1. Shortening of the order-to-service interval by reducing the telephone company engineering time. The short order may be filled out in minutes. Writing the detailed specification manually takes days and is subject to human errors that occur even in the most careful detail engineering.

2. Engineering costs will decrease attractively.

3. Standardization offered by computer processing will provide installation, manufacturing, billing, and other difficult-to-evaluate but real values.

4. The engineer is "out of the nuts and bolts business." This releases his energies for more productive efforts requiring his engineering talents.

5. The ordering form serves as a valuable check list since every question on it must be answered. So delays in jobs due to omissions in ordering should decrease materially,

Feasibility Studies of Computers Used for Engineering

As part of a test of computer practicability, one telephone company made a feasibility study on computer assignment of trunks to trunk link frames in No. 5 crossbar offices.

The studies were directed by N. E. List and developed by G. L. Broxholm, both with the Michigan Bell Telephone Company. This phase of the outline specification is considered among the most complex and time consuming jobs in preparing an outline specification. The assignment routine was programmed for a punched card input–output type computer. The following paragraphs describe the nature of the problem, input requirements, and a reproduction of the machine listing of the output cards produced by the computer process.

OBJECTIVE

The objective is to distribute all trunks as evenly as possible over all frames to insure that as many calls as possible can be completed without blockages.

PROBLEMS

1. There are several types of trunks that must be assigned:

a. Outgoing, interoffice, and intertoll.
b. Incoming, interoffice, intertoll, and tandem.
c. Two-way, intertoll, and CDO.
d. Intra-office and reverting.
e. Marker pulse conversion.
f. Bunched appearances.

2. For equipment reasons the 160 possible appearances on a trunk link frame are divided into 16 levels of 10 appearances each. Each level has certain limitations:

a. 8 levels can be used only for outgoing trunks and the outgoing end of intra-office trunks.
b. 4 levels can be used only for incoming trunks and the incoming end of intra-office trunks.
c. 4 levels can be used for any type of trunk except intra-office.
d. The 12 levels (items a and c) that can be used for outgoing trunks are subdivided into six groups of 2 levels each. With some exceptions, once any trunk of a type is assigned to one of these six groups all the trunks of this type must be assigned to the same group.

INPUT INFORMATION

1. Number of trunk link frames.

2. Number of vacant terminations on each level of each frame and totals for each level and frame.

3. Order of preference of assignment to levels for each group of trunk types.

4. Trunks to be assigned by type, quantity, and group number; see Table I.

The machine process distribution of trunks shown in Table II is felt superior to that normally produced by manual methods.

Projection of these and other feasibility study results to the whole telephone company engineering job indicates a 60% engineering manhour saving over manual methods.

Punched Card Engineering

Detailed job specifications for small new step-by-step dial offices and additions to such offices have generally been prepared by telephone company engineers.

Engineers in at least two Bell Telephone Companies have developed techniques to use punched card processing business machines for detail engineering of small dial offices.

Basically the procedures combine elements of those covered in the foregoing sections. The engineer prepares work sheet forms. He enters the codes, quantities, and associated information pertaining to the desired equipment items.

The machine process produces:

1. The installer's cable running list.
2. Summary of material required.
3. Equipment costs.
4. Installation man-hour estimates.
5. Other elements of a complete specification.

Steps in the Job

Bell engineers feel that much further documentation of engineering information is necessary for most effective automation. Many engineering rules previously used must be closely evaluated and defined before computers can apply them. Engineering procedures will be integrated with related clerical, accounting, and other functions.

Engineering will be a profitable part-time computer job. So these machines will largely be proven-in to handle other, more large scale data processing jobs. Hence, the engineer will not usually have direct choice of the computer available to him. But the kinds and types of computers used by the various Bell Telephone Companies will be limited.

Study of the problems involved in mechanization of engineering has suggested joint intercompany development of engineering programs for computers. This is already underway. The output of such joint effort will be modified as required by the using company to fit its computer and its organization.

Conclusions

The computer will free telephone company engineers from many tedious quasi-engineering tasks. Costs of engineering should be reduced or held in check. Overall intervals will decrease. Accuracy will improve. Resulting standardization will be responsible for further savings. By-products possible—such as cost data, accounting information, power drain data, etc.—may be even more valuable than the tangible advantages seen today.

A Step-Driven Digital Magnetic Recorder

J. G. HANSEN
NONMEMBER AIEE

THE DESIGN and installation of a freight-car information sorting system for the Chicago, Rock Island and Pacific Railroad was recently completed by the Stromberg-Carlson Company. The system, located in the Chicago, Ill., offices of the Rock Island Line, receives information on train make-up from several distant marshalling yards via teletypewriter links, records these messages, and sorts them. The Wheel Report Sorting System, as it is called, sorts the incoming information according to state of origin of shipment and state of destination, and routes this information to teletypewriters assigned to these states. In the course of designing the sorting system, a requirement developed for a means of storing multiple incoming messages efficiently, while sorting units are busy. The storage means must permit simultaneous recording and read-out at different rates, and must also operate intermittently on read-out due to switching of output during sorting. This service can be provided by paper-tape punches and readers with a buffer loop between. However, the information density on paper tape is low, thus creating a need for a physically large buffer storage. This fact, coupled with the need for continuously replenishing the tape, and the maintenance requirements of punches, led to the search for a more suitable means of storage. Magnetic recording presents the possibility of higher information density in addition to using a reusable medium. However, magnetic tape recorders of the conventional capstan-drive type do not generally provide for differing speeds of simultaneous recording and read-out with a buffer loop between for "first in, first out" storage. In addition, the requirement that the read-out be intermittent due to the setting up of connections to different printers is difficult to achieve without sacrificing information density for starting and braking space.

Description

After reviewing the market and not finding a suitable recorder available, the company's Research and Advanced Development Division proceeded to develop a magnetic recorder specifically for the Rock Island Wheel Report Sorting System. A magnetic recorder which would incrementally move the recording medium for each character being recorded or read out, on demand only, offers a means of obtaining varying information rates and instantaneous starting and stopping as required by the system. Storage between recording and read-out could be obtained by the use of a random-fold bin to accumulate the amount of recording medium required.

In order to obtain incremental, or stepping, movement of the recording medium, a simple and rugged mechanism is most desirable. The ratchet and pawl is such a mechanism and was chosen as the driving means for this recorder. There are two driving mechanisms used on each recorder; one for recording and the second for read-out. Construction features include a heavy base casting upon the rear of which are mounted the driving magnet and pawl assembly, and the ratchet gear. On the face of the castings are mounted the recording head assembly, film guides, and 35-millimeter-film drive sprocket. The ratchet used is a 160-tooth gear. This ratchet is directly coupled to the 16-tooth 35-millimeter-film drive sprocket giving ten characters of recording between sprocket holes in standard 35-millimeter magnetic recording film. Longitudinal bit spacing is held to 0.01875-inch centers (approximately 53 bits per inch, per track). Wearing surfaces of the ratchet teeth and the pawl are hardened to minimize wear. The pawl is made "glass-hard" and the ratchet teeth somewhat softer to obtain a match of wearing qualities which extends the life of the combination beyond that which would occur with both teeth and pawl made "glass-hard." Accelerated life tests on the recorder drive mechanism indicate life expectancy of at least 20 million operations, equivalent to continuous operation for approximately 750 hours in teletypewriter service at 75 words per minute, before requiring overhaul. The base castings are of cast iron to provide rigidity for mounting heads and mechanism in accurate alignment. Mass of the castings is large (approximately 2 pounds) and is arranged to prevent the action of the magnet and armature from transmitting unwanted inertial motion to the film. Such undesirable action can cause buckling of the film under the head with possible errors in reading or recording occurring as a result.

Sprocketed film is used as the record-

Paper 60-183, recommended by the AIEE Telegraph Systems Committee and approved by the AIEE Technical Operations Department for presentation at the AIEE Winter General Meeting, New York, N. Y., January 31–February 5, 1960. Manuscript submitted August 7, 1959; made available for printing February 17, 1960.

J. G. Hansen is with the Stromberg-Carlson Company, a Division of General Dynamics Corporation, Rochester, N. Y.

Fig. 1. Step-driven digital magnetic recorder

ing medium to insure accurate longitudinal spacing of recorded bits. Sprocket holes are held to ±0.001-inch center-line spacing tolerance in conformance with the standards of the American Society of Motion Picture and Television Engineers. The thermal coefficient of expansion of acetate film is negligible in this service as is its expansion or contraction due to moisture content. Fireproof film is, of course, used. Use of standard motion-picture film base with magnetic-oxide coating permits the use of standard motion-picture projector sprockets and guides which are also manufactured to close tolerances set by the Society.

Accuracy of bit spacing in the longitudinal direction is required in order that the relative position of each recorded bit be identical with regard to recording and read-out heads. This requirement is brought about by the fact that maximum output signal is obtained by the complete passage of a magnetized portion of film under the read head during each incremental motion of the film. In addition to yielding maximum signal, this requirement prevents false signals being generated by the leading and/or trailing edges of a recorded bit. Five-bit teletypewriter code is used in the Wheel Report Sorting System. A character is represented by a "mark" or "space" in each of five parallel tracks.

At this point it should be made clear that pulse information is recorded in each track of the film as the film is stationary under the record heads and is read off the film as it is moved past the read heads. It is important, when initially adjusting the position of the read head assembly, that the head gaps are set exactly halfway between recorded bits. The procedure used to set the position of the read heads is as follows: Recordings are made in all of the multiple tracks sequentially for several inches of film, using the recording heads. The film is then moved to the reading position where it is arranged to record again in all of the multiple tracks for a short distance along the film. The piece of film is then removed from the recorder, placed momentarily in a suspension of carbonyl iron powder in alcohol, and carefully dried. The relative positions of recording and reading heads is then visible by virtue of the concentration of iron powder at the magnetized spots. The procedure is repeated until the spots made by the read heads are midway between those made by the record heads. In order to insure identical longitudinal spacing for each of the multiple tracks, the recording and reading head groups are rigidly held perpendicular to the film travel and thereby parallel to each other.

The amplitude of pulses generated by the passage of recorded bits under the read heads is kept uniform by the mechanical arrangement of the step-drive unit. Motion of the film is accomplished on the spring return of the magnet armature to its reset position, not on energizing the magnet. This prevents the possible variation in actuating speed which can occur with variable voltage applied to the magnet coil. The action of the pull-up of the armature has then no relation to the movement of film under the heads except that frequency of action determines the average speed of film travel.

Provision for storage of messages between recording and read-out is provided by means of a bin into which the film is inserted and allowed to fold randomly after recording. Fig. 1 shows the storage bin attached to the recorder. Film is withdrawn as messages are read and then fed back into the same bin. As further messages are recorded, the film is again withdrawn by the recording mechanism, passing the previously recorded film under an erasing head, just prior to recording the new information. Thus a loop of magnetic recording film is utilized. In the case of the Rock Island system, 60 feet of film are used in each loop, enough for $1\frac{3}{4}$ hours of recording time at 60 words per minute. In the system used in the report sorter, a means for detecting a taut film condition between recording and read-out is installed. This is in the form of a light metal arm, on the end of which is a roller, riding on the film as a taut condition is approached. When the film raises the arm to a preset position, read-out is suspended when simultaneous recording and read-out are proceeding, or, when read-out only is underway, the action causes the recording mechanism to step in synchronism with the read-out until the end of a message is detected.

Erasure of previously recorded information is accomplished simply by use of a permanent magnet, which biases the magnetic oxide in a condition opposite to that created by recording. This gives maximum change of condition between blank and recorded spaces yielding maximum output pulse amplitude as read out.

As the recorder is used in the Rock Island report sorting system, it operates at a speed of approximately seven steps per second. The design of the recorder is such, however, that it can be operated at 40 steps per second continuously with no modifications. Using slight modification of armature construction and the return spring, the basic unit has been driven, in tests, at 80 steps per second. The recorder as initially designed, then, can be used in service requiring the equivalent of approximately 400 words per minute of teletypewriter data. Driving energy required by the recorder is minimal, with energy being supplied to the mechanism in pulse form, at a rate determined by the data being handled. The driving magnets are energized by transistors in the sorting system from a 48-volt d-c source. The lateral spacing of the heads is not the most efficient based on the width of the film available, since only five tracks are used. With other commercially available heads, 8-track recording could be arranged across the film. If the space available outside the holes were utilized, ten tracks could be used.

Conclusions

The step-driven digital magnetic recorder is a versatile data-storage facility. It permits the simultaneous recording and transmission of digital data at varying rates. Data may be transmitted at any rate from a minimum of less than one character per minute to a maximum of 40 characters per second with no change in pulse amplitude, thus simplifying the design of amplifiers in the transmitting system. Storage of data between receipt and transmission can be as large as required by any particular system, dependent only on the size of bin which can be mechanically fitted to the circumstances. A possible additional application of the recorder is buffer storage of periodic readings of remote data sources between transmissions to a central point.

Reflections on the Traffic Usage Recorder with Emphasis on Traffic Engineering

R. A. BAUERFELD
NONMEMBER AIEE

AS IMPLIED by the title, the intent of this article is to relate the manner of use and value of the Traffic Usage Recorder as applied to telephone traffic engineering. To develop a full appreciation of this, a general knowledge of the responsibility of the traffic engineer is required. In a broad sense, the traffic engineer must see that facilities of the right kind and of the right amounts are in the right place at the right time to give the right grade of telephone service. An important phase in this provision of telephone facilities is in determining the requirements of the telephone subscriber. In the process of estimating subscriber requirements, summarized call carrying and associated equipment usage data are analyzed, projected, and modified to reflect expected growth, new service, and proposed equipment arrangements. The modified basic data are then converted to equipment quantities and trunks through the use of probability tables reflecting the desired grades of service. The first step of this process, the gathering and summarization of usage data, is of prime importance and has been a major problem to the traffic engineer.

Prior to the development of the Traffic Usage Recorder, sufficient accurate usage data was most difficult to obtain. Through the use of peg count registers, data were available that indicated the number of times an item or groups of equipment were called into service. However, this is not usage; the length of time of equipment in use was needed. To convert peg count data to usage it was necessary to apply a holding time or the average length of time per peg count call. Representative holding times were difficult and costly to obtain. The usage equipment at the disposal of the traffic engineer to develop holding times was limited in capacity and subject to considerable error. Therefore, in the process of converting peg counts to usage, reliable holding times were at a premium.

It should also be mentioned that registers were read and the results summarized on a manual basis adding more inaccuracies and expense to the over-all problem. Clearly there was a need for an automatic traffic usage measuring device of proper capacity and utmost reliability.

The Traffic Usage Recorder—Description

In 1955 the Traffic Usage Recorder (TUR), developed by the Bell Laboratories and manufactured by the Western Electric Company, became available for service. Designed for a large capacity, a basic unit or frame is capable of testing up to 3,600 items of equipment almost simultaneously. The TUR is timed to scan all 3,600 test terminals every 100 seconds or 36 times an hour operating associated registers when busy equipment is encountered. In effect, the scorings indicate the number of calls of 100 seconds' duration, which is a basic unit of load measurement employed in traffic engineering. As an example, Table I[1] indicates the number of 100-second calls which can be handled by various size trunk groups to provide a grade of service equivalent to encountering one all-path-busy situation per 1,000 calls. For purposes of a brief general description, the TUR may be broken down into three components: the frame, register rack, and control panel.

The frame, pictured in Fig. 1, consists of timing units, scan and register crossbar switches, grouping fields, and control equipment. The timing units and control equipment contain the relay circuits, timers, and detector circuits that control the over-all functions of the TUR. Six scan switches provide the input terminations and busy signal paths from the items of equipment being measured to the detectors, as shown in Fig. 2. Inasmuch as the six scan switches are of the 100-point 6-wire type, 3,600 input leads may be accomplished. The register crossbar switches in turn provide the path from the detector for the reproduced busy signal. There are six register switches of the same capacity as the scan switches with the 3,600 terminals being cabled to the register grouping fields, where the register switch output terminals may be grouped to traffic registers as desired. Simultaneous operation of a scan switch and corresponding register switch crosspoints allows the inputs to a scan switch crosspoint (6 per crosspoint) to be tested, with any busy signals encountered being reproduced by detectors through the register switch crosspoint to the register grouping field. In addition to the register grouping field, there is a detector grouping field to associate the scan switch contacts with the proper detector.

The traffic registers associated with the TUR are located in a standard register rack bay shown in Fig. 3. Pin jacks at the base of the bay are cabled to punchings in the register grouping field located on the TUR frame. A pin jack may be connected to the desired register by means of a patch cord. Camera and hood assemblies are available to photograph the registers automatically, with two assemblies being required to photograph a rack of 300 registers.

The operation of the TUR is controlled at a relay rack or wall mounted panel consisting of a program timer, keys, and a cycle register; see Fig. 3. During automatic operation, the program timer controls scanning and minimum hour long scans may be programmed as required starting on the hour, half, or quarter hour. Also, the timer is equipped with a day wheel which will permit the elimination of any undesired day or days from the study period. The panel keys control manual scanning, cameras, tests, and miscellaneous operations. A total of 12 TUR frames may be served from one control panel.

Table I. Poisson Capacity Table

Trunks	Hundred Call Second Capacity	Per-Cent Usage
1	0.1	0.1
2	1.6	2.3
3	6.9	6.4
4	15.4	10.7
5	26.6	14.8
6	40.0	18.5
7	54.7	21.7
8	70.9	24.6
9	88.2	27.2
10	107.0	29 7

Paper 60-819, recommended by the AIEE Communication Switching Systems Committee and approved by the AIEE Technical Operations Department for presentation at the AIEE Summer General Meeting, Atlantic City, N. J., June 19–24, 1960. Manuscript submitted March 21, 1960; made available for printing April 22, 1960.

R. A. Bauerfeld is with the Southern New England Telephone Company, New Haven, Conn.

Fig. 1. Author and traffic usage recorder frame

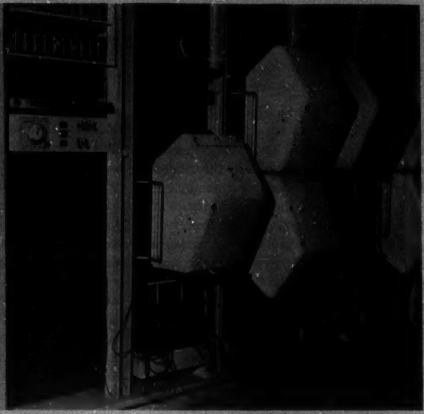

Fig. 3. Traffic usage recorder control panel and camera hood covered register racks

To insure the complete flexibility of the TUR, distributing frames have been provided at the Southern New England Telephone (SNET) Company TUR installations. The busy leads of equipment are cabled to one side of this frame, and the scan switch terminals to the other. This arrangement allows any item of equipment to be cross connected to any scan switch terminal.

The foregoing description of the TUR is by necessity brief as the intent is to provide an appreciation of the apparatus rather than a detailed understanding.

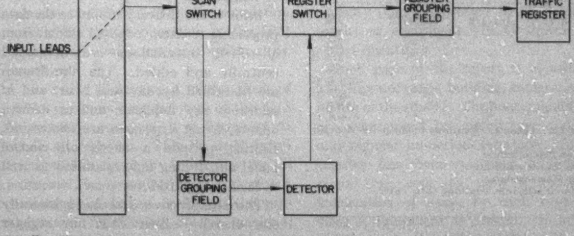

Fig. 2. Schematic showing interrelationship of traffic usage recorder components

The general review in the operation and capacity is considered essential to comprehend the possibilities and value of the TUR to the traffic engineer.[2]

Assignment of Equipment

The Southern New England Telephone Company, one of the first companies to adopt a comprehensive use of the TUR, had 55 frames in operation at the close of 1959, with 6 offices of over 10,000 connector terminals (telephone numbers) and all crossbar tandem offices are being equipped with the TUR; toll trunking is also being measured in the larger toll centers.

Equipment and trunks usually assigned to the TUR in local dial step-by-step offices include line finder groups, rotary and level hunting connectors, service code selectors, local and extended area trunking, and toll connecting trunks. Usage on the above equipment is essential to develop a complete distribution of traffic load through a local dial central office.

Trunk link frames and office link frames as well as major items of common control equipment are assigned to the TUR in crossbar tandem offices. Two TUR features, register grouping and 10-second scan, were not mentioned in the general description of the TUR, but are being used for measuring crossbar tandem equipment. The register grouping feature in a 20-trunk link and 20-office link frame office will allow the substantial saving of 300 No. 14 type registers. The 10-second scan arrangement is designed for equipment with exceedingly short holding times and will test for busy conditions every 10 seconds instead of the usual 100 seconds, lessening the possible error when measuring these items.

The entire Southern New England Telephone intra-company toll network is on a high-usage basis. Although this system is designed to realize trunking savings, a complete usage analysis is necessary to effect efficient loading and therefore all toll trunk groups, including intercompany trunks, are being measured in TUR equipped toll offices.

Scheduling

Studies designed to produce traffic engineering basic data are scheduled by the engineering group. The study period, or sample, should approximate the average busy season with reasonable accuracy and will depend upon the characteristics of the particular office involved. Therefore, study programs should be determined after a thorough analysis of data, and reviewed for accuracy before being applied. In general, SNET Company study periods may be discussed by the type of equipment and trunks being measured.

In step-by-step local dial offices, engineering data are obtained initially on the basis of 5 consecutive business days per month for an entire year. After the seasonal calling patterns have been determined, only months prior to or following an addition, and covering the busy season are studied. The study week is selected to exclude any influences, such as a holiday, in an attempt to obtain basic data during an "average" business week. Four hours of usage are obtained on each day during the study period. The 3:30 to 4:30 a.m. reading is designed to obtain an indication of the equipment which may be in trouble or busied out at the central office, and the 9:30 to 10:30 a.m. and 10.30 to 11:30 a.m readings to furnish a record of the morning busy hours. The fourth hour to be read varies from month to month. This hour is required to obtain the maximum usage of various types of equipment or trunks for which the busy hour does not occur in the morning period. With experience it may be possible to confine studies to a fewer number of hours, obviously reducing costs. All local dial central office TUR's are scheduled for the same study period permitting the comparison of data collected on an originating basis at various offices to be correlated in the development of terminating load distributions, thus avoiding the necessity of measuring an interoffice trunk at both ends. For purposes of illustration, a schedule of TUR readings in local dial step-by-step offices for the first half of 1960 is shown in Table II. Engineering of local dial offices is based on usage during the average busy hour during the busy season.

Unlike local SxS equipment, crossbar tandem equipment is engineered on an average of the "10 high day" busy hour usage base. Experience has shown that peak usage occurs on Mondays, therefore it is felt that a representative 10 high day base may be developed by analyzing Monday loads only. In addition, SNET Company traffic engineers undertake periodic studies to determine frame balance that will influence assignments of trunks.

Toll trunk group usage is desired for 5 consecutive business days per month. The particular week selected is determined in much the same manner as for local dial offices; however, the hours scanned are quite different. A total of 15 hours per day, 3 to 4 a.m. and 9 a.m. to 11 p.m., are scanned in order to develop group and network busy hours. This schedule is maintained 12 months per year. In addition, miscellaneous special studies are scheduled to resolve items such as length of day, a factor applied to busy hour usage to reflect total day usage, and toll traffic loads and patterns during periods of heavy calling such as Christmas or Mother's Day.

Benefits derived from the practice of formal advance scheduling include:

1. A periodic general review as to the basic data required to engineer equipment and facilities satisfactorily. This may lead to deletions or additions to the items of equipment being measured and/or revised study periods.
2. A base from which machine data processing work loads may be estimated.
3. A greater degree of TUR utilization by the local traffic administrator in regard to obtaining data for other than engineering purposes, such as administration of equipment or for special studies.

Processing of Data

Procedures have been developed by the SNET Company by which the automatically photographed TUR register readings are processed by IBM (International Business Machines Corporation) at the SNET data processing center at New Haven. Reports are produced indicating actual loading of the various types of equipment.

Prior to the delivery of film to the data processing center, exposed films from all TUR installations are developed centrally and edited. The film frames are identified by day and hour, and in addition any duplicate and/or camera operation test exposures are eliminated. Editing permits a check on control panel and timing unit operation as well as facilitating IBM key punch operation.

The data processing method is basically one whereby edited TUR film register readings are transferred by a key punch

Table II. Traffic Usage Recorder Schedule
Local Dial Offices

Month	Hours	Tabs Depressed	Month	Hours	Tabs Depressed
Jan. 1960.....	3:30– 4:30 a.m.	3:30 a.m.	.......Feb. 1960...	3:30– 4:30 a.m.	3:30 a.m
	9:30–10:30 a.m.	9:30 a.m.		9:30–10:30 a.m.	9:30 a.m.
	10:30–11:30 a.m.	10:30 a.m.		10:30–11:30 a.m.	10:30 a.m.
	6:30– 7:30 p.m.	6:30 p.m.		7:00– 8:00 p.m.	7:00 p.m.
March 1960..	3:30– 4:30 a.m.	3:30 a.m.	.......April, 1960..	3:30– 4:30 a.m.	3:30 a.m.
	9:30–10:30 a.m.	9:30 a.m.		9:30–10:30 a.m.	9:30 a.m.
	10:30–11:30 a.m.	10:30 a.m.		10:30–11:30 a.m.	10:30 a.m.
	12:00– 1:00 p.m.	12:00 p.m.		6:30– 7:30 p.m.	6:30 p.m.
May 1960....	3:30– 4:30 a.m.	3:30 a.m.	.......June, 1960..	3:30– 4:30 a.m.	3:30 a.m.
	9:30–10:30 a.m.	9:30 a.m.		9:30–10:30 a.m.	9:30 a.m.
	10:30–11:30 a.m.	10:30 a.m.		10:30–11:30 a.m.	10:30 a.m.
	7:00– 8:00 p.m.	7:00 p.m.		3:30– 4:30 p.m.	3:30 p.m.

Detector Test: Following the reading scheduled for 11:30 a.m., on Friday, the Traffic Usage Recorder will be stopped, a detector test made and the results of the test photographed manually. This reading will replace the last scheduled Friday reading and will permit unloading of camera at the same hour each month.

Weeks to Be Read by District

Fig. 4. Reproduction of actual IBM traffic usage recorder results

machine operator into a working card deck containing identification codes gang punched from a master deck. The reading differences are computed and printed on a "report" illustrated as Fig. 4. In addition to differences, average and totals are also computed. From the completion of the key punch operation to the final report, all steps are accomplished by machine.

In order to develop a master deck of IBM cards, an essential tool of the data processing procedure, it is necessary to code all registers. This "coded" information is designed to: 1. Identify the report and the "working" card deck with a minimum of digits; 2. Aid in the programmed functioning of the machine; 3. Provide ready comparisons between results and engineering objectives. The coding for each TUR installation is maintained on a current basis by the traffic engineering group, and is identified on Fig. 4 by a double asterisk for reference. Two items are not coded, capacity (CAP) expressed in CCS, and trunks or equipment (TKS) shown as actual quantities.

Each page of the report is identified as to the exchange, building, camera, and month of the study. The hourly readings are summarized by circuit-type coding and register numerical sequence. Each register has been assigned a 3-digit circuit-type code to allow a machine totalization of usage by each type or class of equipment as desired. In addition to totals, the daily high hour, identified by machine with an asterisk, is averaged and printed under AVG. The column under BAL AVG is an average of the 2nd and 3rd hour or the 9:30 to 11:30 a.m. period, and is used to note the balance of certain items of equipment during the study period.

The general layout of the report facilitates a rapid evaluation of its validity. The results of the scan test, the 4th hour of the 5th day on Fig. 4, are easily compared to the quantity column substantiating the TUR circuitry from the detector to the register. A glance at the 1st hour, 3:30 to 4:30 a.m., will suggest permanents, troubles, or equipment out of service, and TUR trouble may be discovered by comparing a detector group usage register with a circuit-type total for the same entity. The availability of the report not only provides a basic data record, but permits a constant check on the operation of the TUR itself and often an indication of where the trouble may exist. Copies are easily printed and furnished quickly to all who have the need for results.

Value of Data

Traffic Usage Recorder data obtained for traffic engineering purposes are being used primarily to determine various equipment loadings as a base in the provision of facilities. The increased availability of basic data in quantity and reliability lessens the requirements for applied judgment to unknowns, and decreases the expected margin of error and resultant safety factor in estimating future equipment loadings. Inasmuch as a major portion of invested capital is in the vast amount of call carrying central office equipment and outside plant, more efficient utilization of facilities will result in substantial dollar savings. It is in this respect that the TUR has and will continue to realize savings many times its monetary value.

In addition to improved utilization, TUR data are being used to analyze existing traffic characteristics that may suggest future engineering concepts and techniques. Special studies showing load service relationships under various conditions have been undertaken with remarkable success. Also, traffic patterns and subscriber habits influencing loading within an office are being studied.

Although this report highlights traffic engineering with the TUR it should be noted that TUR data are being used very successfully by local equipment administrators to balance loadings by proper equipment assignments. TUR results are also aiding in the equitable distribution of intercompany toll revenues.

Conclusion

Future applications of the TUR may bring about many changes in traffic engineering techniques. It is expected that within the near future, the TUR may be modified permitting more direct checks for correct operation and the collection of usage on a medium that may be fed directly to a computor. TUR data properly coded may be converted to calling rates and projected by growth factors reflecting new service adjustments by computors capable of converting this information into equipment quantities through the use of digested probability tables. Although a completely mechanized operation may be the ultimate goal, it should be recognized that certain traffic engineering judgment factors must be included in the process and reflected in the result.

However, regardless of the future, the TUR has been and will continue to prove invaluable in the field of traffic engineering.

A Voice-Band Transmission-Measuring Set Using Swept-Band Techniques

WORTHINGTON C. LENT
NONMEMBER AIEE

THE NATIONWIDE telephone service which the country enjoys today is largely the result of careful systems engineering of which one objective is the establishment and application of uniform transmission standards. Transmission measurements constitute the essential means by which circuit design can be verified and the performance characteristics dictated by it maintained during operation.

The techniques for performing these measurements are well defined but tedious and time consuming. Achievement of useful results requires the effort of skilled personnel capable of exercising some judgment in application and interpretation. The plant has expanded at a rate exceeding that at which these skills can be supplied in sufficient quantity or at a cost which can be justified. There are only three alternatives: 1. to curtail testing, 2. to meet expanded testing loads with inexperienced personnel and correspondingly unreliable results, or 3. to revise techniques and equipment to reduce testing-time per circuit so that a limited number of properly qualified personnel can handle the increased load.

It is probably safe to say that, in general, the toll trunks have been carefully maintained. Their relative importance and the concentrations of equipment at toll terminals justify the assignment of skilled personnel to ensure proper operation. Furthermore, with the toll facilities under control of a single agency, the application of uniform practices and enforcement of maintenance procedures is possible.

In the exchange plant the situation is neither as simple nor as well defined. Where, in the case of the toll plant, hundreds of circuits under unified control might be involved, the exchange plant embraces trunks and subscriber loops numbered in the tens of thousands under control of many diverse operating agencies. Some of these subscribe to the importance of transmission engineering in various degrees. Others may not even have heard of it.

With the advent of direct distance dialing not only must transmission design be held to tighter limits, but the installed plant must meet more stringent acceptance tests and continue to be maintained with greater care than ever before. There will no longer be the operator to patch around deficient circuits. As a matter of fact, direct dialing, important and far-reaching as it is, could be a serious liability unless transmission design and maintenance practices adequate

---

Paper 60-816, recommended by the AIEE Wire Communication Systems Committee and approved by the AIEE Technical Operations Department for presentation at the AIEE Summer General Meeting, Atlantic City, N. J., June 19–24, 1960. Manuscript submitted March 24, 1960; made available for printing May 17, 1960.

Worthington C. Lent is with the Hallamore Electronics Company, Division of The Siegler Corporation, Anaheim, Calif.

The author wishes to express his appreciation for the co-operation and encouragement of Mr. Harold C. Diddel and Mr. Merle H. Jones of The Pacific Telephone and Telegraph Company at Los Angeles, Calif., and to acknowledge the very important contribution of Mrs. Eileen Kanczuzewski and Mrs. Marsha Rowan who typed the manuscript. Recognition is also due Mr. Arnold Schumacher and Mr. Robert Spaulding of Hallamore Electronics Company, who assisted during various phases of the development.

to support it are established and enforced.

The ultimate solution undoubtedly lies in the development of an automatic device which will continually probe every trunk on a whole-band basis for flatness and net loss and pass it for service or reject it for maintenance with a fault record. Some progress has already been made in this direction on a single-frequency basis. Such a device is certain to be expensive and some years away.

The subject of this paper is an instrument which may well be considered an interim solution and may even represent in nature what the economics of particular situations can ever justify.

The Design Objective

Broadly stated, the design objective of this development rests wholly on the premise that a whole-band visual display of transmission performance, with the ability to use such a display for the quantitative measurement of gain or loss, constitutes the basis of a measuring technique by which testing time can be greatly reduced and in which the transmission information is presented directly in usable form.

This should be accomplished without the need for complicated adjustments or interpretation exceeding the skill level of existing personnel.

To the maximum extent possible the device must be directly adaptable to existing practices and other measuring equipment and accessories with which the personnel is already familiar.

Portability is highly desirable, at least to the extent required for reasonable movement within a central office.

Specifically, the device must have the capabilities to:

1. Measure insertion gain or loss of any of the voice-band equipment or circuits now in service.
2. Provide a simultaneous whole-band display of relative input impedance, and the transmission-frequency characteristic at the output, of devices such as negative-impedance repeaters, equalizer networks, and hybrid networks, whose proper operation depends upon in-circuit adjustment.
3. Provide a whole-band display of the relative input-impedance characteristics of loaded lines to detect load misplacement or other impedance irregularities.
4. Display whole-band trans-hybrid transmission and measure the corresponding loss for the purpose of perfecting terminations and office balance.

There are undoubtedly many other applications of the device which will occur to the skilled worker.

The Design Problem

To reach these objectives several discrete circuit elements must be combined. Each will have performance requirements peculiar to it which must be specified.

Basically, any swept-band visual-display device must incorporate a generator capable of producing a constant-amplitude variable-frequency output over the desired band and a means for displaying the relationship which exists at a common instant between at least two parameters. The ordinary oscilloscope relates amplitude to time. Several devices present a display of amplitude as a function of frequency.

Quantitative information is derived by reference to the graduations of a scale placed over the viewing surface of the cathode-ray display tube. When such a graticule is used a considerable burden is immediately imposed upon the generator, the signal amplifiers, the deflections amplifiers and, indeed, the whole system. If this burden is not properly carried by the system, it is transferred to the operator who must make compensating adjustments.

The generator obeys a definite law relating frequency excursion to the driving-sweep amplitude. This amplitude must be maintained at that value which will cause precise registration of the trace within the horizontal limits of the prechosen scale. The generator must faithfully obey its own law, sweep after sweep, without apparent frequency jitter. For relatively broad-band generators, or narrow-band generators utilizing mechanically driven sweep elements, this condition is not particularly difficult to meet. For voice-band all-electronic generators it is.

Positioning circuits associated with cathode-ray devices are susceptible to drift unless elaborate regulation is incorporated.

The raw output of a swept-band generator appears on an amplitude-frequency display as a constant-amplitude phase-modulated wave. If this wave is passed through any device in which the transmission is not uniform with frequency, the amplitude of the envelope of the wave at the output of the device will reflect the variations in transmission. The envelope is not a trace but the locus of the peak excursions of the output wave. This means that the cathode-ray beam is spending most of the time in tracing out portions of the wave containing no useful information. The result is low trace intensity at the peaks because of the rapid writing-rate.

If some form of detection is used, the envelope information can be captured and the result is a well defined intense line, identical in nature to that of a manual graphic plot.

Now any arrangement by which the signal input to the display device can be reduced to zero during the retrace interval will produce an amplitude reference axis which can be registered with the base line of the scale. There is here, then, a means by which amplitude-frequency characteristics may be displayed and scaled. If it can be assumed that all of the necessary conditions have been satisfied and can be maintained, this system is capable of yielding large quantities of valuable information in a short time and in a form which permits visual observation of the effects of circuit adjustments as they are made. It must be emphasized, however, that it is bound to a prechosen scale with all of the attendant problems of registration in both amplitude and position.

Even in the best of the various forms in which it has appeared this arrangement remains only an amplitude-measuring technique. By itself, it cannot measure or display absolute loss or gain.

Transmission loss (or gain) is defined in terms of the ratio of the power flowing into a network to the power which emerges from it to the load. The measurement of loss, therefore, requires the comparison of two quantities. Under certain conditions one of these can be held constant and considered a reference.

With this discussion as a background it is easier to formulate the specific design problem.

The Swept-Frequency Generator

This vital element of the system must generate a sinusoidal wave of constant amplitude at all frequencies in the commonly defined voice-band, extending from 200–4,000 cps (cycles per second), without frequency discontinuities. The stability must be such that the band limits will be precisely reached on every sweep excursion and such that, within these limits, for every sweep the rate of change of frequency with time shall remain the same. This should be accomplished electronically without resort to mechanical devices.

The output level should be adjustable from zero to the maximum employed in the plant, usually about + 10 dbm (decibels referred to 1 milliwatt).

There are two broad classes of measurements, each of which requires a different internal generator impedance. All insertion-loss measurements are made between specified impedance for both the genera-

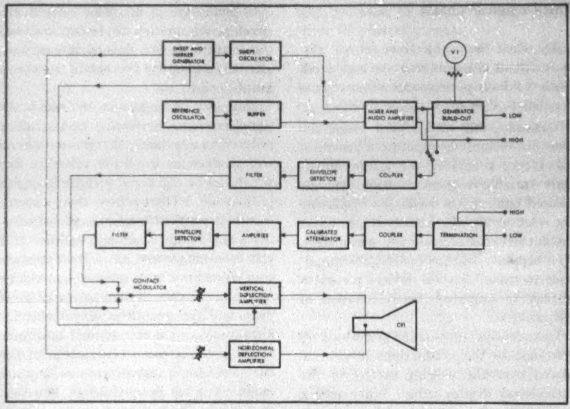

Fig. 1. Functional block schematic

tor and the load. Common practice has emphasized the use of both 600 and 900 ohms. Others may be of interest. Since the impedances may range, the generator itself should have an output branch of very low internal impedance which can be built out to meet specific measurement conditions.

Some apparatus, such as negative-impedance repeaters, depend upon in-circuit impedance conditions for proper operation and can most effectively be adjusted under those conditions. Any measurement device must not disturb them. This can be assured by providing the generator with a high-impedance output branch which will permit bridging at the line terminals.

Since the circuits and the access points of most of the voice-band equipment in the plant are balanced to ground, the generator output branches must also be balanced.

THE DISPLAY

In general, the display must portray, in visual form, the information which the measurement system produces. It must be as large as reasonable size and circuit complexity will permit so that small changes in trace position may easily be resolved. The trace persistence must be such that all of the information presented during at least one complete sweep interval will be visible as a whole. Intensity and trace resolution must permit permanent photographic records to be made with standard equipment. The associated positioning circuits and controls must allow movement of the trace over the entire viewing surface. Deflection in the vertical direction should be related to signal amplitude. Horizontal deflection should be related to the frequency excursion of the swept-frequency generator with the low frequency limit of the band appearing at the left.

THE MEASUREMENT SYSTEM

This, of course, is the heart of the instrument. If it is to measure the absolute loss (or gain) of a circuit or device, provision must be made to take the input power as a reference, compare the power emerging from the device and present the comparison visually in such a way that it can be quantitatively evaluated. The condition for measurement should be completely independent of the absolute level at which the measurement is made. Above all, the quantitative evaluation should not depend upon a graticule, etched scale, or any other graphic scaling arrangement with their associated difficulties of registration and control and other inherent limitations. One condition, and one condition only, should be necessary and sufficient for measurement and the readout should be simple and without ambiguity.

THE SWEEP-DRIVE SYSTEM

The sweep-drive system embraces those portions of the instrument in which all of the timing functions are performed. The basic waveform used to drive the swept-frequency generator over the required range must be generated and shaped in a manner which will result in the proper distribution in frequency along the horizontal axis of the display.

Since no pregraduated scale is to be used with the display, it is necessary to generate a series of marks which, when superimposed on the trace, will permit location of discrete frequencies.

The choice of sweep-rate is related to the persistance of phosphors available in cathode-ray tubes and to the time required for retrace transients to decay to the level below that at which confusion in the display might occur.

ENVELOPE DETECTION

If the display is to contain only those portions of the output wave which bear useful information, some form of envelope detection is necessary. The time-constant of the output filter is important and must be carefully chosen. The upper limit for the cut-off frequency is determined by the lowest frequency in the output wave at which it is desired to display only the envelope. Since, in this case, the lower band-limit has been fixed at approximately 200 cycles, the cut-off frequency must be well below that to avoid clutter from unfiltered components.

The lower limit is fixed by the degree to which the device must accurately portray circuit conditions. One of the most valuable applications of this instrument is the visual display of the standing-wave effects produced on lines by impedance irregularites due to mistermination or improper loading. The filter cut-off frequency must be sufficiently high to permit these effects to be displayed without restriction of their amplitude.

The Design Solution—Functional Description

Having explored and enumerated the several design problems it is now appropriate to examine the means by which the solutions to them have been achieved.

Reference to Fig. 1 will be helpful for this purpose. The various portions of the system will be discussed in the logical order established by the function which each performs.

THE SWEEP AND MARKER GENERATOR

The basic timing waveform is generated by an astable multivibrator operating at a rate of 5 cps. The square-wave output is used for two distinct purposes; to provide pulse marks on the trace for the location of discrete frequency points on the horizontal axis of the display, and to control the timing of the discharge of condensers used in the production of a sawtooth waveform. This timing is such that 1 cycle of the sawtooth is generated for every 4 cycles of the multivibrator.

The sawtooth is used to deflect the

cathode-ray beam in a horizontal direction and simultaneously to effect the frequency excursion of the swept frequency generator. It is produced by driving a step-integrator with pulses from the multivibrator. The grid of a relay tube, in whose plate circuit is inserted the coil of a mechanical relay, is connected to the integrating condenser and so biased that plate conduction occurs on the fourth step of the integrator output wave. The resulting plate current is sufficient to close the relay contacts. There are two sets of contacts. One set is connected across the integrating condenser; the other is connected across a condenser which is charged through a suitable resistor from the main power supply. The values of capacitance and resistance are such as to produce a linear rise of voltage (during the time before the relay operates) which forms the ramp of the sawtooth waveform. When the relay operates both condensers are discharged abruptly and completely and the process repeats.

The synchronous operation of two separate systems is an important requirement for certain types of transmission measurements. Such operation requires rigid control of both the frequency and phase of the individual timing generators. Frequency control is achieved by using the 60-cycle power source as the reference standard. A 12 to 1 countdown circuit generates synchronizing pulses which are applied to the multivibrator whose rate is accurately locked at 5 cps. Phase control is achieved by providing a push-button switch by which the sawtooth generator can be stopped and restarted at any instant.

THE SWEPT-FREQUENCY GENERATOR

There seems to be no direct way, except through the use of mechanically driven elements, to generate phase-modulated waves in the voice-frequency range. Beat-frequency methods are well known and have been used extensively in fixed frequency, and to some extent in swept-band, equipment.

The usual approach is to use a reactance tube as the modulating element in a variable oscillator referenced against a second oscillator operating at a fixed frequency such that the difference is zero when the reactance tube is not excited. The fact that both the variable oscillator and the modulating elements must effect changes in frequency implies instability. This becomes evident both as jitter and in the need for frequent adjustment to compensate for drift.

Since the low-frequency limit of the voice-band is in the region of 200 cps. jitter and drift must be minimized to avoid confusion in the display and error in the presentation in frequency.

The swept-band generaor used in this development is believed to be an entirely new means for generating phase-modulated waves in the audio-frequency range with stability in excess of that now possible by any other known all-electronic methods.

Semiconductor development has recently produced voltage-sensitive elements whose terminal capacitance is a function of the applied reverse-bias voltage. These have been used in many ingenious ways as variable-capacitance devices. When used to vary the frequency of an ordinary oscillator it is necessary, because of their limited capacitance range, to choose a relatively high median frequency or to tolerate a highly instable oscillator at a lower frequncy, if appreciable frequency excursion is required. Neither alternative yields the desired degree of stability.

It is well known, however, that quartz crystals have proved to be outstanding as highly stable elements for the control of frequency. A crystal has two limiting frequencies. The series-resonant frequency is determined solely by the internal crystal constants and cannot easily be altered except by physical modification of the crystal. The antiresonant frequency is determined by the combined effect of the internal constants and the terminal to terminal capacitance which is composed of the capacitance of the crystal mount and whatever capacitance is introduced by the holder and the external circuit. The limiting antiresonant frequency will be that at which all external shunt capacitance is zero. Certain cuts are capable of yielding a range between the limiting frequencies of about 0.04% of the series-resonant frequency.

If a suitable crystal is used in a circuit employing the antiresonant mode, it is possible to vary the frequency by varying the shunt capacitance. The voltage-variable diode is an ideal element for this purpose since it, like the crystal, is temperature-stable.

The crystal frequency cannot be varied over the entire range established by the limiting frequencies. As the series-resonant limit is approached the impedance decreases rather rapidly to the point where the voltage necessary to support oscillation can no longer be maintained.

The generator incorporated in this instrument uses two crystal oscillators operating at approximately 19 mc (megacycles). One of these can be varied continuously in frequency over a range of approximately 5 kc by use of voltage-variable diodes properly biased. The sawtooth waveform from the sweep-drive generator is shaped and superimposed on the bias to provide the cyclical frequency excursion.

The oscillator outputs are fed through load-isolating buffer stages to a modulator in the output circuit of which the phase-modulated wave appears. The oscillators and the sweep drive are adjusted so that the difference frequency ranges from 0–4,000 cps.

The output of the mixer is amplified and fed, in split phase, to a balanced output stage. In order to meet the impedance requirements of the various types of measurement, two branches are provided. The low-impedance leg has an internal impedance of approximately 30 ohms. Jacks are provided for access to internal buildout at both 600- and 900-ohm impedance levels for use in the more common insertion-loss measurements.

The high inpedance leg has an internal impedance of approximately 25,000 ohms which permits bridging the generator across lines without disturbing their impedance conditions.

All access to the generator is on a balanced basis so that no auxiliary transformers are required for any of the normal applications in the telephone plant. Level is adjustable from zero to +10 dbm.

THE MEASUREMENT SYSTEM

The prime requisite of the measurement system is to evaluate a power-ratio independent of the absolute power level. This requires a reference point which is invariant in both amplitude and impedance. Such a reference point is the low-impedance generator output branch. Inasmuch as the impedance is about 30 ohms, any normal buildout will provide sufficient isolation from the load to avoid disturbance. Essentially, then, this is a reference point of constant power. Proper equalization can establish this constancy for all frequencies within the swept band. A voltage-sensitive device is sufficient for indicating the reference condition.

The insertion loss of any device is defined as the ratio of the power which would appear in a specified load, when connected to a generator having an internal impedance equal to the load, to the power which would appear in the same load when the device to be measured is inserted between the load and the generator. The voltage across the load without the device inserted can be considered a reference for power at the load and as

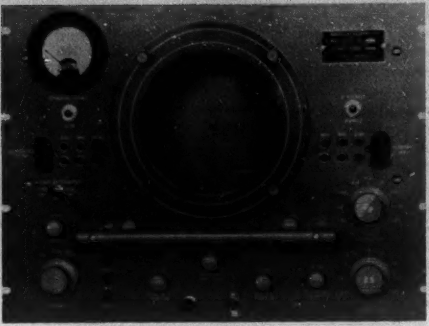

Fig. 2. Front panel view

long as the voltage is held constant the power will be also.

When the device is inserted, the voltage across the load will change. The power will vary as the square of the voltage so that some special type of indicator would be necessary to measure the changes in power.

Suppose, however, that an amplifier is also inserted and that the gain can be adjusted exactly to the value which nullifies the loss of the device under test. The voltage across the load, and therefore the power, will be the same as before the insertion and the indicator will read the same. The need for special characteristics is removed. In fact, not even a calibrated scale is required.

Now, instead of making the gain adjustable, a fixed gain is inserted with an attenuator whose loss can be adjusted. Attenuators can be highly accurate and stable in calibration. With this arrangement, it is possible to make loss measurements completely independent of the absolute voltage level. To do this, the amplifier, attenuator, and indicator are connected to the load before the device under test is inserted. The attenuator is adjusted to a reference setting which will cause a convenient indication. The device is then inserted between the generator and the load and the attenuator readjusted until the same indication is obtained. The difference in the attenuator settings is the loss of the device. Most of the transmission measuring sets in common use today operate in this manner.

The same technique is used in this new instrument. The system employs two independent channels, one of which is associated with the generator for the purpose of establishing the input-power reference conditions. The other branch, which includes the calibrated attenuator and amplifier is used to detect and evaluate changes in output power. Both branches terminate in identical envelope detectors, associated with which are low-pass filters which pass only the d-c and very-low-frequency components in the detector output.

A contact modulator, or "chopper," is used to switch the detector outputs alternately to the input of the vertical deflection amplifier associated with the display. Two distinct traces are thereby produced, one representing the input power, which becomes the reference trace, and the other portraying the envelope of the voltage appearing across the load. The d-c component is preserved through the deflection amplifier so that the traces remain in the absolute positions established by the d-c conditions only and are completely independent of each other. The reference trace, therefore, remains in the set-up position on the display, leaving the other to move freely in relation to it.

The reference channel is identified as the *A* channel, while the channel used for comparison is called the *B* channel. Balanced-to-unbalanced couplers, having very high input impedance, are used to connect the two channels in the various ways dictated by the requirements of the measurement conditions.

The *A*-channel coupler is always associated with the generator. Switching is provided to transfer the coupler input to either the low- or high-impedance generator output branch.

The *B*-channel coupler input appears at jacks, some of which are arranged to pick up internal terminations of either 600 or 900 ohms.

Calibration of the *B* channel is accomplished in all cases by patching the *B* coupler, with a chosen termination, to the corresponding generator output. With the attenuator at reference zero, adjustment of *B* channel gain establishes coincidence of the two traces. This gain adjustment is not distributed during measurement except for recalibration, should it be necessary. All measurements are made, thereafter, by simple attenua-

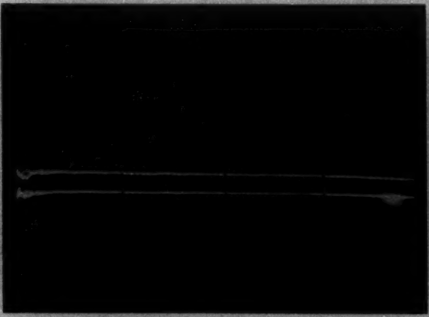

Fig. 3. Typical display under calibration conditions with B-channel trace depressed 1 db from coincidence

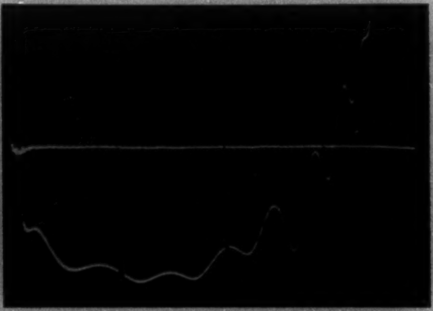

Fig. 4. Typical display of trans-hybrid transmission. Trace coincidences occur at 150 and 3,200 cycles, representing loss of 15 db

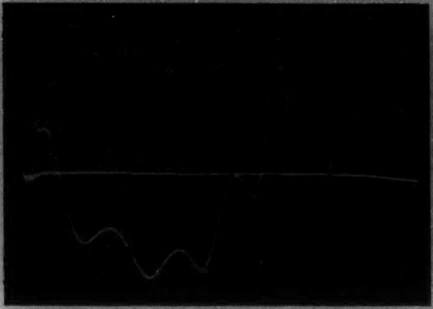

Fig. 5. Display of trans-hybrid transmission with cross-over points at 350 and 2,300 cycles, corresponding to a loss of 25 db. Portions of the B traces remaining below the A trace represent higher loss

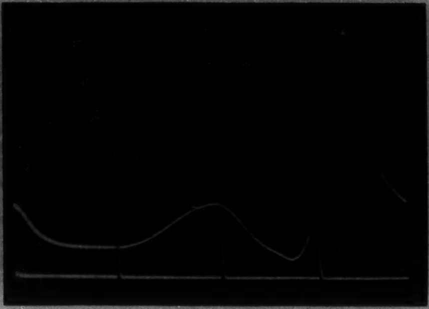

Fig. 6. Display of relative impedance at the input of an artificial 22-gage H-88 loaded line with third load removed

tor manipulation to restore trace coincidence.

For insertion measurements, the *B* coupler patch is removed and transferred to the output of the device under test. The built-out generator is, of course, patched to the input of the device. Any loss or gain in the device is evidenced by the departure of the *B* trace from coincidence with the *A* trace. At those points in frequency, where coincidence is retained the gain or loss is zero. Coincidence may be achieved at any frequency within the displayed band by manipulating the attenuator. The gain or loss of the device is read directly from the attenuator dials to an accuracy of 1 db and may be estimated visually well within that limit. Sufficient gain and attenuator range are provided so that losses as high as 55 db and gains as high as 35 db may be measured. This range is sufficient to embrace that required for measurement of all normal trans-hybrid loss and the gain of all commonly used repeaters.

For bridging measurements, such as those at the terminals of negative-impedance repeaters, the high-impedance generator branch is used. *B* channel calibration is established by patching the *B* coupler, without termination, to the generator. All other steps in the measurement procedure remain the same as for insertion measurements. The reference trace, will, however, now be sensitive to the impedance variations at the repeater and will, therefore, yield important information as to the ability of the strapping to provide nonreflective terminations for the lines.

In connection with measurements of the gain of negative-impedance devices, in circuit, there are certain limitations which should be emphasized. The test sets now in existence sample the line currents flowing into and out of the device and convert them to voltages for measurement. The gain thus measured is absolute only when the impedance on both sides are identical. The apparent gain, as measured, will deviate from the actual insertion gain to the degree that the impedances depart from equality.

This new instrument, while indicating directly the voltages across the lines instead of the currents flowing in them, is, nevertheless, subject to the same limitations since a true power ratio cannot be evaluated from voltage or current measurements alone unless it is known that the impedances remain alike. This is the reason for the discrepancies which have been noticed between insertion gains and those measured directly at the repeater. Usually, the strapping is successful in establishing impedance conditions which minimize the discrepancy.

The location, in frequency, along the horizontal axis of the display is established by pulse-type marks appearing at 1,000-cycle intervals. The start of the trace is, of course, zero and the generator frequency excursion is adjusted so that the termination of the trace occurs at 4,000 cps. Three distinct marks will appear in the interval, at 1,000, 2,000, and 3,000 cps. Since the sweep excursion is essentially linear, visual interpolation between the marks is relatively easy and the points of trace coincidence may, therefore, be located in frequency.

THE DISPLAY

The display system makes use of a 7-inch cathode-ray tube with a long-persistence *P7*, phosphor. An amber filter is placed over the tube face to accentuate the persistence characteristics and to reduce the intensity of the blue-phosphor response.

The tube is electrostatically deflected and focused. The deflection amplifiers are direct-coupled throughout, in the horizontal to preserve sweep linearity and in the vertical, to retain the d-c and low-frequency information in the signal.

Intensity, focus, and positioning controls are provided. Operation potentials are obtained from a high-frequency supply.

With the normal intensity which yields maximum spot resolution, good, printable negatives may be made using Panchromatic-X film, with an aperture of 12.5 and a 6-second exposure. Full-frame views of the tube face will require some sort of lens extension or copying attachment for ordinary cameras. A camera mount will be available as an accessory.

ADDITIONAL CIRCUIT FEATURES

Several convenient circuit features have been incorporated.

The most important of these is to provide the means for determining that the sweep excursion represents exactly the range from 0–4,000 cps, since the marks are uniform in time and must, therefore delineate 1,000-cycle intervals along the horizontal axis of the display. Two networks are used for this purpose and are available on a switched basis to establish the proper alignment. One of these produces a sharp notch at 1,000 cycles and a front panel control on the reference oscillator is used to align this notch with the first pulse-mark. It has been determined that this process insures that the left-hand limit of the trace corresponds to zero frequency. The other network produces a sharp notch at 4,000 cycles and another front-panel control is used to adjust the sweep-oscillator drive until the notch coincides with the right hand limit of the trace. The two remaining pulse marks then accurately locate the 2,000- and 3,000-cycle positions in frequency.

Inasmuch as two independent traces appear on the display, it is desirable to be able to identify one from the other. For this purpose, a push-button switch is provided to disable the *B* channel. A monitor jack is provided so that the operator may listen to the *B*-channel output.

It is contemplated that this instrument will ultimately be used for many of the now-standard purposes in the telephone plant. Presently, it is possible for the installer to dial from an outlying point on a circuit and cause a 1,000-cycle test tone at 0 dbm to be impressed on the office end of that circuit. Provision is made in this instrument to meter the output when the 600-ohm build-out is used so that a swept-band output at 0 dbm may be supplied on the same basis. A companion instrument can then be used by the installer to test the circuit over the entire band. Single frequency tests can often lead to false conclusions as to circuit performance.

Conclusion

Several photographs have been provided to show the physical appearance of the instrument and typical displays under actual measurement conditions.

Fig. 2 shows the instrument as it will appear mounted in a standard equipment bay. Fig. 3 shows the display as it will appear under calibrating conditions with the *B*-channel trace (lower) depressed one db from coincidence. Fig. 4 shows a typical display of trans-hybrid transmission. The reference trace is the straight line. The attenuator has been adjusted so that the trace coincidences occur at 150 and 3,200 cycles and represent a loss at those frequencies of 15 db. Fig. 5 is a display of the same conditions as in the preceding figure but with the attenuator loss decreased 10 db. Here the crossover points occur at 350 and 2,300 cycles and correspond to a loss of 25 db. All portions of the *B* trace remaining below the *A* trace represent even higher loss.

Fig. 6 is a display showing the variation of relative impedance at the input end of an artificial H-88-loaded 22-gage line, with the third load removed.

High-Voltage Static Eliminators for Teletypewriters

L. A. JONAS
NONMEMBER AIEE

F. E. HANSCOM
NONMEMBER AIEE

HIGHLY unfavorable operating conditions are often created by the depositing of static charges on teletypewriter paper tape and rolls. This phenomenon of static electrification will cause delays and require the attention of operating personnel. Messages can even be lost as the copy may jam in moving mechanisms and be mutilated. Although radium devices have been employed for a number of years by the Bell System for static control,[1] the increasing number of state laws regulating the use of radioactive substances made it desirable to find some suitable substitution. The paper discusses the operating principles and design features of a static eliminator utilizing a high-voltage discharge.

Static Factors

In teletypewriter equipment, paper undergoes a number of pressure contacts with other materials. Such contacts include sensing and punching pins, type pallets, platens, sliding surfaces, and the like. The paper can, by some such process, acquire a charge on its surface. The quantity and decay time of the charge are governed by a number of variable factors including paper composition, types of opposing surfaces, relative humidity of the ambient air, moisture content of the paper, and the amount of pressure applied. The influencing factors and the electrostatic phenomenon itself are complex, and for the sake of brevity this background material will not be covered here. It should be realized however that such information is essential for the proper design and evaluation of any static control arrangement. For those desiring more information the list of references is included.

Theory

If the air surrounding charged material is ionized, the material can neutralize itself by selecting those charges it needs to balance its surface electrically. This requires that a sufficient number of charges of the opposite polarity be available. One means to accomplish ionization of ambient air is to apply a high voltage between point electrodes and nearby grounded members. Any free electrons at the negative end will be repulsed toward the positive side. Experiments have shown that there are always some free electrons in the air. These electrons may have been produced by the action of light or cosmic rays, or as a result of the collision of molecules. As the electrons are sped through the air they collide with neutral atoms and displace electrons from the outer ring. These electrons will in turn displace others. By the utilization of alternating voltages both positive and negative ions can be supplied, since each in turn would be repulsed by the discharge points.

Pt. 1
196

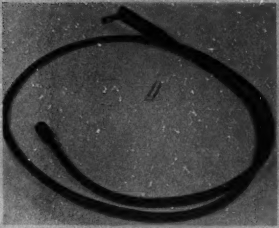

Fig. 3. Inductor point

Utilizing sharp points greatly reduces the amount of voltage necessary to achieve the beginning of ionization, because the electric field is most intense at narrow points. Although an electric field is always perpendicular to a conductor, it is not necessarily uniform but is a function of the geometrical shape of the conductor and will tend to concentrate in those places where the radius of curvature is least.

Application

The static eliminators have been designed as three separate units:

1. A power unit to supply the required voltage at a safe current level; see Fig. 1.
2. An inductor bar for mounting on the model *28* and model *15* page printers; see Fig. 2.
3. An inductor point suitable for mounting on the following tape equipment; see Fig. 3:

Model No.	Equipment
28	typing reperforator
28	reperforator transmitter
14	typing repreforator
14	reperforator transmitter
14	typing unit
28	automatic sending-receiving set
19	automatic sending-receiving set

Power Unit

The power unit consists of a 5,000-volt transformer with a capacitor. These are sealed with a potting compound in a 4-inch by 6-inch by 3-inch metal case. The primary is designed for 117 volts, 50 or 60 cycles. A capacitor has been installed in series with one side of the secondary winding to limit the output current to a maximum of 1.4 milliamperes. This side terminates at a duplex outlet on one end of the case. The other side of the secondary is connected to both a ground stud on the case and to the grounding wire of a 3-wire 6-foot power input cord.

An identical power supply is used for both the inductor bar and the inductor point. The duplex outlet provides for simultaneous use of two static eliminators as in the case of the model *19* or *28* automatic sending-receiving sets, where it may be required to control static on both tape and page copy. Also, there are installations where a large number of table console models of teletypewriters are installed adjacent to and on top of each other. In such cases the savings involved in reducing the purchases of power units could be considerable. In the event that one outlet is used, a plug is supplied as a seal for the unused outlet.

Two flanges with 1/4-inch holes can be used for mounting. The unit may be placed on a shelf or fastened to a rack or wall. The only requirement in locating the power unit is that it be within reach of the inductor cable, out of the customer's or maintenance man's way, and in a dry area.

Inductor Bar

Preliminary studies were conducted to determine the quantity of the static charge on teletypewriter page copy and the best location for a static eliminator. By the use of an electrostatic voltmeter several charge-creating areas in the model *28* teletypewriter were investigated. It was found that at least 70% of the total instrument reading was obtained by the action of the paper being compressed by the rubber platen, and that almost all the remaining reading was obtained by the action of the steel-type pallets striking the paper.

The effects of unrolling the paper, rubbing against the glass and metal edges and sliding over the dome, appears to be negligible. Therefore it was felt that treating the paper immediately after it left the typing area would be sufficient.

Another requirement was that there be some air space around the section of the paper being treated. If the paper is in contact with any solid surface, both the paper and the contacting body will be neutralized as a whole, but once the paper is parted it will be unbalanced electrically as a separate body.

Due to physical interference it was necessary to locate the inductor bar in front of the typing unit and under the glass viewing cover. Accordingly, a transparent bar with sharp points was constructed. There are nine recessed discharge points spaced approximately one inch apart to give full coverage to the paper. The material used is Plexiglass no. *55* which has stability and other required qualifications. A wax finish is given in production to afford protection against marring the surface.

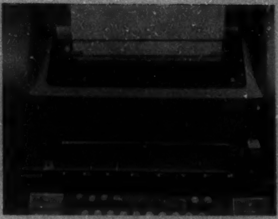

Fig. 4. Inductor bar on model 28 teletypewriter

Sliding metal brackets are provided at each end of the bar. They are adjusted with the aid of a screwdriver to fit either the model *28*, Fig. 4, or the model *15* teletypewriter page printers. One side of the bracket is painted black to reduce glare to the teletypewriter operators.

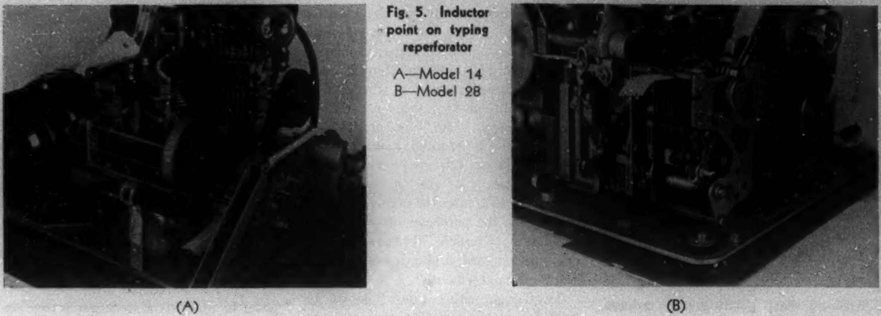
A bare wire is stretched along the length of the bar a short distance in back of the points. The wire is bonded to the metal brackets which in turn are grounded to the teletypewriter cover when they are installed. Without such a close proximity ground the intensity of the electric field would be greatly attenuated and a much higher voltage would have to be employed, probably in the neighborhood of 15,000 volts rather than the present 5,000 volts.[2]

A return path is provided from the proximity ground wire through the frame of the machine to a common ground with the power unit. In most cases the input for the power unit and the teletypewriter will be the same, and this can be used to provide the common ground. If such is not the case the ground stud on the power unit should be bonded to the teletypewriter frame.

Every point in the bar has its own capacitor. This coupling is utilized to restrict further the current to such an infinitesimal amount that not even a mild shock can be felt by touching the points. Measurements show a maximum current to the inductor bar points of less than 0.05 milliampere.

A rubber-covered high-voltage cable is permanently fastened to one end of the bar and a screw-type connector is fastened at the other end of the cable to permit connection to the power unit. There is some power loss in the cable due to inductive effects but it was felt that the use of stand-off insulators was an unnecessary complication. To keep this inductive loss to a minimum, however, the cable is restricted to a maximum length of 5 feet.

Tests were carried out in which the



(A) (B)

Fig. 5. Inductor point on typing reperforator

A—Model 14
B—Model 28

distance from the static bar points to a charged web was varied, and the resulting voltages were measured. They indicated that the optimum distance would appear to be slightly more than one inch. That direct adjacence to the paper is not necessary is an advantage in so far as freedom for locating the neutralizer is concerned.

On the model *15* teletypewriter the distance from the discharge points to the paper is approximately one inch. On the model *28* the distance is somewhat less. This compromise is necessary because one line of the type message is obscured due to the nontransparent edge of the inductor bar. By positioning the bar this line of type is approximately four to five lines above the immediate typing area. It is felt that this would be a very minor objection.

In field and laboratory trials involving the model *28* page printers, static potentials of over 10,000 volts were repeatedly reduced virtually to a zero level by the use of the static bar. How low the actual potential must be kept on teletypewriter paper to avoid difficulties is not yet fully determined. Some tests appear to point to a potential gradient below 1,000 volts. There is also the possibility that further charges might be accumulated in processing after the paper has been neutralized. Therefore it would be advantageous to have the charge remaining after neutralization as low as possible.

Inductor Point

The inductor point consists of a single discharge point mounted at right angles to a coupling capacitor body. As in the case of the bar, the point is recessed. Recessing not only affords protection against scratching of the skin in handling but also lessens the possibility of arcing due to the point being too close to a ground. Arcing not only decreases the efficiency of the static eliminators but can also cause radio interference. The inductor point is made of a highly shock-resistant plastic. This is necessary because of its fairly exposed mounting. A simple 2-piece clamping device is supplied to arrange fastening on any of the tape machines previously listed. It is equipped with a 5-foot inductor cable, as in the case of the inductor bar, to connect to the power unit. No close proximity ground is provided on the inductor point itself since the teletype equipment is able to perform that function. A common ground with the power unit must be assured as with the inductor bar.

Two of the proposed mounting arrangements for the inductor point are illustrated in Fig. 5.

Ozone and Corona

Ionization of air is accompanied by the discharge of ozone gas. Ozone has a fresh, penetrating odor resembling that of very dilute chlorine. The action is reversible and after a little ozone has been processed it is decomposed at the same rate that it is generated. Ozone can be injurious in high concentrations. The maximum allowable concentration in air is given as 0.1 to 1.0 part per millionth of air.[3] The inductor bar was tested in the laboratories with an ozone meter capable of registering amounts far below those of even irritating concentrations. The quantity of ozone liberated by the designed units were so minute as to be undetected on the instrument.

Ionized air at the surface of conductors appears as small tufts and streams visible in the dark. Such ionized air is called corona because of its resemblance to solar corona. With alternating current, corona consists of a more or less continuous glow, reddish blue in color. This effect is visible only in full darkness.

Summary

The high-voltage static eliminators, as designed for teletypewriters, have certain distinct advantages. Unlike radioactive elements, they present no safety hazards. The inductor bar, inductor point, and power unit have been approved by the Underwriters Laboratories, Inc., and the Canadian Standards Association Laboratory; field tests indicate a high ionizing potential which is sufficient, even in severe static conditions, to reduce the static charge virtually to zero. The units are adaptable for a large number of teletypewriter models and surroundings with a minimum of effort. They can easily be modified for those installations where standard mounting arrangements are not yet available. The equipment has a wide positioning range so no fine adjustments are required.

Teletypewriter Selective Calling Applied to Automatic Airlines Reservations

R. W. BRATSCHI

W. D. PENNINGTON
NONMEMBER AIEE

A. L. WHITMAN
MEMBER AIEE

A RECENT PAPER has described the *83B1* teletypewriter selective calling system.[1] The UNIVAC airlines reservation system as a special-purpose application of a general-purpose data processor has also been described.[2] The present paper continues the description of the combination of the two, with special emphasis on the alterations, relatively minor, of the standard teletypewriter selective calling system to permit its use as the communications link between the central processing equipment and various remote agent offices to which the public comes to ask questions, reserve seats, or buy tickets.

A second kind of interconnection will be mentioned here but not discussed in detail. For agent sets located near enough to the processor so that it is practical and economical to run numerous wires between them, a different technique, involving a higher speed of operation, is used. Such a situation is encountered where the processor is in the same building with a large reservations bureau, where a number of telephone clerks receive incoming calls from airlines customers.

However, for offices at distances where it is neither practical nor economical to supply a large number of control channels in parallel, one or more single-channel teletypewriter circuits provide the connecting links. The traffic load per station is low enough so that multistation line operation is possible, at a speed of 100 words per minute, with the necessary automatic controls being supplied by the selective calling system.

Basic Operational Features

As a basis for the more detailed description of what the communication equipment has to do, the principles of operation of the system will be briefly reviewed. At a ticket counter, or other location where airlines personnel meet customers, UNIVAC furnishes a device called an agent set, shown in Fig. 1, which serves as a transmitter of inquiries to the processor, and a receiver of answers from the computer. The agent set can also request the sale of seats, upon which the processor corrects its space inventory file and sends a confirmation of the sale to the agent.

In operation, on hearing a question from a customer, a ticket agent selects a projection slide containing a portion of the airlines timetable showing the flight legs in which the customer is interested. The agent inserts this slide in the set, where it is projected on a glass viewing screen. The set automatically identifies the particular timetable slide by photocell reading of edge coding. The agent then sets up his inquiry by pushing buttons opposite the appropriate timetable lines and columns on the screen and by pushing additional buttons to indicate the date, the number of seats, and the type of transaction. The completion of the entry automatically initiates the sequence of operations which result in the setting up of a connection to the processor. Once the connection is established, it is held until the reply comes back and is registered in lights on the agent set.

The function of the selective calling system is essentially to "poll" (search) the agent set locations, and when one is found with an inquiry to send, to establish the connection to the processor and then, after the transaction is completed, to disconnect and continue its search for others with inquiries ready. Actually, the system does not poll each individual agent set, but rather a number of programmer-scanners each of which has subcontrol of up to eight agent sets; see Fig. 2. Once a programmer-scanner gets a chance to use the line it, in turn, offers one chance to each of its satellite agent sets before it disconnects.

Typical System Layout

Fig. 3 is a typical layout of an airlines reservation system, showing the relation of the reservations processor to the local high-speed programmer-scanners and to the remote telegraphic-speed scanners reached over the teletypewriter selective calling system. Fig. 4 shows in more detail the principal elements of the selective calling system at the control station (at the processor location) and at the various outlying stations.

Operation of Selective Calling System

For the polling operation, the transmitter start circuit operates as it does in a teletypewriter message system. Each programmer-scanner location is assigned a unique 2-letter code, known as a transmitter-start code (TSC). The control station sends these codes out in turn, searching for a programmer-scanner which has an inquiry ready to come in.

The entry of an inquiry or transaction into an agent set, as a result of an agent pushing the proper buttons, causes the programmer-scanner to "bid" for a connection to the processor. With a bid thus registered at the time that the station is polled, polling stops, and the inquiry or transaction is handled. On the other hand, if the programmer-scanner has not made a bid when it is polled, the station

returns a no-traffic response, the letter V, and the transmitter start circuit at the control station proceeds to poll the next programmer-scanner in sequence.

Since all inquires are directed toward a single destination, the processor, no receiver selection is required in this application so that no use is made of the call directing codes (CDCs) used for the selective calling of various receiving printers on a teletypewriter system.

Use of Suppression Code Bar

By adaptation, another use is made of this spare function to save wear and tear on some of the teletypewriter mechanisms.

The heart of the selective calling controls is a device called a sequence selector which is, in effect, a model 28 typing unit with the printing and paper-handling features left off. Its main function is to operate and control a "stunt box,"[3] a device which responds to individual teletypewriter characters to operate contacts or to perform desired mechanical operations

Use is made of the stunt-box mechanisms, as described later, to convert serial line signals to the parallel signals needed by the UNIVAC equipment. Operation of these mechanisms is needed at a particular outlying station only when it is communicating with the processor. They are therefore so arranged that their operation is under the control of the "suppression" code bar. (On a typing unit this is known as the "print" code bar; its position determines whether or not printing will take place. On a sequence selector it often is not used.)

However, here this code bar at the active programmer-scanner location is moved out of the suppression position by the sequential combination of the second letter of the transmitter start code, which is unique to the station, followed by the letter E, sent as the start-of-message code by the selected programmer-scanner. Thus at the desired station, the proper mechanisms are conditioned to operate, while at all other stations they remain disabled. On the end-of-transmission signal the operated code bar at the active station goes back to the suppression position.

Line Held for Reply

After a programmer-scanner has been selected, it holds the line until each one of the agent sets tributary to it has had its chance, if wanted, to send an inquiry to the processor and to receive its reply. The programmer-scanner then automatically generates its end-of-transmission signal, the characters HH, which tells the transmitter start circuit to resume its polling search for traffic. Polling continues with the next station in sequence after the one which has just used the circuit.

Codes

All the signals transmitted over the lines are 5-element characters made up of marks and spaces in the same way as is the Baudot code; however, their meanings in the UNIVAC system are different,

and when copy is obtained on a monitoring teletypewriter, it is not readable as normal message text. In all communications between the UNIVAC equipments in the system, only the first four levels of each character are used for the transmission of intelligence; the fifth level is used for an odd parity check, a mark being supplied in this level whenever there would otherwise be an even number of marks in the character. Of the 32 teletypewriter characters, there are 16 having an odd number of marks; these characters and the corresponding UNIVAC codes are listed below:

Teletype Characters	Significance in UNIVAC Message Text
W	0
(Space)	1
Y	2
P	3
U	4
CAR RET	5
B	6
G	7
J	8
M	9
F	'
C	&
LTRS	(
T	"Ignore"*
E	Space
LINE FEED	Minus sign

* T may appear in first four letter positions of reply as well as at end of message.

The significance of the codes is not changed by being preceded by a "figures shift" (FIGS) or "letters shift" (LTRS) but is a function of the position of the character in the message.

Certain of the above codes have control functions in addition to their use within the message text. Each input message to the processor begins with an E, a character not employed in any of the transmitter start codes. Until this code is received, the processing equipment ignores all the start codes and other signals appearing on the line, with the one exception described below. After a message starts, the receiving equipment at the processor continues to accept characters until a T is received, signifying the end of the input message. T is similarly transmitted at the end of the reply message from the processor. (T as any one of the first four letters of the reply has an information function.)

If an error is detected in an input message, the processor sends back a reply notifying the agent of the fault. If it is a parity error, he is generally instructed to re-enter the message to determine whether or not the fault is of a transient nature. If it is a logical error (e.g., a nonexisting date or flight) an appropriate message is transmitted to the agent so that the correction can be made. If an error is detected in the reply message, the programmer-scanner sends a control message (LINE FEED T) to the processing equipment requesting a repeat of the last reply. LINE FEED is the only character accepted by the processor receiving equipment which is not preceded by an E.

The characters having even numbers of marks are used as transmitter start codes and for other control functions performed by the communications equipment, as follows:

HH, *end-of-transmission*

Sent by a programmer-scanner when it is ready to give up the line. Also transmitted as part of FIGS HH LTRS by the selective calling control station to clear the circuit after an idle-line timeout. This code restores the communications equipment to a polling condition.

FIGS, *station cutoff alarm*

Sent by the selective calling control station as part of the code FIGS HH LTRS after an idle-line timeout, this code causes an audible alarm at the outlying station which has control of the line, and an electrical alarm at the corresponding programmer-scanner. For an optional variation, see the further discussion in the section "Alarms and Protective Features."

AA, *alternate arrangement*

Sent from the central processing site, in case of an outage, to instruct all agents to use temporarily other means of communication, such as the telephone. At each outlying station the control signal, through the programmer-scanner, lights a lamp on each agent set.

Serial-to-Parallel Conversion

Present-day teletypewriter transmission is accomplished by means of serial signals, i.e., signals where the successive signal elements of the characters follow each other in time series on the line. For printing and tape-perforating operations, where a received character is represented by five of the serial signal elements, conversion from serial to parallel is effected mechanically by a device known as the processor mechanism. For the UNIVAC computer input, which requires an electrical input of five signal elements in parallel, a new means was needed. Advantage was taken of the flexibility of the stunt box in the sequence selector.

Six stunt-box slots are used, one for each of the five signal elements of the incoming character and the sixth for a timing and control pulse. Each of the five slots is equipped with a function bar so coded that it responds and closes a contact only when the signal element corresponding to its position is a marking element. Thus, when all of the serial elements have been registered through the selector and the associated mechanism, the five contacts are in the marking (closed) or spacing (open) conditions respectively, depending on the signal elements in the five positions. The contact closures are read into the UNIVAC equipment, after which the contacts open and are ready for the next character.

Of the characters used in this system, (except H and A) eight have marks and eight have spaces in each of the five signal element positions. Assuming that the various characters occur with equal frequency, there would be a marking contact operation in each element position for half of the characters sent. Unless otherwise controlled, these contact operations would occur at every outlying station on a line; this would not affect the UNIVAC equipment because the programmer-scanners at the inactive stations would disregard operations which they were not conditioned to receive and understand. It is to save wear and tear on the mechanisms, as described previously, that the operation of these contacts is suppressed at all stations except the one busy with an inquiry.

Parallel-to-Serial Conversion

Standard conventional teletypewriter means were available for performing the parallel-to-serial conversion. A small multicontact cam-operated distributor, economically mounted on the sequence-selector base and driven by the same motor, accepts the parallel signals from the UNIVAC equipment at either end of the circuit and distributes them serially for transmission on the line.

System Performance

An important characteristic of a reservations system is its speed as manifested by system traffic capacity and the message delivery times at the agent sets. For a given system configuration and processor program, limits are set for both of the quantities. The maximum number of transactions the processor can handle in an hour is 3,600 divided by the processing time in seconds, for current systems approximately 5,000 transactions. The minimum delivery time is the sum of the times required for polling transmission, and processing, currently about 3 seconds. The maximum delivery time, as would be experienced if every agent set in the system made an entry at the same instant, is of the order of 1 or 2 minutes. The actual delivery time fluctuates between these limits, with variations in message length

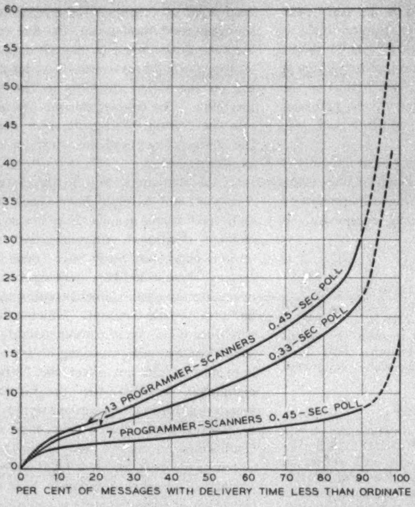

Fig. 5. Computed message delivery times for a particular system

Table I. Types of Messages

	Per Cent of Total Traffic	Number of Characters in a Message	
		Input	Reply
Inquiry	60	12	6
Inventory	30	16	2
Flight status	10	8	3

and in program time, but primarily because the entry is made at random with respect to the time at which that agent set is given a turn to communicate with the processor, resulting in a variable number of other sets which must be processed first. For current systems the actual average response times are generally under 10 seconds.

Prior to putting the first systems into operation, a system simulation was made on a computer at the Bell Laboratories to give a qualitative indication of the sort of performance which might be expected. The method is described in a recent paper.[4] Because of the inevitable uncertainties about the applicability of the assumed parameters to any other system, it should be clear that these results are not of general application. They are thought to be valuable as a general indication of what this kind of system can do, and as a guide to the possible effects of changing certain of the parameters.

Fig. 5 shows the results for three sets of assumed conditions. The delivery time is the time from the moment when the agent has completed the setting up of the message in his set to the moment that the answer is shown on the indicator lights. For reasons associated with the computer simulation program, the curves for delivery times for cumulative percentages above 90 are less reliable; they appear as dashed lines in Fig. 5. The "poll" time is the time per station taken by the selective calling system in searching the stations for traffic. The 0.45-second figure is for the present standard design, using 2-letter calling codes. Where the total number of stations is small enough so that a single letter would be adequate, a modification of the design could be made to give a reduction in delivery times as shown by the curve marked "0.33-second poll."

Even greater benefits, as shown by Fig. 5, could be obtained by reducing the load on the selective calling line by removing some of the stations and putting them on another line. Thus, while with the originally planned arrangement, 90% of the reply messages would be delivered in 30 seconds or less, with the assumed reduced load that time would be reduced to about 8 seconds.

The details of the computation are given in an unpublished memorandum by George J. Smith, formerly of the Bell Laboratories. As background information some of the more significant assumed parameters are extracted here.

The reservations processor was assumed to be handling, in the busy hour, 1,020 transactions over the selective calling circuit and 3,200 transactions locally via the high-speed programmer-scanners; see Fig. 3. There were 44 agent sets connected to 13 outlying low-speed programmer-scanners, seven of these sets at reservations offices and 37 of them at ticket offices. It was assumed that a reservations clerk could enter 40 transactions an hour, and a ticket agent, because of the extra time required in preparing tickets, only 20 transactions an hour. The types of messages were assumed to be as in Table I.

Similar system simulations have been carried on in the St. Paul UNIVAC laboratories, where models of the current systems have been set up in the form of computer programs which can be easily modified to reflect proposed changes in equipment arrangements. Generally the results are summarized in the form of a family of curves showing the average response time as a function of the transaction volume in a peak hour. Each curve in the family represents a particular processor program time. These studies have indicated that changes in program times have results comparable to those produced by the changes in polling time shown in Fig. 5, and that a major factor in agent set response is the employment of an adequate number of separate circuits with the traffic equally distributed among them.

Testing of Stations

The connecting line from each station passes through a telegraph test room, known as the serving test center (STC), in order that the plant maintenance forces may have access to the circuit to locate and isolate troubles which may occur. To avoid unnecessary trips of maintenance men to stations, and to assure that the right man goes, since different groups of men take care of the telephone company equipment and the UNIVAC equipment, it is important to be able to learn as much as possible from the test center as to the nature and location of the trouble.

In ordinary teletypewriter operation, clues as to the nature of trouble can often be obtained by observing the printed copy; since the copy in this case is not English text, it does not give as much information about trouble. Symptoms of trouble are rather the automatic error indications or complete failure to operate.

As one means of helping the isolation of trouble, a second loop, known as the test loop, is provided from the test center to the station. When the station attendant, on request from the test room, operates a specified key, the UNIVAC equipment is cut off from the telephone company equipment, the 5-wire parallel output of the sequence selector is looped back to the 5-wire parallel input of the distributor, and the distributor is arranged to send back on the test loop instead of the regular loop. Thus the test room can send out signals on the regular loop and receive them, for observations of distortion, on the test loop. The test room can thus establish whether there is trouble in the regular loop, or in the *83B1* station equipment. The use of the standard Baudot start-stop code makes possible the use of standard measuring equipment at the test room.

Arrangements can also be made to provide each outlying station with a test slide in the agent set slide cartridge. This is arranged to send a prearranged processor inquiry message, which will elicit a fixed processor reply; the test room connects a monitor printer or reperforator on the circuit and observes the known copy as a clue to the nature of the trouble.

Alarms and Protective Features

The selective calling system is provided with a number of automatic features to safeguard continuity of service, with associated alarms to warn station attendants of trouble.

If during the polling of stations, one does not respond with either a message or the designated no-traffic signal (the letter V), the transmitter start circuit waits about 2 seconds, gives a momentary alarm, and then goes on to poll the other stations. Thus, an interruption from one station does not tie up the system. This momentary alarm repeats on every round of polling so long as the trouble persists. For sure identification, an attendant can operate a key which will stop the polling process the next time the round reaches the offending station.

An open-line condition, occurring during transmission, will cause an alarm. If this should occur during polling, the polling would stop; the continuous search is itself a valuable check on the continuity of the circuit.

If at any time the line remains idle and marking for more than about 10 seconds (subject to change by the user) the transmitter circuit will time out and send the end-of-transmission code automatically. This will clear out any connection which was held up, and alarm the station which caused the holdup. Before the station can make another bid for the circuit, the attendant must push an alarm release button to put out the alarm lamp and remove the lockout condition.

For cases where the attendant has other duties to perform and may be some distance from the *83B* key and lamp panel, an option was added to remove the necessity of manually releasing the alarm. With this option the timeout signal is passed to the programmer-scanner, but the audible and visual alarms on the *83B* equipment do not operate. At the *83B* control station a momentary audible and visual alarm is given. A counter can be provided if the customer wishes to keep a record of the number of time-outs.

If the processor is out of order, an "alternate arrangement" signal (the letters AA) is sent from the processor site to alarm all stations and to tell them that for the time being they must use alternate means of handling their reservations business.

Conclusions

The application of the teletypewriter selective calling system provides a simple and economical communications link for the UNIVAC airlines reservations system. Several airlines are now using the system for a part of their reservations requirements and its use is expected to grow.

A New Control Terminal for Mobile Telephone Service

L. E. GETGEN
NONMEMBER AIEE

GREG McGIBBON
NONMEMBER AIEE

THE *L-2* control terminal which is described in this paper, is a basic element in a complete "package" radio system. The system design is building block in nature with only a few building blocks required for a complete operating system that is devoid of frequently unnecessary embellishments. However, additional panels are available where more than the basic functions are required.

As the functions of the various panels, the possible system arrangements, and system engineering considerations have been discussed in other literature,[1] they will not be considered here. The circuits used in the control terminal are, however, somewhat unusual and have not been fully described elsewhere. Their operation will be the subject of this paper.

Control Terminal Functions

The purpose of the *90101A* control terminal is to provide the interconnection between the landline telephone network at the mobile service operator's switchboard and the radio facilities. The radio transmission equipment may be located either at the central office or at a remote site. System arrangements allow the control terminal to be at either location.

One function of the control terminal is to turn on the radio transmitter whenever the operator plugs into the jack associated with the radio channel. If the operator was initiating a call to a mobile unit, rather than responding to a mobile initiated call, the control unit should also start the 600–1,500-cycle signaling

oscillator and connect it to the transmitter.

Frequency shift signaling with 600 and 1,500 cps (cycles per second) is the most widely used method of selecting the desired mobile unit in common-carrier mobile service today. In the so-called "manual" systems the dialing is performed by the mobile service operator at some type of manual switchboard. Each dial pulse is represented on the radio channel by a frequency shift. Common practice is for the numeral 1 to be reserved for resetting or clearing the mobile unit selectors. Therefore only combinations of the numbers from 2–10 are used in the mobile subscriber's number.

As mentioned previously, when the mobile service operator in calling a mobile unit, plugs into the radio channel trunk circuit, two things take place. First, the base transmitter is placed on the air. Second, the signaling tone is transmitted. This condition is maintained for 2 seconds and then the control terminal shifts the signaling tone and at the same time provides a "start dial" indication to the operator. The frequency shift, in effect, dials a 1 to reset the selectors in all mobile units. Subsequent dialing by the operator shifts the oscillator in accordance with the dial pulses and thereby, selects the desired mobile unit. Four seconds after the final dial pulse, the control unit automatically dials a 1 to reset all mobile unit selectors and to stop the ringing in the selected mobile unit.

For mobile initiated calls to land subscribers, the base transmitter is turned on when the operator answers but the signaling tones are not used.

Circuit Design

The heart of the *90101A* control terminal is the transistor circuitry shown in Fig. 1 as the electronic switch and the dual frequency oscillator.

Physically, each of these transistor circuit assemblies is a $3^1/_2$- by $5^1/_4$-inch glass-epoxy, printed-circuit card. For ease of maintenance, one transistor type is used throughout.

Fig. 3. Operation of oscillator keying transistor

The oscillator assembly is shown schematically in Fig. 2. The purpose of this unit is to provide 600 or 1,500 cycle signaling tones as directed by the electronic switching assembly.

Transistor *Q2* is a conventional Hartley oscillator with *L2*, *C3*, and *C4* forming the 1,500-cps tuned circuit. Varistor *RV1* provides amplitude limiting. The oscillator output is taken from the emitter and coupled to transistor *Q3* via resistor *R5*. Transistor *Q3* is a common-emitter, class *A* amplifier which provides the signaling tone output through transformer *T4* to the control unit. Resistor *R2* causes sufficient a-c current feedback to maintain the output at approximately 0 dbm (decibels above one milliwatt) with little distortion. Typical waveforms are shown in Fig. 7-1.

Keying of the oscillator is performed by transistor *Q1*. When the *Q1* base is more positive than terminal *13*, *Q1* is biased to cutoff with the collector acting as emitter. In this condition the transistor appears as a very high impedance in series with *C1* and *C2*, and the oscillator tuned circuit consists only of *L2*, *C3*, and *C4*. The resulting oscillator output is 1,500 cps.

When the base is more negative than terminal 13, two conditions are encountered. These depend upon the polarity at *C1* and *C2* in respect to a-c ground. If the *C1*, *C2* point is negative, the emitter base junction is back biased and the collector-base junction is forward biased. This situation is depicted in Fig. 3(B). It will be noted that these bias conditions are correct for transistor action except that in this particular case the collector is being used as the emitter and the emitter is used as the collector. The bias

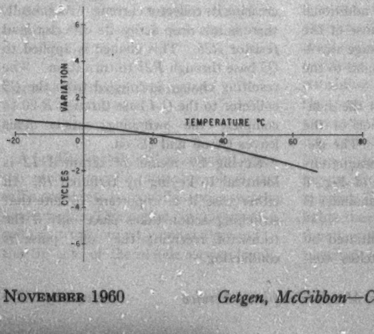

Fig. 4 (left). Temperature characteristics of dual frequency oscillator at 600 cps

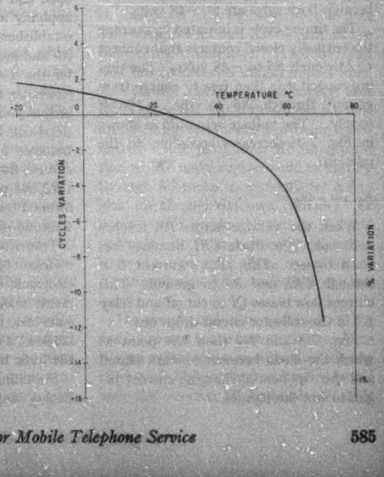

Fig. 5 (right). Temperature characteristics of dual frequency oscillator at 1,500 cps

voltage to terminal 14 is sufficiently large to insure that the transistor is operating in the saturation region. This is the shaded area of Fig. 3(A). As indicated in the figure the slope of the characteristic shows a high ratio of current to voltage; that is, a low acting-collector to base impedance.

When the polarity at *C1*, *C2* reverses, both junctions of *Q1* are forward biased—the emitter-base junction caused by the change in emitter polarity and the base-collector junction caused by the bias conditions previously assumed. This, in effect, is depicted by the two forward biased diodes of Fig. 3(C). Again, the impedance from *C1* and *C2* to a-c ground is low. As a result, for either situation shown in Fig. 3, the capacitors *C1* and *C2* are effectively placed in the tuned circuit and the oscillator frequency is 600 cps.

The characteristics of the oscillator assembly as a function of temperature are shown in Figs. 4 and 5. It will be noted that the frequency variation over the operating temperature range of −20 to +50 C (degrees centigrade) is considerably less than 1%. This is well within the system requirements.

The electronic switching assembly shown in Fig. 6 consists of a 2-second time-delay circuit, a 4-second time-delay circuit, and a bistable switch. To simplify maintenance, a single type of transistor is used in all these circuits.

In the quiescent state, the 4-second-time-delay transistor *Q1*, is biased on through the path from −24 volts, the *Q1* emitter-base junction, resistor *R3* and *R4* to the −48-volt supply. Diode *CR1* is back biased as its anode is tied to the −48-volt supply through normally closed contacts and its cathode is at −25 volts. Time-delay capacitor *C12* has no charge because both sides are at −48 volts.

The timing cycle is initiated by opening the normally closed contacts that connect *C12* through *R5* to −48 volts. The timing capacitor is then free to charge from ground through *R6* to the −48-volt supply. The voltage across *R6* as shown in Fig. 7-9, decreases according to the relation:

$$E_{R-6} = -48\epsilon^{\frac{-T}{RC}}$$

When the voltage across R6 reaches −25 volts, the diode *CR1* becomes forward biased. This allows current flow through *CR1* and *R6* to ground. This current flow biases *Q1* to cut off and relay *K5* in the collector circuit drops out.

Figs. 7-8 and 7-4 show the point at which the diode becomes forward biased and the exponential charging current begins to flow through *R4*.

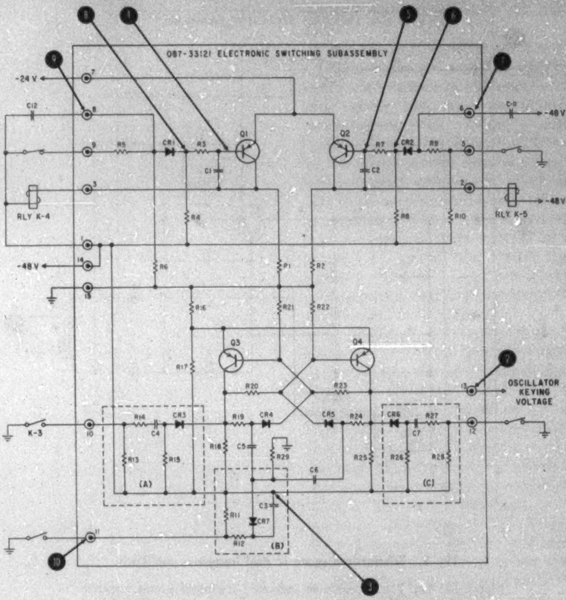

Fig. 6. Schematic diagram of the electronic switching assembly

Note: See Fig. 7 for waveforms indicated at circled points 2–10

The 2-second time delay circuit consisting of transistor *Q2*, and its bias network, is completely analogous to the 4-second delay circuit except for a difference in time constant elements and in the method of starting the timing cycle. In the quiescent state, the switching contacts are open and the timing cycle is started by applying a ground at terminal 5. This establishes a charge path for *C11* through *R9* and subsequent action is the same as for the 4-second delay circuit. Fig. 7-7 shows the voltage across *R9*. At the two second point, a change in the exponential slope can be noted. This is where *CR2* becomes forward biased and additional current flows through *R9* because of the *CR2*, *R8* path. The base voltage waveforms, Figs. 7-5 and 7-6 are similar to the 4-second circuit counterparts.

Transistors *Q3* and *Q4* form the symmetrical bistable switch portion of the electronic switching assembly. The elements making up the pulse forming circuits are those in the boxes of Fig. 6 labeled (*A*), (*B*), (*C*). The remainder is the basic bistable switch.

Switching action may be initiated by closing any one of the switches connected at terminals *10*, *11*, *12*. If switching at terminal *10*, for example, is to be considered note that with *K3* contacts open there is no charge on *C4* as both sides are tied to a common voltage through *R13* and *R15*. Diode *CR3* is back biased in this condition. When *K3* is closed, *C4* charges, principally through *CR3* and *R18*, to form a positive pulse across *R18*. This pulse is coupled via *R20* to the base of *Q4*. This pulse is of the polarity to turn *Q4* off. Therefore, if *Q4* is in the off state when the pulse arrives, no switching action takes place. However, if *Q4* is on, the pulse attempts to turn it off by decreasing its collector current. As a result, there is less drop across its collector load resistor *R25*. This change is applied to *Q3* base through *R23* to turn it on. The resulting change is coupled from the *Q3* collector to the *Q-4* base through *R*-20 to complete the switching action. This leaves *Q4* off and Q3 on.

Keying by means of terminal *12* is identical to keying by terminal *10*. In either case it is important to note that switching action takes place only if the transistor receiving the "off" pulse is conducting.

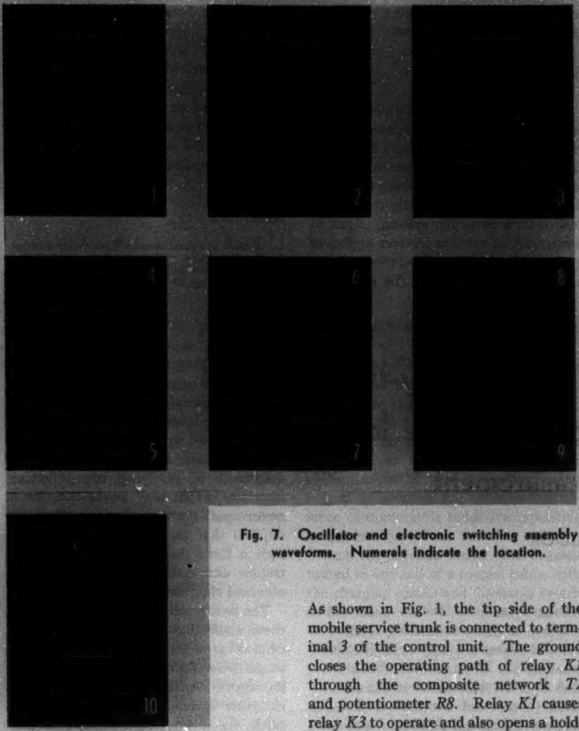

Fig. 7. Oscillator and electronic switching assembly waveforms. Numerals indicate the location.

Keying by terminal *11* is similar to that of the other two terminals with the exception that the trigger pulses are applied to the bases of both transistors. Thus, there is a change of state for each keying pulse regardless of which transistor is on. Figs. 7-10 and 7-3 show dial pulses followed by a 4-second delay pulse at the (B) network input and output.

The purpose of the bistable switch is to provide the appropriate keying pulses to the signaling oscillator. The output is taken from the collector of *Q4* at terminal *13*. Typical waveforms are shown in Fig. 7-2.

Control Terminal Operation

LAND TO MOBILE CALL

A land to mobile call is initiated when the mobile service operator plugs the calling cord into the mobile service switchboard jack. This action, by means of a suitable trunk circuit, applies a ground to the tip side of the mobile service trunk. As shown in Fig. 1, the tip side of the mobile service trunk is connected to terminal *3* of the control unit. The ground closes the operating path of relay *K1* through the composite network *T2* and potentiometer *R8*. Relay *K1* causes relay *K3* to operate and also opens a holding path to the 4-second time-delay circuit (electronic switch terminal *9*). Relay *K3* lights the busy lamp, keys the base transmitter via terminal *17*, operates relay *K9*, and applies ground to terminals *5* and *10* of the electronic switch. Relay *K9* connects the signaling oscillator to the transmitter input terminals.

System operation requires an initial signaling frequency of 600 cps. This condition is assured by the ground applied to switch terminal *10* by relay *K3*. The ground applied to terminal *5* starts the 2-second timing period as previously mentioned. After 2 seconds has elapsed, the 2-second time-delay circuit causes *K5* to release. Relay *K5*, then, removes the remaining −48-volt holding path from electronic switch terminal *9* (one was removed by *K1*) to start the 4-second timing period. It also lights the "dial" lamp at the control terminal and by sending a ground through the composite network *T-2* and the ring side of the line, lights the operator's dial lamp. Another function of *K5* is to apply a ground to terminal *12* of the electronic switching assembly to shift the tone to 1,500 cps. This, in effect, dials a 1 to reset the selectors in all of the mobile units.

Upon receipt of the start dial indication, the mobile service operator can proceed to dial the desired mobile unit. The dialing operation intermittently breaks the ground to relay *K1*. Relay *K1* operates the electronic switch in accordance with the dial pulses via the ground to the electronic switch terminal *11*. The electronic switch, in turn, shifts the dual frequency oscillator.

Each dial pulse, by means of the connection to electronic switch terminal *9*, also resets the 4-second time-delay circuit. Four seconds after the final dial pulse, the 4-second time-delay circuit releases relay *K4*. Relay *K4* applies a ground to the electronic switching assembly terminal *11*, to dial a 1 which stops the ringing in the selected mobile unit and also resets all of the mobile unit selectors. Relay *K4* also de-energizes slow-release relay *K9* which removes the signaling oscillator from the transmitter input.

MOBILE TO LAND CALL

To initiate a call, a mobile subscriber first listens to ascertain that the radio channel is idle and then momentarily pushes his transmit button. Receipt of the r-f (radio-frequency) carrier by the base station receiver causes a ground to be placed on terminal *18* of the control unit. This operates relay *K7*, while the carrier is on, to light the "receive" lamp. Relay *K7* energizes relay *K6* which locks up through its own contacts and contacts of *K8*. In operating, it lights the control unit "line" lamp and sends a ground through the composite network *T2* to light the mobile service operator's line lamp.

When the operator responds, a ground is placed on the tip side of the line. This energizes *K1* and *K3* to turn on the base station transmitter. It will be noted that this condition is similar to that when the operator initiates a call except that *K6* is energized. It is this difference that keeps the signaling tones from being transmitted. The path from *K8* to ground through *K6* make contacts and to battery through *K3* make contacts allows *K8* to lock up through its own contacts. In doing so, *K8* breaks the path to *K9* and prevents it from applying signaling tones to the line. The operation of *K8* also releases *K6* to extinguish the line lamp.

The circuit has been arranged so the line connected to the base station receivers is open except when an r-f carrier is being received. This action is controlled by *K7* and the receiver Codan relays. This prevents the radiation of receiver noise in case of faulty squelch operation during intervals when the base transmitter is on and a mobile unit is not transmitting.

During the periods when the mobile unit is transmitting, *K7* not only connects the receive line to the mobile service operator, but also inserts a reverting level attenuator in the transmit path. This provides the proper level to the base transmitter for the mobile signal. The retransmitted mobile signal is used for mobile to mobile calls and permits other mobile units to monitor both sides of the conversation, as in conventinal party-line service.

Summary

The *L-2* control terminal which requires only $10^1/_2$ inches of rack space can provide all the functions necessary for control of a radio-telephone communication system. It is recognized, however, that additional features are frequently required or desired for a particular system. Most of these, such as satellite receiver appliques for using more than one base receiver with a system; line amplifiers for increasing transmission levels; automatic gain adjusting amplifiers for preventing overmodulation; trunk terminating panels; carrier monitoring devices; and power supplies do not change the requirements of the control terminal. Therefore, they can be added on a modular basis as necessary. The *L-2* control terminal, in each instance, performs the basic control functions.

Proposed Monocycle-Pulse Very-High-Frequency Radar for Air-Borne Ice and Snow Measurement

JOHN C. COOK
NONMEMBER AIEE

Synoposis: It is suggested that a single electromagnetic pulse having a length in space of the order of a meter can be radiated and received by low-*Q* (broad-banded) antennas. Rough calculations indicate that peak powers of 100 kw probably can be generated with existing electronic components, capable of producing usable signal returns from large semispecular surfaces at distances of the order of miles. The resulting "untuned all-video-radar system" would constitute an electromagnetic analogy to the well-known seismic reflection method of geophysical prospecting, in which a single compressional acoustic pulse (under ideal conditions) is emitted isotropically and reflections are received from successive extensive, flat-lying, reflecting surfaces. A single vhf (very-high-frequency) pulse should combine the advantage of good distance resolution with less tendency than microwaves to be absorbed or scattered by the imperfections in natural materials. Preliminary experiments at 125 mc (megacycles) indicate that interfaces less than 60 cm (centimeters) apart could be so resolved. The development and initial application of the method as a rapid air-borne method of profiling the thicknesses of radio-transparent layered materials, such as floating fresh-water ice (for aircraft landing areas) and the polar continental ice sheets. Potential applications in high-speed extraterrestrial communication may also exist.

Problem

THERE is need for an air-borne means to determine instantaneously and, if possible, continuously, the thickness of floating natural ice masses such as the polar sea ice pack, as possible emergency, scientific, or logistic-support landing fields for aircraft. There appears also to be a need for information concerning the detailed contours of the rock underlying the polar ice caps of Greenland and Antarctica, since these data are now being laboriously garnered by seismic expeditions traveling on the surface. A need has also been expressed for means to determine rapidly the extent and thickness of permafrost in ice-free land areas of the polar regions. In response to these needs, the author proposed in 1956 to develop airborne electromagnetic methods for measuring the thickness of frozen materials, on the assumption that frozen materials, having extremely high electrical resistivity should be more or less transparent to radio waves. A subsequent study, under the sponsorship of the Air Force Cambridge Research Center,[1] has shown that radio waves probably would be severely attenuated in sea ice and permafrost, although useful information might nevertheless be obtained electromagnetically from these types of materials.

With fresh lake ice and continental snow-ice sheets, which are relatively radio-transparent because they have resistivities of the order of 10^6 to 10^7 ohm-meters,[2–4] there still remains the problem of scattering by inhomogeneities within the ice and irregularities upon its surface. Therefore, in accordance with well-known physical principles, electromagnetic energy of the longest possible wavelength should be used to secure deep penetration of these materials. However, the requirement of resolving two reflecting interfaces which may be as little as a meter apart (in the case of floating ice) requires that the radiated energy be in such a form that both adequate penetration and distance resolution can be obtained simultaneously.[5]

The best possible compromise between these conflicting demands would be to employ a radio wave consisting of a single cycle of a vhf carrier as the exploring agent. An analogous single acoustic pulse is employed for probing the earth for plane, acoustically-reflecting interfaces in the seismic-reflection prospecting method.[6] In practice, a single cycle of either acoustic or electromagnetic energy is difficult to generate. However, a series of single pulses (equivalent, by Fourier's principle, to a sum of infinite wavetrains of many frequencies) can readily be generated. After reflection, the waveform received may be different from that transmitted, because of changes in the relative phases and amplitudes of the various frequency components in the equivalent spectrum. From these changes the dispersion, absorption, and layering of the reflecting body and hence its structure, dielectric constant, and re-

Paper 60-994, recommended by the AIEE Radio Communication Systems Committee and approved by the AIEE Technical Operations Department for presentation at the AIEE Pacific General Meeting, San Diego, Calif., August 8–12, 1960. Manuscript submitted March 21, 1960; made available for printing July 13, 1960.

John C. Cook is with Southwest Research Institute, San Antonio, Tex.

The author wishes to thank The Air Force Cambridge Research Center, in particular Dr. James A. Peoples, Jr., under whose direction this work was supported under Contract no. *AF 19(604)-2137*, for the opportunity to perform this brief preliminary study.

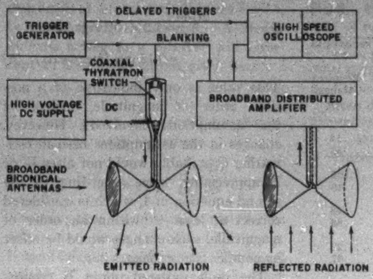

Fig. 1. Hypothetical untuned, "all-video" radar system

sistivity could perhaps be deduced. A narrow search beam would not be required in the case of large, flat-lying reflecting interfaces (any more than it is in seismic prospecting) because rays arriving at angles very far from normal incidence would be reflected away, beyond the region sampled by the receiving antenna. The requirements of the problem and the limitations of vhf electromagnetic pulses therefore seem well suited to one another.

Proposed Radiating System

A single burst or pulse of electromagnetic energy can theoretically be generated by the acceleration of a charge, Q. This amounts to starting or stopping a flow of electric current. The radiation is emitted from the charge itself. In order to generate a single short wavelet, the circuit containing the charge during its acceleration must be kept compact in the intended direction of radiation. A loop radiating edgewise, for example, should be less than half the required pulse "wavelength" in diameter. Directed radiation can be obtained while preserving the coherence and shortness of the emitted pulse only by using a large parabolic reflector, since resonant or multielement antenna structures would radiate a wavetrain when excited with a pulse.

A simple and natural generating antenna for the purpose would consist of two oppositely charged conducting bodies side by side. If these were suddenly connected together, as by a spark or thyratron switch, the flow of charge would be in a straight line and most of the radiation would be emitted sidewise. The charged conductors could be shaped like the halves of a nonresonant, broad-band vhf antenna to encourage radiation of all the frequency components in the spectrum of a short pulse; this is equivalent to prevention of resonant "ringing" and consequent emission of other wavelets subsequent to the first.

One form of such an antenna might be two coaxial opposed cones with their points close together ("biconical" form).[7] The cone angles should be broad and their heights of the order of a quarter of the desired pulse wavelength. A resistive coating might be used to further insure critical damping of the antenna and absence of appreciable inductive-capacitive reverberation.

Such an antenna might also be connected to one end of a coaxial cable, with the charging means and discharge switch at the other end. The discharge-current wave from the switch would be confined within the cable until it emerged into the the exposed conductors of the antenna. Their radiation would occur during a time equal to the sum of the current-wavefront rise time t and the time needed for the current front to spread over the entire antenna. Echoes within the cable could probably be prevented by good matching at the antenna end. Fig. 1 shows a video-radar system with such an antenna.

The switch suggested for such an arrangement is a type *5C22* hydrogen thyratron in series with one or two voltage-multiplying gaps. It would be arranged as the center conductor of a coaxial line which would have tapered matching sleeves at the ends for cable connection. This switch, described by Heard,[8] would be capable of generating discharges of 30 to 50 kv and 500 amperes with a minimum rise time, $t = 1.8$ mμsec (millimicroseconds). Since radiation occurs only during acceleration of the current, which is completed in time t, the corresponding pulse wavelength would be $ct = 54$ cm if only that portion of the circuit adjacent to the switch is considered. Longer radiation pulses would generally be generated by virtue of the fact that additional, finite time is required for the wavefront of current acceleration to be propagated over the surface of the antenna.

Nomenclature

I_θ = radiation intensity in direction θ
Q = radiating charge
t = time, or input pulse duration
θ = elevation angle or phase angle
ϕ = azimuth angle
R = distance from antenna center
c = velocity of light
v = velocity of radiating charge
T = period of radiated pulse fundamental
W = total radiated energy per pulse
q = input charge
C = antenna capacitance
V = supply potential difference
$\lambda = cT$ = pulse wavelength
δ = depth of conduction in antenna skin
n = number of conduction electrons per cm^3
l = distance of charge displacement
P = peak radiated power
G = antenna gain
A = wavefront area
E = electric-wave intensity
r = reflection coefficient of surface
h = height of antenna above surface
p = power density in space
E_s = signal voltage at receiver
F = receiver noise figure
k = Boltzmann's constant
Δf = receiver bandwidth
p_s = received signal power
p_n = receiver noise power
ρ = resistivity of medium
ϵ = dielectric permittivity
α = attenuation coefficient
μ = magnetic susceptibility
$\omega = 2\pi/T$ = angular frequency
Z = receiver input impedance or intrinsic impedance of medium

Estimate of Radiated Peak Power

To calculate the intensity of the electromagnetic pulse emitted by such equipment, an equation derived by Sommerfield for X-ray emission may be used. (See either Smythe's[9] equation 14.12.10; or Stratton's equation 37, p. 475 of reference 10.)

$$I_\theta = \frac{Q^2(dv/dt)\sin^2\theta}{16\pi c^3 R^3 \cos\theta}\left[1 - \frac{1}{[1-(v/c)\cos\theta]^4}\right] \tag{1}$$

is the total pulse energy per-unit area radiated in direction θ, the angle between the directions of v and of R. Gaussian units are used throughout. This must be integrated twice to give the total radiated energy:

$$W = \int_0^\pi \int_0^{2\pi} I_\theta (R\,d\theta)(R \sin\theta\, d\phi) \doteq \frac{Q^2 v}{3c^3}\left[\frac{dv}{dt}\right] \doteq \frac{2Q^2v^2}{3c^3T} \tag{2}$$

In performing the integration, it has been necessary to clear fractions in the bracket, expand top and bottom by binomial theorem, and neglect all terms involving the v/c correction. This can safely be done for the purposes of an order-of-magnitude calculation since v/c is small, according to the following reasoning.

The maximum charge, q, that can be

Table I. Calculated Video-Radar Performance

		10,000	$(2.3)10^{-6}$	59	0.059	53
	5	100	0.14	107	14	5
		10,000	$(1.4)10^{-5}$	67	0.14	45
0.3 meter, 1,000 mc, $\Delta f=1{,}400$ mc, $Z_{in}=300$ ohms	2	100	$(2.3)10^{-4}$	79	0.18	43
		10,000	$(2.3)10^{-8}$	39	0.0018	83
	12	100	8.3×10^{-3}	85	1.1	27
		10,000	8.3×10^{-7}	45	0.011	67

caused to move through the switch depends upon the antenna capacitance C and the supply potential V, since $q=CV\approx\lambda V/2$ esu (electrostatic units). The movement of q across the gap causes the "compressional" displacement of a much larger charge Q in the surface of the antenna, which does the actual radiating. Q can be estimated from the length of the antenna $\doteq\lambda/2$, its circumference, taken as 1 cm or greater, the "skin depth" $\delta=6.6\sqrt{\lambda/c}$ cm, and the valence-electron charge per cm^3 of copper, n, which is, very roughly:

$$n=\left(\frac{2\text{ electrons}}{\text{atom}}\right)\left(6\times10^{23}\frac{\text{atoms}}{\text{mol}}\right)\times\left(\frac{1\text{ mol}}{63\text{ grams}}\right)\left(\frac{8.9\text{ grams}}{\text{cm}^3}\right)\times(4.8\times10^{-10}\text{ esu})=8.3\times10^{13}\text{ esu/cm}^3$$

$$\text{and } Q=\frac{\delta n\lambda}{2}=6.3\times10^{9}\,\lambda\text{ esu} \quad (3)$$

where mol is the abbreviation for gram molecular weight. The distance "effectively moved by q" (by the electric wave spreading over the antenna surface) is approximately from the midpoint of one side of the antenna to the midpoint of the other, approximately $\lambda/4$. The average distance l, actually moved by Q is much smaller: $l=(q/Q)(\lambda/4)$. The time required is at least the pulse period T, so, assuming $V=30$ kv $=100$ esu, and $T=t+\lambda/4c=2.3\times10^{-9}$ seconds, the mean charge velocity is:

$$v\leqslant\frac{l}{T}=\frac{q\lambda}{4QT}=\frac{\lambda V}{4\delta nT}=2{,}530\text{ cm/second} \quad (4)$$

for the values assumed, whereas $c=3\times10^{10}$ cm/second, so $(v/c)<<1$ and may be neglected in the formula for I_θ.

Taking the value for v estimated in equation 4 and inserting it in approximate equation 2, the average radiated power P during the pulse is:

$$P=W/T=\frac{2Q^2v^2}{3c^3T^2}=1.2\times10^{12}\text{ ergs/second}$$
$$=0.12\text{ mw (megawatt)} \quad (5)$$

This value is only indicative of a possible order of magnitude, because of the assumptions involved. However, changes in the assumptions used in estimating Q probably would not alter W or P appreciably, since according to the second equation in 4, which is considered correct at least to within an order of magnitude, such changes would be offset by compensating changes in v.

The peak radiated power is proportional to v^2, hence to the square of the applied voltage V. It also depends slightly upon the pulse duration T, which is the only other independent variable; the pulse wavelength λ and the antenna dimensions, hence all other quantities, are determined once T has been chosen.

Reception of VHF-Pulse Radiation

Typical broad-band vhf antennas have a "gain" G of the order of 2 to 7, compared to a hypothetical isotropic radiator. The peak radiated power flowing through each square cm at a distance R from a vhf antenna emitting pulses of total peak power P is:

$$\frac{dP}{dA}=GP/4\pi R^2 \quad (6)$$

When the pulse wavefront encounters a smooth plane reflector of reflection coefficient $r=E/E_0=\sqrt{p/p_0}$, the ray paths are folded back and reach the source re-

* For normal incidence only.

gion again at a total path distance $R=2h$, twice the flying elevation h. A similar antenna acting as a receiver will intercept an area of wavefront given by:

$$A=G\lambda^2/4\pi \tag{7}$$

The peak power intercepted by the receiving antenna is therefore:

$$P_s=\left(\frac{G\lambda^2}{4\pi}\right)r^2\left(\frac{GP}{4\pi(2h)^2}\right)=\frac{G^2\lambda^2r^2}{64\pi^2h^2}P \tag{8}$$

Assuming that the antenna is matched to the receiver input, one half of this power is available for amplification. The signal voltage E_s at the receiver input is given by:

$$E_s=\sqrt{\frac{p_sZ}{2}} \tag{9}$$

where Z is the input impedance, which is of the order of 3,000 ohms for typical miniature tubes at 100 mc. Suitable 1,000-mc amplifiers are not known to the author, but an input impedance of 300 ohms will be assumed. This formula permits estimation of the required gain, $g=20 \log (25/E_s)$ db (decibels), to drive the display oscilloscope. The voltage required for a 1-cm deflection of typical high-speed oscilloscopes is 25 volts.

The noise power already present at the receiver input is:

$$p_n=FkT(\Delta f)=5(4\times10^{-21})1.4c/\lambda \text{ watts} \tag{10}$$

Here the receiver has been assumed to have a noise figure $F=5$, a value commonly attained in good vhf practice. The bandwidth figure $\Delta f=1.4f=1.4c/\lambda$ results from the requirement of critical damping ($Q=0.76$) to prevent ringing and prolonging of the video pulse into a wave-train in the antenna and receiver. The power signal-to-noise ratio in db at the receiver output is therefore (for λ in meters):

$$10 \log\left(\frac{p_s}{p_n}\right)=10 \log\left(\frac{G^2Pr^2\lambda^3}{3575\pi^2ch^2}10^{-21}\right)$$
$$=10 \log(1.2\times10^{11}\lambda p_s) \tag{11}$$

Table I summarizes some numerical results obtained by applying these formulas to an air-borne ice-surveying situation, for several combinations of extreme values for height h, antenna gain G, and pulse wavelength λ. A peak transmitted power of $P=10^5$ watts and a minimum specular reflection coefficient $r=0.2$ (see Table II) are assumed throughout. It is seen that the signal-to-noise ratios are all ample and, in fact, the transmitted power might be greatly reduced for some combinations of conditions.

Suitable video amplifiers for a receiver[11] are available only for the longer wavelengths. Spencer-Kennedy Laboratories' model *202D* chain amplifier has a pass band of from 1 kc to 210 mc, a gain of 20 db and an output voltage of 4 volts. An additional special stage of two would be desirable to drive the oscilloscope. This arrangement should be usable up to flying heights of 1,000 meters. If two chain amplifiers were cascaded, operation at 100 mc up to $h=10{,}000$ meters should be feasible.[12]

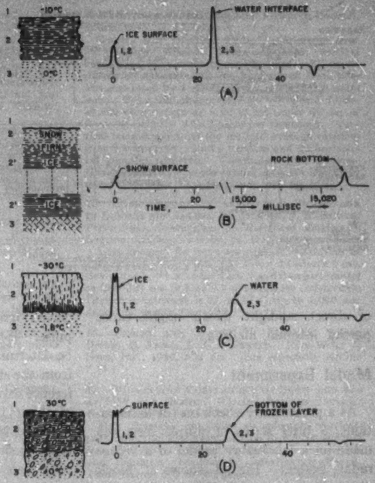

Fig. 2. Hypothetical appearance of reflected video pulse sequences from various terrains

Application to Ice Measurement

Table II presents values of the vhf radio-reflection coefficients of various types of interfaces between natural layered materials common in the Arctic and Antarctic. The resistivities ρ and dielectric constants ϵ/ϵ_0 used were obtained from the literature[13–15] or experiment.[1] The attenuation coefficient α, velocity v, and useful working depth d in each material were calculated by assuming a maximum permissible absorptive attenuation of $E_0/E=6$ in the theoretical formulas, using mks (meter-kilogram-second) units:[16]

$$E/E_0=e^{-\alpha z},\ d=(\text{logn } 6)/2\alpha \tag{12}$$

$$\alpha=\omega\sqrt{\frac{\mu\epsilon}{2}\left[\sqrt{1+\frac{1}{\epsilon^2\rho^2\omega^2}}-1\right]} \tag{13}$$

$$v_p=\frac{1}{\sqrt{\frac{\mu\epsilon}{2}\left[\sqrt{1+\frac{1}{\epsilon^2\rho^2\omega^2}}+1\right]}} \tag{14}$$

The complex reflection coefficients r were calculated (except those given by Saxton[17]) by means of the Fresnel formula:[18]

$$r_{12}=\frac{Z_2-Z_1}{Z_2+Z_1} \tag{15}$$

where Z is the intrinsic impedance of a medium, given in mks units by the equation:

$$Z=\sqrt{\frac{\mu}{\epsilon(1+1/j\omega\rho\epsilon)}} \tag{16}$$

Fig. 2 summarizes the hypothetical effects of various natural reflectors upon a video pulse according to the predictions of Table II. At vhf, for relatively low values of resistivity ρ, as in sea ice, the medium would become dispersive (higher-frequency components traveling faster) and also would act as a low-pass absorptive wavefilter, according to equations 13 and 14. The air–ice interface would reflect the high-frequency components better, according to equations 15 and 16; see also reference 19. An attempt has been made to depict these effects qualitatively in Fig. 2. Resistivity data, necessary to determine the wave velocity in the ice hence its corrected thickness, could probably be calculated from spectrometer analyses of the transmitted and received waveforms.

Best results in measuring thickness would be expected with fresh-water lake ice and continental glaciers. According to Stern[2] any measurements involving radio waves should be made when the ice is cold and dry, preferably in the absence

of direct sunlight which might cause partial internal melting.

Model Experiment

As a preliminary check on the assumptions, a brief series of simple tests was made on a laboratory model of a video-radar system. Fig. 3 shows a block diagram of the equipment used.

The radiating equipment consisted of a broad-band cone-and-plane antenna and a pulse-sharpening spark gap. Pulses of direct current at 550 volts, 0.2-μsec long, were supplied by a conventional radar modulator. A series-isolating resistor was used to make the antenna characteristics independent of the modulator and power cable. The ideas for this video source were developed after reading Potok's article.[20]

The receiving system consisted of a wide-band aircraft antenna connected directly to the deflection plates of a fast-sweep oscilloscope through 6 feet of low-loss 55-ohm coaxial cable. None of the available amplifiers, including that in the oscilloscope, had enough bandwidth to pass the expected video pulses. Echoes in the antenna cable were combated by means of a 55-ohm carbon-film terminating resistor at the oscilloscope plates.

The oscilloscope was triggered either before the modulator, as shown, or afterward by the initial transmitting antenna transient, picked up by induction in the trigger cables. Either trigger could be chosen by adjustment of the trigger threshold bias control of the oscilloscope. Pretriggering displayed the entire received waveform, but with so much jitter (0.3 μsec, arising at the spark) that it could not be intensified enough for analysis. Post-triggering stopped all jitter, but failed to display the early portion of the strong wave group leaking into the receiver directly from the transmitter. Available antenna cables provided insufficient time-delay of the received signal to permit viewing the initial pulse. Hence, its waveform could not be determined, although it was estimated from the distances involved in the interference experiments to be a damped train of about 13 125-mc waves, as shown in Fig. 4. This demonstrates that waves of much shorter duration than the trigger pulse can be generated by an antenna spark gap (or a thyratron, probably). Because of the pressure of other work, no serious attempt was made to "clean up" reradiation from nearby objects or to increase the antenna damping to determine whether the wavetrain could be shortened thereby.

It has been suggested by J. D. King, Southwest Research Institute, that such a damped wavetrain could be radiated as a single pulse by employing an alternative technique: the wavetrain would be fed by cables differing in length by λ to two different, equal antennas placed close together. Attenuation in the two cables would be adjusted so that the first and subsequent cycles radiated from one antenna would cancel the second and subsequent cycles from the other, leaving its uncanceled first cycle as the only energy radiated. Presumably the same arrangenent could be used as a nonresonant receiving antenna.

Because of the lack of an amplifier, the radiation could not be seen on the oscilloscope for antenna separations greater than 17 meters. Hence, attempts to bounce reflections from large, fixed flat surfaces (e.g., metal buildings) failed because sufficient range could not be used to separate the reflection from the tail of the direct leakage signal.

However, a movable corner reflector 1 meter square could be identified on the oscilloscope by motion of the interference "kink" produced in the tail of the leakage wavetrain, Fig. 4. A movement by only ±30 cm in range could be detected. It was estimated that, if a suitable amplifier had been available, and if the radiated wavetrain had been properly shortened, fixed reflectors only 60 cm apart could be resolved with this system. Such high resolution has never been achieved as yet, with a pulsed-radar system in the vhf portion of the r-f (radio frequency) spectrum.

Other Applications

It should be pointed out that applications of vhf video radar are limited because of the difficulty of obtaining narrow antenna beam width at such frequencies. However, this is not a serious impediment for specular reflection from large flat surfaces such as natural bodies of ice. Vhf antenna beams of small angular width could be obtained in a monocycle system only by the use of large parabolic reflectors, since multi-element antennas would lengthen the pulse into a wavetrain. Such reflectors probably must either be mounted on the ground or must float weightlessly in extraterrestrial space. Applications to communications in space may arise. It is surmised that there will be circumstances in which attenuation by internal scattering is a limiting factor. Two examples might be: 1. probing the atmospheres of the giant planets by radar, and 2. high-speed telegraphic communication through vast distances filled with rarified, inhomogeneous matter. Under such conditions, the basic idea here proposed might have value: that of combining the required long radio wave and the desired short signal duration in single electromagnetic pulses.

Much sharper distance resolution in microwave radar could be achieved if desired by the monocycle-pulse technique, when suitable broad-banded r-f amplifiers become available. However, the finite angular beam width achievable limits lateral resolution seriously, unless several receiving antennas and interference techniques are used to increase it.

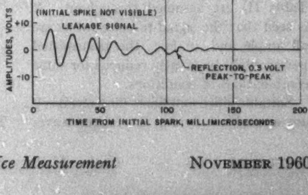

Fig. 4. Observed radiation waveform with reflection

Therefore, resolution in range of a few centimeters might not be worthwhile at present.

◆

Discussion

Frank R. Dickey, Jr. (General Electric Company, Syracuse, N. Y.): Dr. Cook's very interesting paper presents convincing arguments for believing that a wide-band vhf radar will be useful for exploration of ice layers. It certainly is to be hoped that further experiments will be made soon to prove whether or not this is indeed the case.

The method of generating wide-band radio waves by means of a spark gap or gas discharge is one in which I happen to have had a little experience. It undoubtedly is the simplest method known for generating the high-power short-duration pulses which are required in the proposed application. Dr. Cook's estimate of the power output from a spark radiator represents reasonable numerical value, although some of the steps taken in his calculation seem to require further justification. In regard to estimating the power output from such a device, I would suggest the expedient of calculating the electrostatic energy in the field surrounding the radiating elements immediately before breakdown of the gap and then of assuming that all of this energy is radiated at radio frequencies and in the lowest frequency mode of damped oscillation. Naturally, this procedure gives only an upper limit, since some of the energy is used in ionizing the gap and in other losses. However, experiments which I made, reported in reference 1, showed it to give at least the right order of magnitude in the case of very small mercury spheres discharging to a ground plane, in which case the efficiency would be expected to be no higher and probably lower than in the vhf case. At any rate, Dr. Cook's estimate of the power output is probably conservative.

Edward M. Little (U. S. Navy Electronics Laboratory, San Diego, Calif.): This looks like a promising method for measuring ice thickness from the air. However, at 125 mc, the accuracy is only ±30 cm (±1 foot), so the operation is marginal at 100 mc. At 1,000 mc, 10 times the resolving power, a 1,000-mc video amplifier will have to be available; none exist now.

This method should be usable on first-year sea ice after late spring when a large part of the brine has drained out but before interior melting is severe; and on old, essentially fresh pack ice, especially in the winter when internal and surface melting is at a minimum.

At Shippegan, New Brunswick, I obtained for the top layer of the ice 30 to 50 ohm-meters in February at an air temperature of −7 C and 100–500 ohm-meters in April at an air temperature of +5 C. These values are lower than those of the author's.

The working depths in fresh ice that Dr. Cook tabulates, if obtainable in practice, would make possible continuous thickness measurements over any glacier or ice cap and would be an extraordinary development for glaciologists who now depend on tedious surface seismic measurements.

John C. Cook: The discussions submitted are most encouraging and tend to support my belief that the proposed technique is feasible and potentially valuable. Unfortunately, in the 3 years since the initial studies reported here were completed, funds to develop and test the idea have not been found.

The method suggested by Mr. Dickey for

estimating the radiated power from the stored electrostatic energy is much more direct, less awkward, and intuitively better than the method used in my paper. The stored energy W and the power P available during a discharge time T can readily be estimated from the antenna capacitance C and potential difference V just before discharge: $W=(1/2)CV^2$ and $P=W/T$.

Inserting reasonable values compatible with the assumptions used in the paper, $V=100$ esu, $T=2.3\times10^{-9}$ seconds, and $C=14$ esu (calculated by assuming an antenna consisting of two spheres 12 cm in radius, 36 cm apart center-to-center), the maximum possible radiated energy and power are found to be: $W=7\times10^4$ ergs and $P=3$ mw. It appears that my earlier estimate of 0.12 mw is indeed conservative.

Dr. Little's values for the resistivity of sea ice are roughly comparable to the values of 20 to 200 ohm-meters given in my Table II. As shown in reference 1 of the paper, variations of sea-ice resistivity with salinity (i.e., history), specimen orientation, test frequency, and temperature extend through several orders of magnitude. The values used in Table II represent my best guesses for new sea ice in midwinter (air temperature −25 C) as measured at vhf with the electric field perpendicular to the brine tubules. They may, again, be conservative when applied to mature sea ices (which predominate in some parts of the arctic ocean), since Dr. Little's measured values of resistivity are, to me, unexpectedly high for the air temperatures he mentions. Either direct video-radar tests, or a thorough study of r-f electrical properties should be made on representative arctic sea ices. Such experiments would establish whether the video-radar method, in addition to its potentialities for land-ice exploration, might also be used to measure the thickness of sea ice from aircraft in flight.

Two-Wire Operation of N Carrier Systems

R. W. DEAN
ASSOCIATE MEMBER AIEE

E. M. KARKAR
NONMEMBER AIEE

THE SAN FRANCISCO BAY area, like many other metropolitan areas, has had a tremendous population increase in a very short period of time. More people mean more industry and more homes. The demand for telephone circuits to give these customers the service they desire has created a cable and conduit problem. Short-haul carrier systems have made great strides toward the relief of this problem, but even these have been only a partial answer. The purpose of this paper is to describe an experiment made by The Pacific Telephone and Telegraph Company for further utilization of existing cable plant to meet this rapidly increasing demand for service.

The *N1* carrier system was designed to provide 12 two-way conversations on two nonloaded cable pairs or a quad within the same cable sheath, using separate pairs and a different frequency band for each direction of transmission; one direction to use the low-frequency band 44 to 140 kc, the other direction to use the high-frequency band 164 to 260 kc. The *N1* carrier system has been described in a previous paper.[1] Open-wire carrier systems have for many years used filters to operate on an equivalent 4-wire basis over a single pair of wires. By applying these techniques to the *N* carrier system it is possible to operate them in cables in the same manner as other systems operate on open-wire pairs. For lack of a more descriptive term, the systems operated in this manner have been designated "2-wire *N* carriers," and will be referred to as such in this paper.

General

The cables crossing the San Francisco Bay were selected for 2-wire *N* carrier-system trials because of the paired and/or quadded cables that were available. The Pacific Telephone and Telegraph Company installed four of these systems using Lynch Communication Systems, Inc., *F-1154* filters. The information received from testing these systems can be used as a guide for engineering of similar systems. Fig. 1(A) shows a schematic layout of the two systems installed between San Francisco and Oakland. Fig. 1(B) shows a schematic of the two systems installed between San Francisco and San Rafael. The systems between San Francisco and San Rafael will be the ones more fully described in this paper because they are more complex.

The first two experimental systems were installed between San Francisco Juniper and Oakland Main offices, with repeaters at San Francisco toll office and Yerba Buena Island repeater station. These systems were operated 4-wire in 19-gage quadded toll cable between San Francisco Juniper and San Francisco toll offices. From San Francisco Toll to Yerba Buena Island and on to Oakland Main the systems were operated 2-wire in 19-gage paired submarine cable.

After these systems were put into operation and thoroughly tested with satisfactory results, they were turned over to regular traffic use for a trial period of 6 months. The following five different types of traffic circuits were assigned to these two systems: two full-period leases, four foreign-exchange circuits, nine crossbar tandem to crossbar tendem, four crossbar tandem to *4M* switching machine, three *3CL* switchboard to *4M* switching machine. During this trial period no circuit outages or system trouble was experienced.

The second two systems, with which this paper is most concerned, were installed between the San Francisco main and the San Rafael office. These systems were operated 2-wire from San Francisco Main to San Rafael in 19-gage quadded cable, with a system working on each side of a quad. There are two repeaters between these offices as shown in Fig. 1(B). The one nearest San Francisco Main, Point Cavallo, is an auxiliary repeater and normally receives its power from San Francisco. The one nearest San Rafael, Alto Junction, is a main-power point. The section between San Francisco Main and Point Cavallo is 6.85 miles in length, and is partly submarine cable. The section between Point Cavallo and Alto Junction is 6.67 miles and is buried cable. The section between Alto Junction to San Rafael is also buried cable and is 7.20 miles in length.

The conversion to 2-wire from 4-wire on these systems and the testing procedures were as follows. Both systems were lined up on a 4-wire basis. Noise, crosstalk, and channel response tests were then made on both systems. The first system was then converted to 2-wire operation in the section between San Rafael and Alto Junction repeater. All

noise, crosstalk, and channel response tests were then repeated. This procedure was repeated one section at a time until the system was operating 2-wire from San Rafael to San Francisco. The second system was then converted to 2-wire in the section betwen San Rafael and Alto Junction on the pair left idle when the first system was converted to 2-wire. The system continued to operate 4-wire on its own quad between Alto Junction and San Francisco. All noise, crosstalk and channel response tests were then repeated on both systems. This procedure was repeated for each section until both systems were operating 2-wire, one on each side of the same quad from San Francisco to San Rafael.

Filter Design

The low-pass high-pass directional filters were designed by Lynch Communication Systems, Inc. These provide a minimum loop rejection of 60 db (decibels), pass all frequencies below 140 kc on the low-pass side and pass all frequencies over 160 kc on the high-pass side. The schematics of the filters are shown in Fig. 2. The balanced arrangement contains four coils and eight capacitors for the low-pass side, while the high-pass contains three coils and ten capacitors. The impedances in and out are 135 ohms balanced. The frequency response of the filters is shown in Fig. 3. The passband losses for the two channels adjacent to the filter crossover does not vary more than 1/2 db at the corners. The attenuation at the crossover point at 150 kc is a minimum of 30 db to ensure the 60-db minimum-loop loss requirement. The reflection coefficient in both pass bands at no point exceeds 10%.

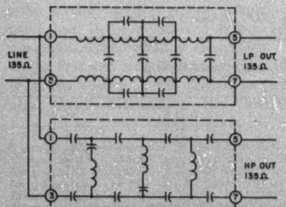

Fig. 2. Schematic of 152-kc Lynch type of F-1154 high-pass low-pass filter

The high-pass and low-pass elements of the filter are separately packaged in a hermetically sealed container measuring $3^1/_4$ by $3^3/_8$ inches by $4^1/_8$ inches high. Two complete filters (four containers) required for one repeater are mounted on a $3^1/_2$ by 19-inch mounting plate, which is arranged to include the battery-feed isolation filters for each side of the repeater. Fig. 4 shows a schematic of the repeater filter and network panel and Figs. 5(A) and (B) show the filter panel. The center container holds the battery-feed isolation filters which are exposed in the front view, Fig. 5(B).

Filter Installation

The filters used for the experimental systems were installed for convenience of cutover from 4-wire to 2-wire and not for maintenance or flexibility. At the terminals the filters were installed in vacant bay space close to the terminals. At the repeater points they were installed close to the frame for convenience of swinging jumper wire.

In a permanent 2-wire installation the filters should be installed near the frame or cross-connect terminals, with both equipment and line side of the filters appearing on frame or terminals, whichever is used. This should be done at both the terminals and repeaters to allow complete flexibility for reassigning filter and associated repeaters for routine or emergency maintenance, or for reassignment of equipment to other systems. Fig. 4 shows a schematic diagram of a repeater, its filters, and building-out equipment.

Transmission Consideration

NOISE

Table I shows a set of noise measurements taken on one of the tested systems. These measurements were taken between the hours of 11 p.m. and 7 a.m. in order to have a minimum amount of disturbance from office dial noise. All noise measurements were made with a *2B* noise-measuring set calibrated 144 and read *F1A* weighted. The noise measurements shown in Table I were made at the +10 point on the channel units (E_1, E_2 jacks), but they have been corrected and are all in decibels adjusted (dba).

If a 2-wire *N* carrier system were to be installed in a route where no power feed was required to auxiliary repeaters, it would still be necessary to use the trans-

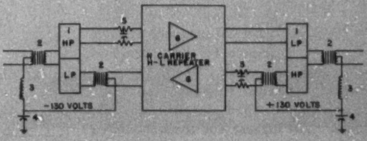

Fig. 4. Detailed schematic of repeater showing filters and power feed

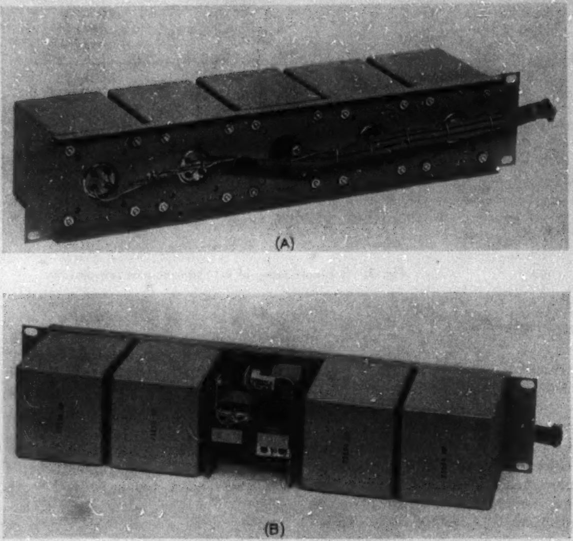

Fig. 5. **Filter mounted on plate**

A—Back view of filters showing wiring
B—Cover removed to show power-feed filters

former with a center tap to ground for suppression of longitudinal noises on the line side of the filters; see Fig. 1(B), San Rafael to Alto Junction section. This was found to be necessary in both experimental installations.

As can be seen in Table I, noise begins to increase noticeably as the third section is converted to 2-wire. Calculations based on these measurements shown in Table I indicate a limit of about five repeater sections should be set on a 2-wire system having repeater sections of between 6 and 7 miles in length. The amount of noise in a different 2-wire *N* system of three repeater sections could be less than the one covered here if the repeater sections were shorter. This is true because the artificial lines and/or span pads used to build out a repeater section are on the 4-wire side of the filters and therefore would add more attenuation in the loop around a repeater. This can be seen in Fig. 4.

CROSSTALK

The two systems covered in this paper were checked for both near-end and far-end crosstalk. The only measurable near-end crosstalk that was found showed up as intrachannel side tones. The highest side tones measured were still down to about −50 dbm (db referred to 1 milliwatt). Most channels were in the order of −60 to 65 dbm. These side tones also appeared in the experimental systems in paired cable, but were not of any consequence.

There was a small amount of far-end crosstalk that could be measured with the measuring equipment available. This only appeared when the systems were operating 2-wire for two sections and 2-wire for three sections. If the far-end crosstalk had been intelligible, it could have been reduced to unintelligible babble by switching systems from one quad to another at repeater points.

Table I. **Noise Measurements in DBA Corrected to 0 Point**

Channels Measured	4-Wire, 3 Sections	2-Wire, 1 Section; 4-Wire, 2 Sections	2-Wire, 2 Sections; 4-Wire, 1 Section	2-Wire, 3 Sections
1	10.1–11.1	11.7–13.7	11.6–12.6	15–16
2	16.6–17.6	12.7–13.7	12.1–14.1	16.1–17.1
2	15.8–17.8	11.6–12.6	10.6–12.6	16.7–17.7
4	12.4–13.4	14.6–16.6	14.6	18–20
5	9.2–10.2	14.4–16.4	13.2–14.2	14.2–15.2
6	10.2–11.2	13.5–15.5	11.3–12.3	14.3–16.3
7	10.4	10.5	11.3–12.3	16.3–18.3
8	11.9–12.8	15.4	11.7–12.7	15.7–17.7
9	8.4– 9.4	8.7	11.4–13.4	12.3
10	7.5– 8.5	7.7	8.7	10.7–12.7
11	9.8–10.8	12.9–14.9	12.8–14.8	14.2–16.2
12	15.0–16.0	12.1–14.1	13.1–14.1	13.2–16.2

There was no measurable far-end crosstalk on the systems that were tested in the paired cable.

CHANNEL RESPONSE

The channel frequency response of the 2-wire *N* system was comparable to the 4-wire installations of the same length, the one exception being channel 1. The roll-off of channel 1 due to filter action was comparable to a slightly longer system. This can be overcome in the 2-wire systems in the same manner as it is now overcome in the 4-wire system if it is of any consequence. That is, use channels 2 through 13, instead of channels 1 through 12.

In both experimental installations it was considered unnecessary to use channels 2 through 13 as channel 1 roll-off was only about 1 db more in the 2,800 to 3,000-cycle range when comparing 2-wire to 4-wire. There was little or no change in the other channels all the way across the frequency band.

Power

The power feeding of auxiliary repeaters presents a problem in a 2-wire system. This problem, however, only exists if there is more than one auxiliary repeater between power points. The principal use of 2-wire *N* carrier will be in metropolitan areas. This means repeaters can be located in central offices with an occasional auxiliary between mains.

In both experimental installations there was only one auxiliary repeater between power points. In the case of the Oakland to San Francisco Juniper systems San Francisco Toll fed negative 130 volts to Yerba Buena Island repeater station on the first system, while Oakland fed positive 130 volts. This arrangement uses a ground return. However, by having San Francisco Toll feed positive 130 volts on the second system and Oakland feed negative 130 volts, the ground currents were equalized. If this method is followed with all 2-wire systems through a cross section, the maximum current through ground return would be one system unbalance when an odd number of systems were installed. This method of alternately feeding positive and negative voltage was also the method used on the systems between San Francisco and San Rafael; San Francisco Main being one power plant and Alto Junction being the other.

At an auxiliary repeater that has both 2-wire and 4-wire systems, the repeater mountings will not be strapped the same as for receiving power from a remote supply. If at any time there should be a need to transfer equipment from a 2-wire to a 4-wire or vice versa, the strapping of the mountings must be changed.

Line-Up and Maintenance

The 2-wire *N* carrier systems require no special equipment for line-up or maintenance. In lining up these systems the standard procedures should be followed. This is possible because this arrangement of 2-wire operation is actually a change in the facility over which the system is operating, and not a change in the system itself. This facility change does means, however, a change in power-feed arrangements and must be remembered for maintenance or reassignment; see the section on power.

Conclusions

Based on the data received from the experimental systems, it has been demonstrated that *N1* carrier systems can now be operated 2-wire for short distances, using available equipment, without exceeding the transmission limits of the systems.

Establishment of a 450-Mc Vehicular Radio System in the Los Angeles Basin

G. APPLEGARTH
NONMEMBER AIEE

IN ORDER to supply additional mobile-radio-telephone service to the public in the greater Los Angeles area, The Pacific Telephone and Telegraph Company applied for four 450-mc (megacycle) radio channels in June 1956. At that time there were only six channels available for the domestic public mobile-telephone service (MTS) in the 450–460-mc common-carrier radio-frequency (r-f) band.

We have had considerable experience in mobile radiotelephony, particularly in the 460-mc citizen mobile-frequency band. Therefore, certain aspects of transmission and equipment operations on these frequencies were familiar. However, a few unique conditions concerning marriage and compatibility of equipment between radio station and the general telephone plant had to be considered before an integrated system could be established.

The first and most important concern of a new system is the desired service area. After determining the desired coverage, as specified by the Commercial Department, a detailed study of the topography of the greater Los Angeles area and the surrounding territory was made. From our engineering experience with the existing 460-mc private mobile systems and from Kenneth Bullington's radio propagation studies, we decided to establish base transmitters at our Mt. Wilson toll office.[1]

The communication industry considers the Mt. Wilson location a utopia for broadcasting r-f energy. The mountain top is a virtual forest of antenna structures and antennas placed by frequency-modulated (FM) and television broadcasters. Common-carrier and mobile communicators, and miscellaneous common carriers, have also contributed to the array of transmitting antennas. Figs. 1 through 3 are views of antennas and antenna systems on Mt. Wilson.

Mt. Wilson, with an elevation of 5,700 feet above mean sea level, is located 4 miles northeast of the city of Pasadena

Calif. In determining the average terrain in accordance with Rule *21.115* of the Federal Communications Commission's (FCC) rules, an elevation of 2,898 feet above mean sea level is derived. Figs. 4(A)–(H) show profiles of the topography taken at 45-degree increments from true north. Rule *21.115* requires profile information between the 2-mile and the 10-mile points on these radials, to determine the average terrain figure. In our particular case the general service area does not conform to this treatment and we are serving mobile subscribers 20 to 40 miles air-line distances from Mt. Wilson. The terrain of the general service area of the Los Angeles basin falls between 100 and 1,000 feet above sea level. This situation gives the Mt. Wilson site an advantage of approximately 5,000 feet above the topography in about 65% of the general service area. Another interesting fact is that the mountain top is in a line of sight from about 75% of the general service area. Fig. 5 illustrates this favorable condition.

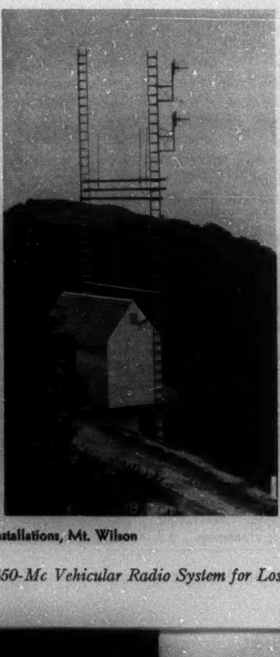

Fig. 3. Private mobile installations, Mt. Wilson

Our company maintained private mobile 460-mc base stations at the Mt. Wilson location for several years prior to the contemplated 450-mc common-carrier offering. From time to time interference problems plagued our private mobile units at this site. However, the nature of the operation permits them to be resolved quite reasonably by moving the carrier frequency a few kilocycles. In the case of the common-carrier offering, interference problems were not as easily resolved. We were necessarily restricted by the fixed assigned frequencies of these channels. Also, new stations at Mt. Wilson were going on the air at a rapid rate. The intermodulation products, direct interference, and off-channel discriminator pulling could not be accurately determined in advance of their contemplated operation. High-intensity r-f fields from high powered r-f transmitters gave many interference problems to the communication receivers when maximum sensitivity was expected. In view of these conditions, it was decided to place only the transmitters on Mt. Wilson and to locate the receivers in various areas throughout the Greater Los Angeles basin.

The topography of the Los Angeles basin created a problem in the determination of receiving sites which would permit a balance between talk-out and talkback. After considerable map study of the area, it was decided to establish four receiver sites to cover the proposed service area. Fig. 5 shows the four locations: 1. Verdugo

It was necessary to measure field intensity of the radiated r-f energy in order to determine the actual service area. A survey of the propagation from Mt. Wilson over the Los Angeles area was conducted on a frequency of 454.750 mc per second. Three phases of the complete survey are described here.

Survey Method

The following survey method was used to determine the field-strength contour of 37 db (decibels) above 1 μv (microvolt) per meter (37 dbu) which defines reliable service area as given in the FCC rule *21.504*.

An actual mobile-service condition was simulated. A General Electric Company mobile transmitter-receiver combination, type *WTE42*, option *0* for the 454.750-mc (QH channel) and 1/4-wave whip antenna was installed in a test vehicle. A Varian Associates graphic recorder model *G-10* was used to measure the grid current of first limiter–last i-f (intermediate-frequency) stages of the receiver. Fig. 7 shows the equipment arrangement. The Varian graphic tape recorder was calibrated to record 37 dbu at a center-scale point on the chart paper. To determine the 37-dbu field strength contour it is necessary first to change limiter-last i-f current recordings to μv input to the receiver, then μv input to μv per meter. The necessary conversion is shown in the Appendix where 37 dbu is approximately 3-μv input to the receiver.

The vehicle was driven over the required service area with concentrated attention given to the periphery and to the internal shadowed areas as determined from several years experience providing mobile service in the Los Angeles area. These data were accumulated by coding each field-strength observation on the Varian graphic tape recorder with a number. Simultaneously, a voice recording of this number and a street intersection, mileage marker, or prominent terrain feature was made which was to be associated later with this observation number. This was also tied to a time base so all recorded data could be synchronized in order to obtain an intelligent data analysis.

Control Measures

Because of different sources of variable performance, a method of control is required in order to minimize spurious

data. These variables are associated both with the mobile unit and with the base transmitter.

MOBILE-UNIT CONTROL MEASURES

The primary input power to the radio survey equipment was supplied by a Leece-Neville Company heavy-duty alternator. This arrangement provided a heavy-duty primary power source that would not vary when the automobile engine was up to speed required for traffic conditions.

The receiver-recorder was calibrated in the vehicle while the engine was operating at moving-traffic conditions. Before calibration, the equipment was operated for 30 minutes under this environment in order to stabilize circuit elements.

Calibration of the receiver-recorder was accomplished by using a Measurements Corporation standard signal generator, model 560 FM. The mobile equipment was calibrated at the beginning of each day's activities. It is recognized that exacting or laboratory measurements require a continuous check on test-equipment calibration. However, from past experience and in consideration of the

final results desired it was decided that the test would be conducted with a calibration of equipment at the beginning and at the end of each test run. The receiver-recorder held the required degree of calibration for the necessary data accumulation. After the initial calibration the vehicle engine and radio equipment were operated continuously until final calibration at the end of the day's survey. The calibration of the receiver-recorder at the end of a test run confirmed our past experiences. The slight differences noted in calibration between the beginning and end of each test run was easily adjusted in the data analysis. The signal generator was continuously operated until all further necessity for calibration of survey receivers had passed. This meant that the signal generator operated continuously for approximately 2 weeks.

A simultaneous correlation between the first limiter–last i-f stage current meter, a discriminator voltage meter, equipment supply voltage meter, and the stylus displacement was made during calibration. This correlation provided a service check on the recorder performance during field work with a signal input of 3 μv. Calibration readings were posted at the meters so that frequent checks of equipment performance could be made during data accumulation.

Data observations were made only while the engine rpm were such that the primary supply voltage from the vehicle's electrical system was constant. Recordings on the Varian graphic recorder made under primary low-input-voltage conditions were not summarized in the data analysis.

Base-Transmitter Control Measures

An installation similar to that in the mobile unit was made in a laboratory. The signal from the base station was continuously monitored at this fixed location during the time that field observations were made. This insured that variations of base-transmitter power would be recorded so that compensatory adjustments could be made in the data analysis. Because the radiated energy as measured in the laboratory did not change during the field work, adjustments were not required.

Data Analysis

The voice-recorded observation numbers, time, and location were correlated, and equivalent μv values were assigned to each graphic-recorder observation. This operation involved considerable latitude of judgment because the value assigned was a compromise based first, upon an average of the field-strength variations and second, upon the trend of the variation in that area. During this and previous propagation surveys the short-term variation was observed to exceed the full scale of the recorder. In this case the variations of field strength were in excess of 18 db.

An average was derived from the data and recorded on a suitable map which resulted in the 37-dbu contour. Establishment of the 37-dbu contour required 3,410 separate field observations. Fig. 8 shows a map plan of the 37-dbu contour of the coverage from Mt. Wilson. The coverage line does not surround Mt. Wilson because the survey was limited to the community of interest: Los Angeles and the neighboring cities for which Los Angeles may be regarded as the marketing center. North of Los Angeles the mountain terrain which with Mt. Wilson, is in a national forest, is not crossed by a public-road net. The intent of the service contour was to enclose the service area with a continuous line as far as possible. Therefore the contour line was drawn on the map where the averaged signal level first dropped below the standard 37 dbu on the test runs into the foothills. It was also recognized that further into the mountains there are many areas where the field strength is equal to or greater than the 37-dbu standard. This same procedure was used along the hills separating Santa Monica from Reseda and the hills between Whittier and Pomona. The line between El Toro and Corona Del Mar was placed there because it most suitably joined the limits of coverage on US Highway 101 and 101 Alternate. It is of interest to note that the 37-dbu contour circumscribes the area considered as the limit of reliable telephone service, and also provides protection to our urban MTS 450-mc system from cochannel interference according to part 21 of the FCC's rules.

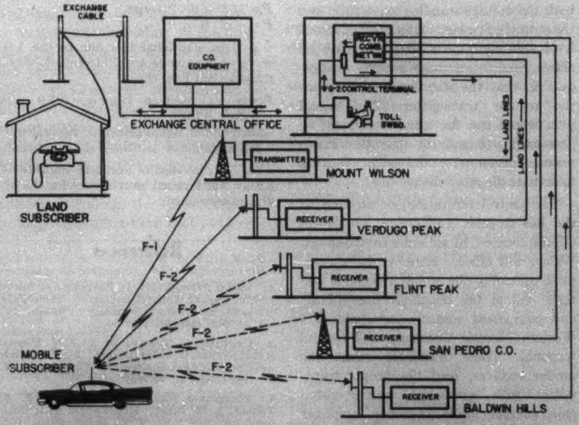

Fig. 9. Los Angeles urban 450-mc common-carrier MTS-equipment arrangement

General Information

Common carrier (MTS) is a semiduplex system employing two different frequencies per radio channel. One frequency is for the base-station transmitter and mobile receiver while the second frequency is for the mobile transmitter and base-station receiver operation. The base station is operated in a full duplex condition, i.e., during the service period the base transmitter comes on the air and remains on the air until the service period is terminated. The mobile transmitter is operated as a push-to-talk (transmitter on) type of operation. One requirement for the continuous operation of the base station and the 2-frequency assignment is a rebroadcast feature which allows a mobile-to-mobile telephone conversation. Another reason for a continuous operation of the base transmitter is to signal any mobile subscriber wishing to use the channel that the channel is busy and already in use. By monitoring the base-station frequency, the complete two-way conversation may be heard when a mobile-to-land telephone station or when a mobile-to-mobile conversation is held. However, when monitoring the mobile transmitting frequency only the mobile transmission is heard. Fig. 9 shows the 450-mc system in Los Angeles.

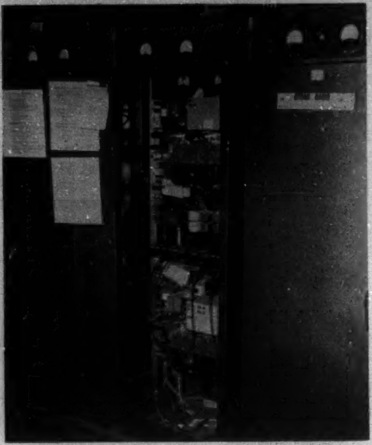

Fig. 10. Regular and standby transmitter with associated patch jack field

At present the 450-mc MTS channels in service are:

Channel	Base Transmitter, Mc	Mobile Transmitter, Mc
QA	454.45	459.45
QB	454.55	459.55
QH	454.75	459.75
QM	454.95	459.95

The base-station equipment is General Electric Company Progress Line model *4ET24A* with an output power of 15 watts or +12 dbw (decibels above one watt). After consideration of transmission-line loss and antenna power gain there is approximately +12 to +13 dbw of effective radiated power. This radiated energy results in a receiver power in the service area of −127 to −89 dbw to the General Electric Progress Line *4ER26B* mobile receiver.

Common-carrier MTS operating tolerances are outlined in part 21 of the FCC's rules as:

1. Frequency stability ±.0005% to the assigned frequency (approximately ±2.3 kc).
2. Measure the operating frequency with equipment capable of ±0.00025% tolerance (approximately ± 1.1 kc).
3. Frequency deviation of ±15 kc (frequency modulation).

For service protection we have installed standby transmitters. This protection is accomplished with the use of one 2-frequency standby transmitter per two regular transmitters. The transmitter change-over is semiautomatic and is, readily placed in service by putting one patch cord up in the 2-frequency transmitter, which connects the telephone line, connects the control function, and actuates the antenna change-over relay to the standby transmitter. To place a standby transmitter in service instead of a regular transmitter takes approximately 2 seconds. In order to replace the standby with regular transmitter the patch is pulled down. Approximate time is 1 second to accomplish this change. Fig. 10 shows the patch jack field.

We plan to make the regular to standby change-over automatic. Two plans are currently being studied. One plan is by the use of M.C. Jones Electronics Company Station Guardian which measures both the voltage standing wave ratio and the output r-f power. At a predetermined level this equipment would actuate an alarm circuit and cause a relay change-over so that the standby would replace the regular transmitter. The second plan would use the same equipment to give an alarm and the operating maintenance personnel would push a button to actuate the relay change-over.

Our control terminals are situated at the Los Angeles Toll Office, 434 South Grand, located 16 air miles from our Mt. Wilson toll office. Here we have complete control of the mobile telephone system. All of the telephone lines (audio and equipment control) terminate in a Western Electric Company *G-2* control terminal. These terminals select the proper receiver, feed the proper transmitter with automatic voice-operated gain control audio-frequency amplifier and afford the maintenance personnel test facilities to properly maintain the system.

Along with system control we maintain a frequency-measuring center where we can measure carrier frequency and frequency deviation to ±0.0001% or approximately ±450 cycles. In our special test center, we are employing unusual techniques which are discussed in a companion paper.[2]

We have all four of the "Q" 450-mc MTS channels loaded up to 60 subscribers per channel. We have applied for four additional 450-mc common-carrier channels which we hope to put into service sometime in 1960. These four additional channels will give some relief to the large demand for this type of telephone service in the Los Angeles metropolitan area.

Appendix

The equation used to determine μv input to the mobile receiver is:

$$P=\frac{\left(\frac{E\lambda}{\pi}\right)^2}{4R}$$

where

E = volts per meter (field strength)
λ = wavelength, meters
R = resistance of 1/2-wave antenna, ohms

If

$E=37$ dbu $=70.79\ \mu v$/meter: $\log E=\bar{5}.84997$
$\lambda=0.6597$ meters: $\log \lambda=\bar{1}.81935$
$R=72$ ohms: $\log 4R=2.45939$
$\pi=3.14$: $\log \pi=0.49715$

in logarithm form the equation becomes:

$$\log P=2\ (\bar{5}.84997+\bar{1}.81935-0.49715)-2.45939$$
$$\log P=\overline{13}.88495$$
$$P=7.673\times10^{-13}\text{ watts}$$
$$P=-121.9\text{ dbw}$$

Adding additional loss due to the 1/4-wave whip antenna and 10 feet of *RG-58/U* transmission line, then:

Power at receiver input = −121.9 dbw −6 db = −127.9 dbw
Closed-circuit signal-generator equivalent = 2.953 μv

Therefore, because of accuracy limitations, 3.0 μv will be used as reference for the 37-dbu measurement.

Use of Moon or Satellite Relays for Global Communications

LEANG P. YEH
NONMEMBER AIEE

THE RANGE of global communications has been limited, in the past, by the ionospheric mode of propagation for the very high frequencies, and by the ground-wave mode of propagation for the very low frequencies.

There is a possibility, however, of extending the range by means of moon or satellite relays. This paper investigates this possibility from the practical system performance point of view.

Moon Relay

Range Versus Usable Time

As shown in Fig. 1, the plane of the moon's orbit around the earth is inclined to the plane of the ecliptic (the earth's orbit around the sun) at an angle of about 5.1 degrees, the earth's axis is tipped about 23.5 degrees from the perpendicular to the ecliptic, and the moon's axis is inclined about 6.5 degrees from the perpendicular to the plane of its orbit. In addition, the period of the earth's revolution around the sun is about 365 days, while that of the moon's revolution around the earth is only about 27 days.

Because of these astronomical complexities, the usable time of moon relay, the total time per day during which two stations on the earth's surface can see the moon simultaneously, varies from day to day by amounts depending on the longitudes and latitudes of the two stations. Daily periods during which moon relay is possible at Greenwich meridian can be derived from the times of moonrise and moonset obtained from the "American Ephemeris and Nautical Almanac"[1] for latitudes from +60 degrees to −60 degrees, or from "The Air Almanac"[2] for latitudes including the polar regions. For longitudes other than that of Greenwich, a method of obtaining the local time of moonrise and moonset is given in "Navigation and Nautical Astronomy."[3]

The range of moon relay (great-circle distance) may be computed from the known longitudes and latitudes of the two stations.[4]

A definite relation exists between the range and usable time of moon relay between two earth stations. Simple cases when both stations are located at the equator or at the same longitude will serve as good examples.

The moon-relay geometry at the equator, considering the earth as an idealized sphere, is shown in Fig. 2. If the mean distance between the earth and the moon is taken as 240,000 miles and the earth's radius as 4,000 miles, the angle θ is approximately equal to 89 degrees. Relay between stations A and B has a range of approximately 6,000 miles and a usable time of about 6 hours per day, assuming that both transmitting and receiving antennas are steerable to follow the moon. However, one can trade range for usable time.

The relation between range and usable time is illustrated in Fig. 3. If the two stations (A and C in Fig. 2) are 12,000 miles apart, or approximately half the circumference of the earth, relay is impossible because the two stations can see the moon simultaneously at only one instant. If usable time of, say, 10 hours per day is required, the range is only 2,000 miles.

When the two stations are located at the same longitude, range and usable time are independent. The usable time is about 12 hours for all ranges up to about 12,000 miles, half the circumference of the earth.

In general, therefore, the usable time of moon relay between two earth stations varies from zero to 12 hours per day, and the range varies from zero to 12,000 miles.

Moon Echoes

The first use of radar equipment to obtain echoes from the moon was reported independently by the U.S. Army[5] and Bay[6] of Hungary. Subsequently, experimental work has been carried on in Australia,[7,8] England,[9] and the United States.[11–12] The possibility of obtaining moon echoes is well confirmed today.

The basic radar equation for the median received power for a target subtending an angle greater than the antenna beam width may be expressed as:

$$P_r=\left(\frac{P_t g_t}{4\pi d^2}\right)A_b\left(\frac{A_r}{4\pi d^2}\right) \tag{1}$$

where

P_r = median received power
P_t = transmitted power
d = transmission path length = 240,000 statute miles for moon echo
A_b = effective echo area of the target
A_r = effective area of receiver antenna
g_t = transmitter antenna power gain = $4\pi A_t/\lambda^2$
A_t = effective area of transmitter antenna
λ = wavelength = c/f
c = velocity of light = 3×10^{10} cm (centimeters)/second = 3×10^{8} miles/second
= 186,000 miles/second $\approx 10^9$ feet/second
f = frequency

Expressing both A_r and A_b as power gains,

$$g_r=\text{receiving antenna power gain}=\frac{4\pi A_r}{\lambda^2} \tag{2}$$

and

$$g_b=\text{echo area power gain}=\frac{4\pi A_b}{\lambda^2} \tag{3}$$

Substituting equations 2 and 3 into 1:

$$P_r=P_t g_t g_r g_b\left\{\left(\frac{\lambda}{4\pi d}\right)^2\right\}^2 \tag{4}$$

The factor $(\lambda/4\pi d)^2$, sometimes called the free-space attenuation or loss, is the ratio of received to transmitted power for line-of-sight transmission in free space (a region free of all objects that might absorb or reflect energy) between isotropic antennas (antennas with a power-gain ratio of unity).

For system design, it is more convenient to use decibels (db) instead of power ratios. Expressed in db, equation 4 becomes:

$$10\log_{10}P_r=10\log_{10}P_t+G_t+G_r+G_b-2L_{FS} \tag{5}$$

where

The work covered by this paper was initiated while the author was with Electronics Division, Westinghouse Electric Corporation, Baltimore, Md., and completed at Aerosciences Laboratory, General Electric Company, Philadelphia, Pa.

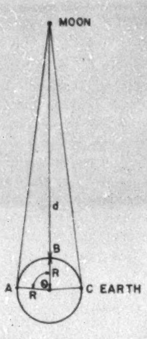

Fig. 2. Moon-relay geometry at equator

$$\cos\theta = \frac{R}{Rd}$$

$R \approx 4{,}000$ miles

$=$ true earth radius

Mean $d \approx 240{,}000$ miles

$\theta \approx 89$ degrees

Relay between A and B:

$$AB = \text{range} \approx \frac{2\pi R}{4}\ 6{,}000 \text{ miles}$$

Time ≈ 6 hours

$10 \log_{10} P_r =$ received power in dbw (db relative to 1 watt)

$10 \log_{10} P_r =$ transmitted power in dbw

$G_t =$ transmitted antenna power gain in db

$G_t =$ transmitted antenna power gain in db

$$= 10 \log_{10} g_t = 10 \log_{10} \frac{4\pi A_t}{\lambda^2} \qquad (6)$$

$G_r =$ received antenna power gain, db

$$= 10 \log_{10} g_r = 10 \log_{10} \frac{4\pi A_r}{\lambda^2} \qquad (7)$$

$G_b =$ echo area power gain in db

$$= 10 \log_{10} g_b = 10 \log_{10} \frac{4\pi A_b}{\lambda^2} \qquad (8)$$

$$L_{FS} = \text{free space loss in db} = 20 \log_{10} \left(\frac{\lambda}{4\pi d}\right)$$

$$= 20 \log_{10} \left(\frac{c}{4\pi d f}\right)$$

$$= -[36.6 + 20 \log_{10} d_{mt} + 20 \log_{10} f_{mc}] \qquad (9)$$

where

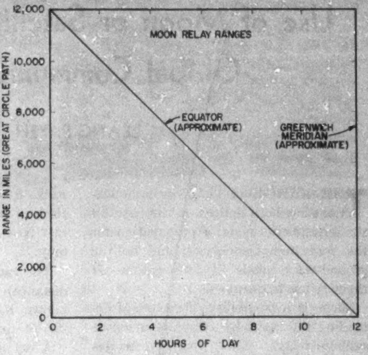
$d_{mt} =$ transmission path length, statute miles

$f_{mc} =$ frequency, megacycles (mc) per second

It should be noted that free space loss bears a negative sign as shown in equation 9. This negative sign has been taken into account in equation 5.

In equation 5, the power gains G_t, G_r, and G_b are calculated from the effective areas A_t, A_r, and A_b, which are sometimes quite different from the physical areas. For parabolic antennas with circular cross section and taper illumination (intensity at edge 10 db down from that at center), the effective area is approximately 0.64 of the actual area, and the gain becomes:

Fig. 3. Range versus usable time



$$G = 10 \log_{10} \frac{4\pi}{\lambda^2} \left(\frac{0.64\pi D^2}{4}\right)$$

$$\approx 10 \log_{10} 2\pi \left(\frac{D}{\lambda}\right)^2 \qquad (10)$$

where $D =$ diameter of antenna aperture. The half-power (3-db) beam width or beam angle of a parabolic antenna with taper illumination is given by:

$$\alpha = \text{beam width} \approx 70 \frac{\lambda}{D} \text{ degrees} = 1.22 \frac{\lambda}{D} \text{ radians} \qquad (11)$$

For the target, the moon in this instance, it has been shown by Norton et al[13] that the effective echo area would be equal to the projected area if the moon were an idealized body whose surface were smooth, perfectly reflecting, and spherical.

Effective echo area of ideal moon

$$= \pi\left(\frac{\text{Moon's diameter}}{2}\right)^2 = \pi(1080)^2$$

$$= 3.66 \times 10^6 \text{ square miles} \qquad (12)$$

Since the moon is far from an idealized body, the effective echo area must be modified accordingly.

First, the moon's surface is not perfectly reflecting. The power-reflection coefficient, p, of any surface is a function of its dielectric constant and may be expressed as:

$$p = \left(\frac{1-\sqrt{E}}{1+\sqrt{E}}\right)^2,\ p \leqq 1 \qquad (13)$$

where $E =$ dielectric constant of moon's surface. Several values of power reflection coefficient have been postulated a shown in Table I.

Second, the moon's surface is not perfectly smooth. The roughness of the surface scatters radiation in all directions, tending to increase the echo cross section by a so-called directivity factor, q. Again different values have been postulated for this factor. Grieg[14] gives a q value of 8/3. Here the assumption is made that Lambert's cosine law of reflection may be applied to a rough or diffuse moon. Kerr's[7,8] value is 5 for 20 mc. His reasoning is that, since optical directivity of the moon's surface to sunlight is 5.7, it should be smaller for radio wavelengths. A value of 5 is therefore suggested.

Because the energy is returned from the whole of the visible hemisphere of the rough moon and not only from the first Fresnel Zone[5] as in the case of a smooth surface, the improvement in directivity is complicated or counteracted by two other effects:

1. Pulse elongation effect. The duration of the returned pulse is increased by the time T, required to travel forward and back along the radius of the body. In the case of the moon,

$$T = \frac{2 \times \text{moon's radius}}{\text{velocity of light}} = \frac{2 \times 1{,}080}{186{,}000} = 0.0116 \text{ second}$$

Table I. Moon's Power-Reflection Coefficient, p

	Mofenson,[5] Dewitt[10]	Kerr[7,8]	Grieg[14]
Type of surface		dry rock	rock
Dielectric constant	6	5	5
Reflection coefficient	0.18	0.15	0.15 (0.10*)

* A value of 0.10 is recommended by Grieg.

Table II. Frequency Spread, f_p, Maximum

Wavelength, Meters	Frequency, Mc	Frequency Spread, Cps
10	30	2
1	300	20
0.1	3,000	200

Grieg[14] has found that power reduction factor, m, due to pulse elongation effect may be expressed as:

$$m \approx \frac{t}{T} \text{ for } t<T \text{ only; } m<1 \tag{14}$$

where t=pulse length. If $t \geqq T$, there is no power reduction.

The pulse elongation time, T, of 0.0116 second has been challenged recently by Senior et al,[15] who used a "quasi-smooth" moon theory. On the basis of experimental results, they estimated that the active echo area is within a region less than one third of the moon's radius in extent, and that the maximum pulse elongation is thereby reduced from 11.6 ms (milliseconds), corresponding to the full depth of the moon, to no more then 600 μsec (microseconds). As will be seen later, this concept seems to agree with some of the moon-echo experiments[16,17] using short pulses in the United States.

2. Frequency spread effect. If the body is rotating, there is a frequency spread, f_p, in the spectrum of the echo proportional to the velocity, v_s, of the moon. According to Pawsy et al,[18] this maximum frequency spread, f_p, is equal to:

$$f_p = \frac{4v_s}{\lambda} \tag{15}$$

where

$$v_s = \frac{\text{circumference of moon's body}}{\text{rotation period}}$$

$$= \frac{\pi(2\times 1{,}080)\text{miles}}{27^1/_3 \text{ days}}$$

$=2.8\times 10^{-3}$ miles per second $=4.8$ meters per second

λ = wavelength

Table II shows the magnitudes of f_p at various wavelengths.

If the bandwidth, B, of the receiver is less than this frequency spread, only a part of the energy is received. The power reduction factor, s, due to frequency spread effect may be expressed as[18]

$$s = \frac{4B}{\pi f_p} \text{ for } B<f_p \text{ only; } s<1 \tag{16}$$

If $B \geqq f_p$, there is no power reduction.

In most experimental setups, the receiver bandwidth, B, would be larger than the frequency spread, f_p, as indicated in Table II. The frequency spread effect will therefore be neglected.

Summing up, the effective echo area, A_e, becomes:

$$A_e = \pi\left(\frac{\text{Moon's diameter}}{2}\right)^2 pqm \tag{17}$$

where

$$p = \text{power reflection factor} = \left(\frac{1-\sqrt{E}}{1+\sqrt{E}}\right)^2 \qquad p \leqq 1$$

q = directivity factor $\qquad q \leqq 1$

m = pulse elongation factor $= t/T \qquad m \leqq 1$

A summary of the system parameters and measured and predicted received signal powers of the major moon-echo experiments are shown in Table III. In this table, the general parameters and measured received signals are taken from the original papers; the effective echo area of the moon is calculated from equation 17, using $p\times q=0.1$ and $T=10^3$ μsec; the predicted received signal is calculated from equation 5; the receiver sensitivity or the receiver thermal noise level, N, is calculated from the following:

$$N = \text{receiver sensitivity} = FKTB \text{ watts} \tag{18}$$

where

F = effective receiver noise figure

K = Boltzmann's constant $=1.38\times 10^{-23}$ joules/K (degrees Kelvin)

T = 290 K, ambient temperature at the earth's surface

B = receiver bandwidth

$KT = 1.38\times 10^{-23}\times 290$
$= 4\times 10^{-21}$ watts $= -204$ dbw

The measured circuit loss, L_c, is the total transmission loss of the two-way radar or passive-relay system between isotropic transmitter and receiver antennas:

$$L_c = 10\log_{10} P_r - 10\log_{10} P_t - G_t - G_r \tag{19}$$

where P_r = measured received signal power.

E. Measured Received Signal:								
Maximum received signal, dbw	−159	−140	−160					
Average received signal, dbw	−168	−150	−165	−157	−130	−152	−138	−155
Minimum received signal, dbw	−177	−160	−170					
F. Measured Average Circuit Loss:								
Circuit loss, db	−251	−235	−259	−247	−271	−252	−304	−258

It can be seen that the predicted median received signal levels agree surprisingly well (within ±2 db) with measured values in all cases. The only losses not taken into account in the predicted calculations are those due to the feed and coupling in the antenna circuits. However some of these losses may have already been included in the consideration of the antenna gains. In any event, such losses probably do not exceed 2 to 3 db.

Some conclusions may be drawn from Table III:

1. For continuous wave (cw) and long pulse signals (1,000 μsec or longer), the effective echo area of the moon may be considered as 0.1 of the projected area. For shorter pulses, the pulse elongation effect should also be considered.
2. A circuit loss of 250 db between isotropic antennas for 100 mc, and a 6-db increase of loss per octave increase of frequency may be used for future moon-echo system design using long pulses or cw. For pulse lengths shorter than 1,000 microseconds, an additional power reduction factor, t/T, should be used; t=pulse length in μsec and T=1,000 μsec. Fig. 4 shows the moon-circuit loss for various frequencies, and Fig. 5 the power-reduction factor in db for various short-pulse lengths.

SYSTEM CONSIDERATIONS

Two types of moon relay are possible: using the moon as a passive reflector, and using the moon as an active repeater station. At present, only passive relay is feasible; active relay must wait until equipment can be set up on the moon.

The use of the moon as a passive reflector for earth-to-earth relay has been thoroughly analyzed theoretically by Grieg et al.[14] It was concluded that the most important consideration for such a system is the moon's surface. If the moon is smooth, there is no limitation to the type of transmission possible, telegraphy, voice, or wideband. On the other hand, if the moon is rough, essentially only narrow-band telephony and telegraphy can be accommodated.

Experiments over many decades have concluded that the moon's surface is rough for optical frequencies. Whether this is also true for radio frequencies is highly debatable and cannot be settled until more extensive experimental data are available. It is most probable that the moon's surface is neither smooth nor rough, but a mixture of both.

In any communication system the minimum usable carrier-to-total noise-power ratio (the threshold), is of utmost importance. This ratio determines whether the input signal can be detected in the presence of noise associated with the receiver input, including the antenna system. This is the first limitation on the system performance.

In the region of 100 to 10,000 mc, considered feasible for moon relays, the thermal noise inherent in the receiver predominates at isolated locations where the receiver terminals are likely to be located. The following discussion is limited to thermal noise only.

The minimum usable carrier-to-noise power ratio depends on the modulation techniques used. For practical system design, a value of 15 db seems to be an average acceptable figure.

The received carrier power, C, in dbw may be expressed as:

$$C=10\log_{10}P_t+G_t+G_r-L_c-L_F-L_L \qquad (20)$$

where

C=received carrier power, dbw
$10\log_{10}P_t$=transmitter power, dbw
G_t=transmitter antenna power gain, db
G_r=receiver antenna power gain, db
L_c=moon-circuit loss, db, from Figs. 4 and 5
L_F=fading allowance, db
L_L=other losses in db such as feed and coupling losses in antenna systems, etc.

The thermal noise power, N, in dbw may be obtained from equation 18:

$$N=10\log_{10}(FKTB) \qquad (21)$$

The carrier-to-thermal-power ratio in db then becomes:

$$\frac{C}{N}=10\log_{10}P_t+G_t+G_r-L_c-L_F-L_L-10\log_{10}(FKTB) \qquad (22)$$

From equation 22, system parameters could be determined.

FADING AND SYSTEM RELIABILITY

Of the parameters in equation 22, only the fading allowance, L_F, is yet to be established. The moon-echo experiments indicate that the received signals are subject to continuous fading of 20 db or more at both slow and fast rates. The slow fading, with a period of an hour or less, is believed due to the Faraday effect (the plane of polarization of the radio waves is rotated as they traverse the ionsphere in the presence of the earth's magnetic field). This effect has been reported to vary inversely between the first and second power of frequency. Above 400 mc the effect seems negligible.

The fast fading, with a period of seconds or longer, is believed due to the moon's libration (an apparent oscillation of the moon's face, as seen from a point of the earth, arising from the diurnal rotation of the observer on the earth and from variations in the moon's orbit). Browne et al[9] have analyzed 2-minute sample recordings and found the fading distribution to be very close to Rayleigh's equation. Moreover, atmospheric refraction in the troposphere and multipath effects may also have some bearing on the fading of the received signal. Therefore the fading characteristic is a combination of many effects.

In general, a fading margin of 10 to 20

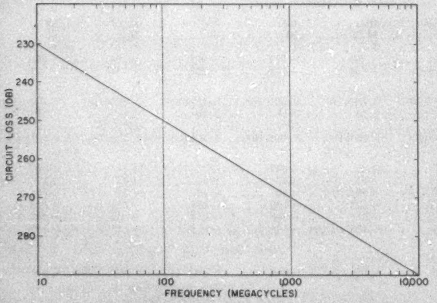

Fig. 4. Moon circuit loss

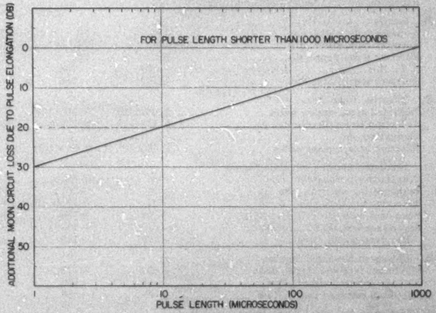

Fig. 5. Pulse elongation effect

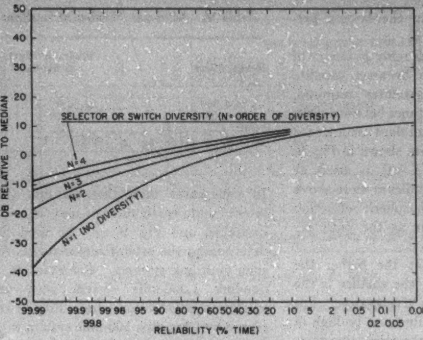

Fig. 6. Fading allowance and reliability

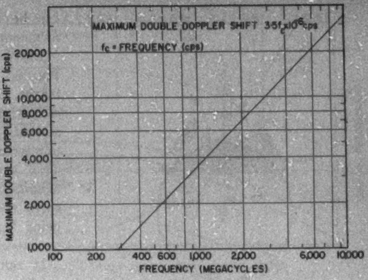

Fig. 7. Maximum moon-relay Doppler shift

db or even more should be allowed for a workable system. Extensive signal-level measurements on a long-term basis are required to determine the more reliable statistical fading characteristics. In the present study, a Rayleigh fading distribution as shown in Fig. 6 is assumed. From this distribution curve, the reliability of the system can be determined if the fading allowance is known. At the present state of the art it is not expected that a moon-relay system would be able to have a reliability of more than 99%. A fading allowance of 20 db, therefore, is recommended; see the Rayleigh curve in Fig. 6. At 99% reliability, the fading is approximately 20 db.

Fading may be reduced by diversity techniques as indicated in Fig. 6, where fading distributions for several orders of diversity are also plotted. Fig. 6 is reproduced from another paper by the author.[19]

DOPPLER SHIFT

Another factor worth considering is the Doppler shift of the carrier frequency resulting from the relative motion between the moon and the earth. For a round trip betwen earth and moon there is a double Doppler shift. The magnitude of the Doppler shift depends on the location of transmitting and receiving terminals, the frequency of operation, and the month and hourly period. A method of calculating this double Doppler shift is given by Grieg et al.[14] The maximum that can be expected at various frequencies is given by the following:

d_s = maximum double Doppler shift, cps (cycles per second)

$$\approx 3.5f \times 10^{-6} \text{ cps} \qquad (23)$$

where f = carrier frequency, cps.

Equation 23 is plotted in Fig. 7. It can be seen that for an upper uhf (ultrahigh-frequency) system, say 10,000 mc, the double Doppler shift may be as high as 35 kc. Although smaller Doppler shifts have been successfully compensated by several practical schemes, such large shifts may be a serious problem.

SAMPLE CALCULATIONS

The choice of frequency to be used for space communications has been discussed in another paper.[20] It was found that the frequency ranges are as shown in Table IV.

A sample calculation for a typical 2,000-mc system is shown in Appendix I. The system will, therefore, work 80% of the time (see Fig. 6). For a reliability of 99% some means, such as using a diversity system or increasing the power and antenna size, must be used.

Satellite Relays

ORBITAL REQUIREMEMTS[21–24]

Since the satellite must travel in the centrally directed force field of the earth, its orbit lies in a plane passing through the center of the earth. There are three possible types of orbital planes:

1. Circumpolar, passsing through the two poles of the earth.
2. Equatorial, passing through the earth's equator.
3. Inclined, at an angle to the earth's equator. If the angle of inclination is equal to the ecliptic angle, it is sometimes called the ecliptic plane.

Inasmuch as the orbital period is much shorter than that of the earth's rotation, the orbital path described on the earth will not retrace itself in successive revolutions, but will look like a spiral inscribed on a sphere, so that even a circumpolar path will not lie exactly on a meridian. However, there is one exception, the case of equatorial orbit. When a satellite is in an equatorial orbit, it will remain at all times above the equator. This is the most ideal condition for satellite relays.

The shape of the orbital path is also very important. The path may be a "great circle," with the center of the earth as its center; or, more generally, a "great ellipse" with the earth's center as one of its focuses. Whether the path is circular or elliptical depends on the injection conditions, primarily the injection velocity and angle. There is only one combination of injection velocity and angle that will cause the satellite to orbit in a circular path. Any slight errors will put the satellite in an elliptical orbit.

Another interesting aspect is the lifetime of the satellite. The most significant parameters that affect the lifetime are the frontal area density of the satellite, expressed as mass (in pounds) per-unit frontal area (in square feet); and the atmospheric density, expressed as slugs per cubic feet (slug = pound/32.2). It is obvious that a large satellite at too low an altitude will not stay up long. Methods[24] have been proposed to calculate the lifetime of satellites in circular or elliptical orbits. Due to the difficulty in estimating accurately the atmospheric densities at altitudes of hundreds or thousands of miles, the calculated life is bound to differ from practical results.

Table IV. Optimum Frequency

Antenna System	Frequency Range, Mc
Isotropic–Isotropic	40– 100
Isotropic–Directive	100– 300
Directive–Directive	2,000–4,000

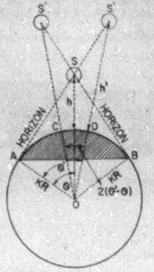

Fig. 8. Satellite-relay geometry, circular equatorial orbit. Shaded area is spherical cap on earth's surface within which line-of-sight communication from satellite will be received

h = height when horizon at A and B meet

$$= \frac{KR}{\cos\theta} - KR$$

R = true earth radius = 4,000 miles

K = effective earth radius factor

$$\theta = \cos^{-1}\frac{KR}{KR+h} \text{ radian}$$

$$h' = \text{satellite height} = \frac{KR}{\cos\theta'} - KR$$

$$\theta = \cos^{-1}\frac{KR}{KR+h'} \text{ radian}$$

$$n = \frac{2\pi}{2(\theta'-\theta)} = \frac{\pi}{\theta'-\theta}$$

n = number of satellites required

$AB = 2KR \times \theta$ = range

$S'A = (KR+h')\sin\theta'$

= maximum slant distances

RELAY GEOMETRY

As discussed in the previous section, the most ideal conditions for relay occur when the satellite is in a circular equatorial orbit. Practically, it may be difficult to fulfill this condition, but the closer this ideal is approached, the better is the performance of the system predicted.

Fig. 8 shows the ideal relay geometry. When the satellite is at a height, h, where the horizons at earth stations A and B meet, relay is impossible because the two stations can see the satellite simultaneously at one instant only. If the satellite is in orbit at a height, h', instead of h, it is seen simultaneously by the two stations through an angle $2(\theta'-\theta)$. Therefore, if there are $n=(2\pi)/(2(\theta'-\theta))=(\pi)/(\theta'-\theta)$ satellites, each at an angular distance of $\theta'-\theta$ from the other, an uninterrupted relay is possible provided that the satellites are equidistant from each other in the same circular equatorial orbit. Such conditions cannot be met in practice, but slight orbital deviations can be tolerated from the system performance point of view.

Based on the satellite relay geometry of Fig. 8, the relations between satellite height, number of satellites required, ranges (great-circle distance between earth stations), and maximum slant distance for uninterrupted relays are shown in Fig. 9. True earth radius ($K=1$) is used at heights of hundreds of miles or more above earth, the effect of atmospheric refraction being negligible as far as the path geometry is concerned.

It can be seen that the higher the satellites are in orbit, the smaller is the number required for a given range. For long ranges, the satellite must be high in orbit. Furthermore, the minimum number of satellites required depends on the range. Table V gives the numbers required for various ranges.

As discussed before, the minimum satellite height for a given lifetime depends on the atmospheric density and satellite size and mass. A height of 300 miles is considered sufficient to maintain a fair sized satellite in orbit for quite some time.

One interesting parameter is the maximum slant distance, the distance which the relay system is expected to cover. It may be several times larger or smaller than the range (the great-circle distance between the two earth stations), depending on the number of satellites used. For instance, as shown in Fig. 9, a 1,000-mile range requires a maximum slant distance of 2,000 miles with ten satellites and 5,000 miles with four satellites, but only about 500 miles with 300 satellites. The smaller the number of satellites, the longer is the maximum slant distance compared with range. This puts rather stringent requirements on some of the vital parameters of the relay system, such as transmitted power and antenna sizes or gain, because of the longer distances to be covered.

A satellite-relay system between two earth stations (earth-satellite-earth) is a simple two-hop link in radio terminology.

Table V. Minimum Number of Satellites

Range, Miles	Minimum Number of Satellites
Up to 4,000	3
5,000–6,000	4
8,000	6
10,000	11

In some cases, more than one link with intermediate earth stations may be more desirable, and Fig. 9 may be used for determining the orbital requirements for such multilink systems. For example, a one-link 1,000-mile system with ten satellites, each 430 miles high, may be replaced by a two-link 500-mile system with an intermediate earth station, with either ten satellites 300 miles high or eight satellites 430 miles high.

For uninterrupted relay, the satellite must be tracked continuously by the two earth stations. In practice, the relay is intermittently interrupted because of the time required to return the antenna to its initial position for tracking the next succeeding satellite, after the first has been tracked to its disappearance below horizon. For a large antenna, the interruption may be quite long because of the large mass involved.

Although an uninterrupted satellite relay system generally requires a large number of satellites, a few schemes may be used to improve the situation:

1. Four equidistant satellites may be placed in a circular equatorial orbit at a height of 22,500 miles (approximately 26,500 miles from the center of the earth). At this height, the satellites appear to be stationary relative to the earth and can serve as relay stations between any two locations on earth, using one-link or multilink arrangements, depending on the range. As discussed previously however, use of a small number of satellites considerably extends the slant distance to be covered, increasing the requirements of some of the vital system parameters.

2. The number of satellites might be reduced without changing the spacing between them, reducing the usable time accordingly. Consider the 1,000-mile-range

Table VI. Satellite Velocity, Orbital Period, and Doppler Shift

Satellite Height, h', Miles	Satellite Velocity, V: Miles/Hour	Satellite Velocity, V: Feet/Second*	Orbital Period, T, Hours	Single Doppler Shift, f_m, Cps: f = 100 Mc	Single Doppler Shift, f_m, Cps: f = 1,000 Mc	Single Doppler Shift, f_m, Cps: f = 10,000 Mc

1,000,000	1,130	1,660	5,500.0	170	1,700	17,000

* 1 mile/hour = 1.47 feet/second.

† At this height, the orbital period is 24 hours. The satellite appears stationary relative to earth.

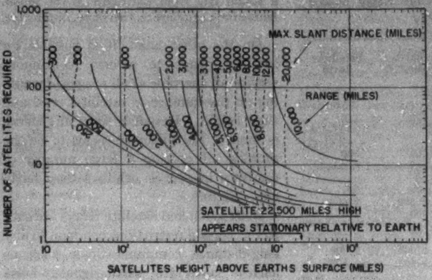

Fig. 9. Number, height, range, and slant distance of satellite

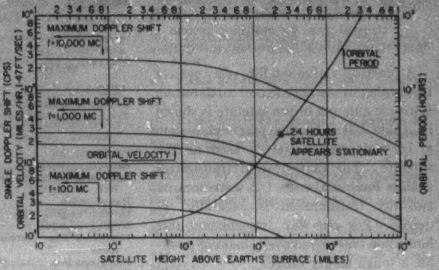

Fig. 10. Doppler effect, orbital velocity, and period

10-satellite system as an example. If five satellites were used instead of ten and the same spacing maintained between satellites (36 degrees of arc in this case), the relay would work half of the time.

3. Fixed (nontracking) antennas might be used. As the satellite passes over the first earth station, it receives and stores the message. As it passes over the next earth station, a common or trigger signal causes the satellite to transmit the stored message. The usable time depends on the antenna beam width of the earth station and is, in general, quite limited since widening the beam for more usable time decreases the gain of the antenna. In order to relay a large amount of information, therefore, a fast rate of transmission must be used. This scheme has been demonstrated recently by the United States "score satellite," a 8,750-pound intercontinental ballistic missile (Atlas) with a 4-minute message-storage time.

SYSTEM DESIGN

Although available data are still sketchy, the radio observations of satellites indicate that the satellite signals like moon echoes, are subject to continuous fading at both slow and fast rates. As indicated earlier, the slow fading is due to the Faraday effect. The fast fading probably results from the spinning of the satellite. Through use of higher uhf and the recently advocated satellite stabilization technique, the fading may be reduced considerably. This, however, must be confirmed by extensive experiments. In the present study, the same magnitude of moon relay fading allowance is recommended for satellite relay.

Since the satellite is a moving object, the carrier frequency is subject to a double Doppler shift for a two-hop link. The maximum single Doppler shift in cps, f_{ss}, may be calculated by:

$$f_{ss}=\frac{fV}{c} \tag{24}$$

where

f = carrier frequency, cps

V = velocity of satellite relative to earth, miles per hour

c = velocity of light, miles per hour = 186,000 ×3,600 miles per hour

The velocity of the satellite is proportional to its height above earth's surface. For a circular path, the velocity may be expressed[21] as:

$$V=R\sqrt{\frac{g}{R+h'}} \text{ miles per hour}$$
$$=\frac{1.13\times10^{6}}{\sqrt{(4000+h')^{1/2}}} \text{ miles per hour} \tag{25}$$

where

R = earth's true radius, miles = 4,000 miles

h' = satellite height above earth's surface, miles

g = 32.3 feet/second^2 = 79,000 miles/hour^2

The orbital period, T, the time required for the satellite to complete one orbit of the earth, may be expressed as:

$$T=\frac{2\pi(R+h')}{V} \text{ hours} \tag{26}$$

Combining equations 24 and 25:

$$f_{ss}=\frac{f}{600(4{,}000+h')^{1/2}} \text{ cps} \tag{27}$$

Combining equations 25 and 26:

T = orbital period, hours

$$=5.5\times10^{-6}(4{,}000+h')^{3/2} \tag{28}$$

Satellite velocities, V, single Doppler shifts, f_{ss}, and orbital period, T, for various satellite heights are tabulated in Table VI and plotted in Fig. 10. Both passive and active relays are feasible. For an active relay, the carrier-to-thermal-power ratio may be expressed as:

1. Earth-to-satellite:

$$\frac{C_s}{N_s}=10\log_{10}P_t+G_t+G_r-L_{FS}-L_F-L_L-10\log_{10}(FKT_sB) \tag{29}$$

where

C_s = received carrier power, dbw, at the satellite

N_s = thermal noise power, dbw, at the satellite = 10 $\log_{10}$ $(FKTB)$

P_t = transmitted power, dbw, at the earth station

G_t = transmitted antenna power gain, db earth station

G_r = received antenna power gain, db satellite

L_{FS} = free-space loss, db (calculated on the basis of maximum slant distance rather than the range)

L_F = fading allowance, db

L_L = other losses in db such as feeder and coupling losses in antenna systems, etc.

F = effective receiver noise figure

k = Boltzmann's constant = 1.38×10^{-23} joules/K

T_s* = ambient temperature of the satellite (assumed the same as the earth station) ≈ 290 K

B = receiver bandwidth

$KT_s=1.38\times10^{-23}\times290—4\times10^{-21}$ watts = −204 dbw

2. Satellite-to-earth:

$$\frac{C_E}{N_E}=C_s+G_s+G_t'+G_r'-L_{FS}-L_F-L_L-10\log_{10}(FKT_EB) \tag{30}$$

where

C_E = received carrier power, dbw, at earth station

N_E = thermal noise power, dbw, at the earth station = 10 $\log_{10}$ FKT_EB

G_s = gain at the satellite repeater

G_t' = transmitted antenna power gain, db (satellite)

G_r' = received antenna power gain, db (earth station)

T_E = ambient temperature at earth station = 290 K

L_F = fading allowance, db

---

* The ambient temperature of the satellite is a rather controversial issue. Methods[35, 36] have been proposed to calculate the skin temperature under various assumptions, but they lead to widely different conclusions concerning the mean temperature. However, it has been reported[37] that the skin temperature of the American satellite Explorer I was found to vary from 270 K to 340 K, and the inside temperature from 100 F (degrees Fahrenheit) to 120 F [40 C (degrees centigrade) to 50 C, 313 K to 323 K]. In the present case, 290 degrees is assumed.

$10\log_{10} M$ = degradation in performance in db due to power summation of thermal noise for multihop system

M = number of hops = 2 (in this instance)

A practical active satellite relay system using a high-gain antenna on earth but an isotropic antenna in the satellite is shown in Table VII. In this practical system a 1/2-watt transmitter is used in the satellite. The earth-station transmitter is thus limited also to 1/2 watt because two-way transmission is generally required. For one-way transmission this limitation will be removed, making possible a much longer range.

It is interesting to note that four times (+6 db) more transmitter power and four times (+6 db) satellite-repeater power gain is required if the antenna size is reduced to one half. Conversely, if the antenna size is doubled, both transmitter power and satellite-repeater power gain can be reduced to one quarter (−6 db).

A typical passive system with 15 satellites 460 miles high and using the same frequency, transmitter power, and antenna size as the typical moon system discussed earlier (see Table IV), is shown in Appendix II.

Assuming that the satellite is a sphere with an effective echo area equal to 0.5 of the projected area, then:

$$10\log_{10}\frac{4\pi A_b\times 0.5}{\lambda^2}=62=\text{echo-area gain of satellite}\qquad(31)$$

where

A_b = projected area of satellite $=\pi r^2$

r = satellite radius

λ = wavelength = 0.5 foot (at 2,000 mc)

From equation 31:

$$\frac{4\pi A_b\times 0.5}{(0.5)^2}=1.58\times10^6$$

$$\frac{4\pi(\pi r^2)\times 0.5}{(0.5)^2}=1.58\times10^6$$

$$r\approx 140\text{ feet}$$

A sphere 280 feet in diameter is required to give the same performance as the moon relay for a relay range of 2,000 miles. Unless inflated devices are used, it is doubtful whether it is possible to put a sphere 280 feet in diameter in orbit at this time.

Moreover, the angles subtended by a 280-foot satellite at a distance of 2,000 miles is very small, on the order of 10^{-3} degrees, and unless its orbit can be predicted with fair accuracy, radio tracking will not be easy. Fortunately, from the experience gained in the observation of the Russian and United States satellites, determination of satellites' orbits is no longer considered a serious problem.

Table VII. Active Satellite Relay System, Two-Way

System	Earth–Satellite	Satellite–Earth
Satellite repeater gain, db		+121
Transmitter power, watts	1/2	1/2 (+121−124 = −3 dbw)
Frequency, mc	300	300
Satellite antenna	isotropic	isotropic
Earth antenna (parabolic), feet	60	60
Range, miles	2,000	2,000
Satellite height, miles	460	460
Number of satellites	15	15
Maximum slant distance, miles	2,000	2,000
Free space loss (L_{FS}), db	−153	−153
Transmitter antenna gain (G_t), db	+ 33	0
Receiver antenna gain (G_r), db	− 0	+ 33
Line loss (L_L), db	− 1	− 1
Net transmission loss, db	−121	−121
Transmitted power (P_t), dbw	− 3	− 3
Median received power (C), dbw	−124	−124
Receiver noise figure (F), db	+ 6	+ 6
Thermal noise per cycle (KT), dbw	−204	−204
Receiver bandwidth (B= 3 kc), db	+ 35	+ 35
Thermal noise power (N), dbw	−163	−163
Multihop degradation, db		+ 3
Net noise power, dbw	−163	−160
Median C/N, db	39	36
Minimum usable C/N, db	15	15
Fading allowance, db	24	21
Reliability, %	99+	99

Again referring to Fig. 9, it can be seen that there is little possibility that the size of the satellite can be substantially reduced by increasing the number of satellites. For instance, if 200 satellites are used for a range of 2,000 miles, the maximum slant distance is reduced to 1,000 miles. Since the size of the satellite required is proportional to the square of the slant distance, it is reduced to $(1{,}000/2{,}000)^2\times280$ or 70 feet, which is still quite large. Therefore, an active satellite relay has a better chance of competing with moon relay at the present time.

Conclusions

Both moon and satellite relays are feasible means for the extension of global communications. In the present state of the art, moon relay seems to have some edge over satellite relay, and since the moon is free for all, moon relay may be the cheapest way to extend the range of global communication. There are, however, certain limitations that must not be overlooked.

1. While the usable time of moon relay is continuous, it is limited and varies from day to day, and depends on the locations of the earth stations and the great-circle distance between them. In practice, a compromise between usable time and range must be observed.
2. It takes 2.5 seconds for a signal to take a round trip from the earth to the moon. Immediate response is, therefore, impossible.

On the other hand, it is possible for satellite relays to achieve continuous service all the time at all ranges, depending on the number of satellites used and their height. Response time, in general, is short. The difficulty seems to be the problem of putting a large number of satellites in precise orbits with a fairly long lifetime.

Both moon and satellite relays are subject to certain restrictions common to any long-distance communications, such as narrow bandwidth, small signal-to-noise ratio, and low system reliability. Therefore, intensive research and development are required on high-power r-f (radio-frequency) transmitters, high-gain antennas for both satellites and earth stations, low-noise amplifiers, bandwidth reduction, novel modulation techniques, etc.

Satellites have the advantage of being readily controllable while the moon is not. Although it may take some time before this advantage can be fully realized, the research and development of satellite relays should not be overlooked in the future planning of global communication systems despite their present limitations.

Appendix I. Typical Moon-Relay System

Parameter	Value
Frequency	2,000 mc
Transmitter power	10kw cw
Antenna size	60-foot parabolic
Antenna beam width	0.6 degree
Transmitter power, P_t	+ 40 dbw
Antenna gain, G_t+G_t	+ 100 db
Median circuit loss, L_c	− 276 db
Line losses, L_l	− 4 db
Median received power, C	− 140 dbw
Noise figure, F	9 db
Noise power per cycle (kT)	− 204 dbw
3-kc bandwidth, B	35 db
Noise power, N	− 160 dbw
Median C/N	20 db
Minimum usable C/N	15 db
Fading allowance, L_F	5 db
Reliability	80% (no diversity) 99% (triple diversity)

Appendix II. Passive Satellite System Relay

Frequency	2,000 mc
Transmitter power	10 kw
Antenna size	60-foot parabolic
Antenna beamwidth	0.6 degree

Range	2,000 miles
Satellite height	460 miles
Number of satellites	15
Maximum slant distance	2,000 miles
Transmitted power	+ 40 dbw
Transmitter antenna gain	+ 50 db
Receiver antenna gain	+ 50
Free-space loss	− 338 db
Line losses	− 4 db
Echo-area gain	+ 62 db
Median received power	− 140 dbw
Noise figure	+ 9 db
Noise power per cycle	− 204 dbw
Receiver bandwidth $(B=3$ kc)	+ 35 db
Noise power	− 160 dbw
Median C/N	20 db
Minimum usable C/N	15 db
Fading allowance	5 db
Reliability	80% (no diversity) 99% (triple diversity)

Synthesis of a Resonant Transfer Filter as Applied to a Time Division Multiplex System

P. J. MAY
NONMEMBER AIEE

T. M. STUMP
NONMEMBER AIEE

IN A PREVIOUS PAPER,[1] Perkins describes a time division multiplex transmission path, developed for use in an electronic switchboard.[2] This transmission path incorporates the use of a "resonant transfer" filter, the operation of which was first described in reference 3. This type of filter and the associated theory have since been described by several authors.[4,5] The purpose of this paper is to present a method used to synthesize an economical network whose characteristics will allow it to operate efficiently in this system. The first sections cover the general requirements on the network and the special conditions imposed to effect a proper operation of the networks in a resonant transfer system. The general method of synthesis is then presented which involves both the steady-state and transient responses. Since the actual synthesis by use of well-known procedures of insertion parameter theory are familiar to most filter designers, the details of the synthesis are omitted and only the general procedure is given.

In Figs. 1, 2, and 3 is shown the transmission characteristics of a typical line circuit employing this type of filter design. Specifically shown are insertion loss, side-band suppression, envelope delay, and impedance as functions of frequency.

Filter Specifications

Referring to Fig. 4 where networks N_1 and N_2 are low-pass filters the following attenuation requirements must be met:

1. The network N_1 must attenuate frequencies above one half the switching frequency f_s. Because of the modulation process of the switch, input frequencies greater than $f_s/2$ can be translated into the audio band. As an example, if $f_s=12{,}500$ cps (cycles per second) and the generator signal is 9,000 cps, a frequency component of 3,500 cps is developed at the input to network N_2. Therefore, unless 9,000 cps is attenuated by N_1 it will cause a 3,500-cps signal to appear at the output.
2. The network N_2 is a smoothing filter which must attenuate the side bands about f_s developed by the modulation process. The exact attenuation specifications placed on N_1 and N_2 depend on the performance required of the system.

In addition to attenuation, specifications may be placed on the input and output impedance of the system and upon the envelope delay distortion.

Paper 60-822, recommended by the AIEE Communication Switching System Committee and approved by the AIEE Technical Operations Department for presentation at the AIEE Summer General Meeting, Atlantic City, N. J., June 19–24, 1960. Manuscript submitted March 21, 1960; made available for printing April 19, 1960.

P. J. May and T. M. Stump are with the Stromberg-Carlson Division of the General Dynamics Corporation, Rochester, N. Y.

Credit is due to Heinz Kammin, who designed filters for this application, and to G. Sager, without whose thorough knowledge of magnetics the practical realization of these filters would have been impossible. Also appreciated is the assistance of various members of the Computations Group of Stromberg-Carlson Company in the solution of the inverse Laplace transforms on an electronic computer.

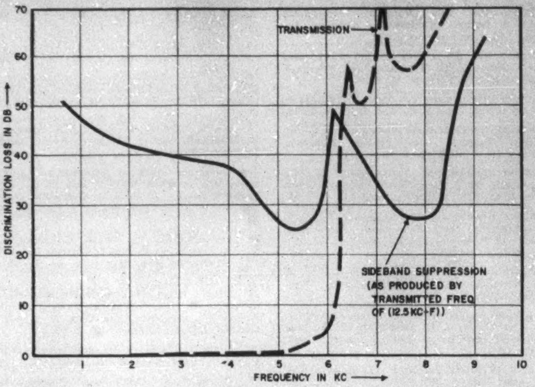

Fig. 1. **Insertion loss and side-band suppression of typical line circuit employing resonant transfer filters**

Conditions for Synthesizing Resonant Transfer Filters

Because of the periodically operating switch between the filters, a straightforward steady-state filter design will not necessarily give the required attenuation, phase, and impedance.

The following treatment will first state the design conditions imposed on the low-pass filter networks N_1 and N_2 of Fig. 4 and then show why these conditions are necessary. The three main conditions are:

1. The capacitors C_S and C_R must have a discharge curve which rings through zero at a period T equal to the sampling period. This type of curve is shown in Fig. 5.
2. The networks N_1 and N_2 are filters designed to work into an open-circuit termination, with capacitors C_S and C_R being at the open-circuit side.
3. For an impedance match

$$C_S = C_R = \frac{T}{2R} \tag{1}$$

The equality $C_S = C_R$ also assures a complete transfer of charge from network N_1 to N_2, provided L is adjusted so that

$$\tau = \pi\sqrt{LC}$$

where $C = C_S = C_R$ and τ is the switch closure time. The assumption that $\tau << t$ is also made.

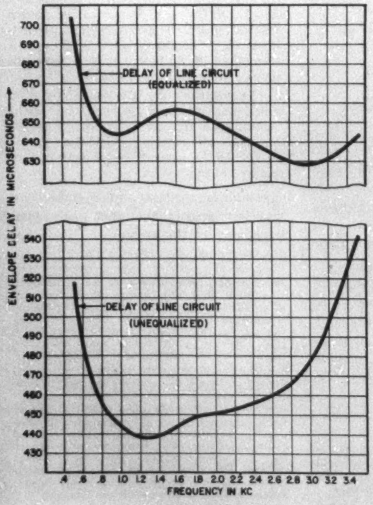
This treatment also supposes that series isolating coils L_1 and L_2 are incorporated in the filter designs, as shown in Fig. 4. This is done by requiring a full k section[6] performance in the design of the filter. Apart from the simplicity of analysis, it was found that the actual design was simplified by requiring this configuration. Otherwise, in requiring $C_S = C_R = T/2R$, the values of C_S and C_R would be equivalent input capacities, and would be difficult to control.

Theory of Operation

The operation of the switch is such that the voltage appearing across C_S before the switch closes appears across C_R when the switch opens again and, likewise, the voltage across C_R appears across C_S; see Fig. 6. Since capacitor C_R discharges its voltage in a period T and rings through zero in a period T, the voltage E_R is zero at each instant before the switch is closed. Therefore, no charge is transferred back to C_S, and hence, at each instant after the switch opens, E_S is zero.

The network N_1 may then be considered as driven by current pulses from the switch side, the amplitude of these pulses being of the exact value needed to bring E_S to zero at the end of each pulse.

The voltage E_S then becomes the sum of two voltages; the steady-state open-circuit voltage produced by the generator E_g, and the voltage produced by the



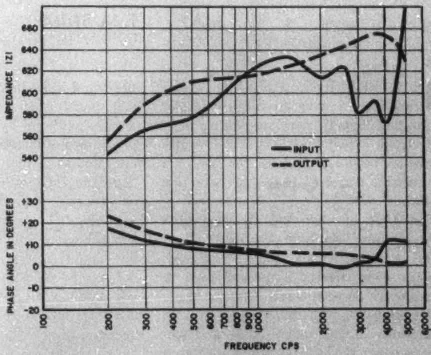


Fig. 2 (left). **Unequalized and equalized delay of line circuit**

Fig. 3 (above). **Input, output impedance and phase angle of line circuit**

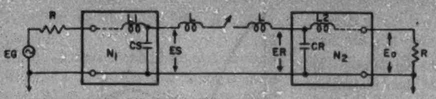

Fig. 4. Resonant transfer system

current pulses (superposition theorem). These voltages and their resultant are shown in Fig. 7.

The resultant voltage E_S at each instant prior to the switch closing, is at the exact value of the open-circuit voltage operating under steady-state conditions. This is true because it was required that capacitor C_S have a discharge curve which rings through zero in the period T.

The current pulses driving N_1 vary in amplitude following the steady-state open-circuit voltage of network N_1. These same current pulses also drive N_2 with an opposite polarity.

Since N_1 is designed as an open-circuit filter, the voltage E_{Soc}, and thus the amplitude of the current pulses as a function of frequency, can be controlled by the steady state design of N_1. In the pass band the amplitude of the current pulses varies as the ripple built into N_1. This is the reason for designing N_1 as an open-circuit filter. The network N_2 is effectively being driven, as shown in Fig. 8.

The current I consists of a pulse train modulated by a signal of the frequency of E_g, the envelope of which varies with frequency as the ripple of network N_1.

Examining the transmission of the fundamental frequency component, N_2 is operating from a constant current source into a finite load impedance. Since a current generator has an infinite impedance, and N_2 is designed to work into an infinite impedance on the C_R side, the transmission will be the same as the steady-state transmission of N_2. Thus, in the pass band the voltage E_0 will vary with frequency as the sum of the ripple of N_1 and N_2.

The filter N_2 must have a sufficient rejection to the other components of the current I shown in Fig. 8. The amount of rejection depends on the system specifications.

Impedance Matching

The current pulses composing I in Fig. 8 can be easily handled mathematically if the current consists of flat-topped pulses. Then the conventional pulse amplitude modulation equations may be used.[7] The current pulses of this system are actually half sine waves. In this analysis a flat-topped pulse of the same area will be used.

The equation for an individual current pulse is

$$I=\frac{E_{S-}}{2}\sqrt{\frac{C}{L}}\sin\frac{t}{\sqrt{LC}} \qquad (2)$$

where $t=0$ at the start of the pulse, $t=\tau=\pi\sqrt{LC}$ at the end of the pulse, and $E_{S-}=$voltage E_S at the instant the switch is closed. The area of this pulse is

$$\text{Area}=\int_0^{\pi\sqrt{LC}}\frac{E_{S-}}{2}\sqrt{\frac{C}{L}}\sin\frac{t}{\sqrt{LC}}\,dt = E_{S-}C \qquad (3)$$

A flat-topped pulse would have a width equal to τ and an amplitude of

$$A=E_{S-}\frac{C}{\tau} \qquad (4)$$

The envelope of the pulse train will be $Av=E_{Soc}C/\tau$, since the value of E_S follows the open-circuit voltage E_{Soc}. Av is now equal to the amplitude of the modulated signal in a pulse amplitude modulated system.

The modulating frequency component[7] is

$$I_{\text{fund}}=\frac{2E_{Soc}C}{\omega T\tau}\sin\frac{\omega\tau}{2} \qquad (5)$$

since

$$\tau\ll T \qquad (6)$$

$$T>\frac{1}{2f} \qquad (7)$$

Therefore

$$\sin\frac{\omega\tau}{2}\cong\frac{\omega\tau}{2} \qquad (8)$$

$$I_{\text{fund}}\cong E_{Soc}\frac{C}{T} \qquad (9)$$

For maximum power transfer N_2 would give no attenuation and the current would flow through the load resistance. The output voltage would then be

$$E_0=I_{\text{fund}}R \qquad (10)$$

and for maximum power transfer

$$E_0=I_{\text{fund}}R=\frac{E_g}{2} \qquad (11)$$

For maximum power transfer it must be assumed that N_1 gives no attenuation, so that

$$E_{Soc}=E_g \qquad (12)$$

Therefore

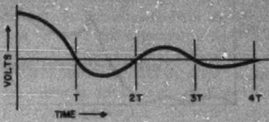

Fig. 5. Discharge curve of transfer capacitors C_s and C_r

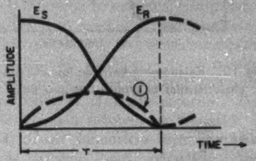

Fig. 6. Voltage versus time relationships during energy transfer in switch closure time

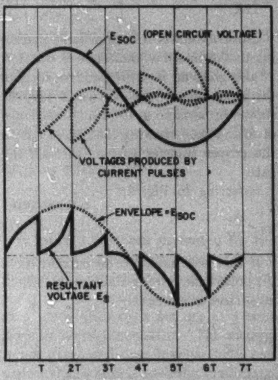

Fig. 7. Voltages produced across capacitor C_s

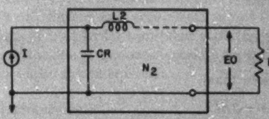

Fig. 8. Equivalent circuit of N_2

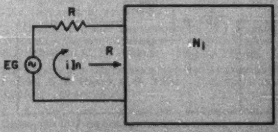

Fig. 9. Equivalent input circuit when impedances are matched

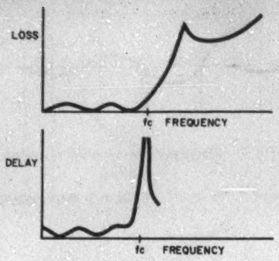

Fig. 10. Relationship between loss and delay characteristics of typical low-pass filter

$$I_{\text{fund}}R=\frac{E_{goc}}{2} \tag{13}$$

$$\frac{E_{goc}CR}{T}=\frac{E_{goc}}{2} \tag{14}$$

$$C=\frac{T}{2R} \tag{15}$$

This is a condition for impedance matching to obtain a maximum power transfer. It also gives an input impedance of R to the input of network N_1, which may be shown by assuming an input impedance of R and then showing that this leads to the proper transfer current through the gate.

Referring to Fig. 9,

$$i_{IN}=\frac{E_g}{2R} \tag{16}$$

If this is a fundamental current, then the pulse train flowing through the switch must have an envelope:

$$i_{\text{env}}=\frac{E_g}{2R}\,\frac{T}{\tau} \tag{17}$$

since

$$C=\frac{T}{2R} \tag{18}$$

Then

$$i_{\text{env}}=\frac{E_gC}{\tau} \tag{19}$$

Note that

$$\tau=\pi\sqrt{CL} \tag{20}$$

Then

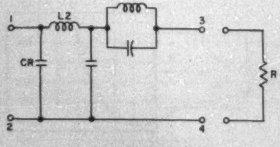

Fig. 11. Typical filter circuit for resonant transfer application

$$i_{\text{env}}=\frac{E_g}{\pi}\sqrt{\frac{C}{L}} \tag{21}$$

Finally, note that the actual pulses are half sine waves rather than rectangular pulses. Thus, the factor $\pi/2$ must be applied to obtain the peak amplitude of the envelope:

$$i_{\text{env}}=\frac{E_g}{2}\sqrt{\frac{C}{L}}=\frac{E_{goc}}{2}\sqrt{\frac{C}{L}} \tag{22}$$

This is identical to the solution of the resonant transfer circuit, which gives pulses of the same peak amplitude.

Filter Synthesis

The synthesis of this type of filter is not completely analytic nor exact, per se. It is rather an approximation to meet the specifications outlined above.

In view of the transient discharge and charge of capacitors in the resonant circuit which causes the transfer of energy from a send to a receive mechanism, one factor to be noted is that a type of isolation is required after the receive capacitor which causes all the charge to be stored there. The isolation chosen was an inductor which then becomes part of the filter design.

The filter could, of course, be designed with the use of the number of k sections[6] that would be necessary for the discrimination dictated by carrier and sideband suppression. In the interests of economy of elements, a design incorporating peaks of theoretically infinite attenuation at finite frequencies (m sections)[6] was chosen. This would give proper discrimination for the fewest number of elements.

Because of the isolation consideration mentioned and in view of the use of m sections, a nonmaximum species[8] filter was necessary. In the interests of economy, the insertion parameter approach to the filter design was chosen. This would give the optimum response for a given number of reactances of a given quality. Image parameter designs were considered as well, but the discharge response of these filters was found to be inadequate for this particular application. The insertion parameter design also gave another degree of freedom due to the choice of ripple. The terms "k section" and "m section" are borrowed from image parameter theory to describe the circuit, but not necessarily its operation. It is clear from the considerations in the previous section that the design had to be an open-circuit type. If the discharge curve is correct, the attenuation and phase of the filter in its circuit operation would approach quite closely the steady-state response, and could therefore be anticipated. This makes the design of the filter basically a steady-state problem.

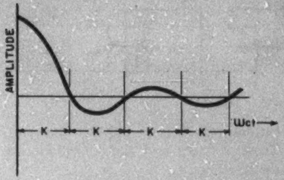

Fig. 12. Discharge of receive capacitor C_r through filter into load

Since the cutoff of the filter is determined primarily by the capacitor discharge transient, it was convenient to have other parameters to allow some freedom in the choice of the circuit. With a given circuit configuration there were three aspects to the synthesis which allowed the freedom desired (assuming insertion parameter design). These were value of ripple, pole location, and order of pole extraction.

As the title of this article indicates, the filter was applied to a time division multiplex system. From the simplest of considerations, then, the filter was to pass the audio of the transmission path, and reject the carrier (determined by the sampling rate) and the side bands. Once the carrier is fixed, many designs are possible which will give the proper discrimination to carrier and side bands.

Usually, extenuating circumstances force the design to a specific approach. In this particular application, it was the linearity of phase in the pass band of the filter which dictated the cutoff. As is well known, with the advent of high-speed data transmission, linearity of phase with its resultant low envelope delay distortion is mandatory on transmission paths. There are two requirements on a transmission path, as far as delay is concerned, for the faithful reproduction of pulse transmission: 1. linearity of phase resulting in low envelope delay distortion, and 2. zero or $n\,\pi$ zero phase intercept.

The second point is obviated with the use of modulation. That is, the transmission will be faithful if a modulated signal is transmitted through a nonzero (including $n\pi$) phase intercept system, and if (assuming no attenuation distortion) the phase-versus-frequency characteristic is linear over the frequency band of transmission. For base-band transmission, the zero intercept must be considered. Because of the linear phase consideration, the cutoff of the filter was kept as high as possible.

Fig. 10 depicts the phase and envelope delay of a typical low-pass filter configuration. The slope of the phase curve rapidly increases in the vicinity of cutoff so that an attempt must be made to keep the cutoff as far removed as possible from the frequencies over which the phase is to remain linear. All pass phase equalizer sections with complementary phase characteristics can be added to the transmission path to increase the linearity of phase. However, an effort to reduce the phase distortion in the first place makes the equalization problem much easier and also keeps the absolute level of envelope delay down to a minimum. This last factor becomes important where synchronization based on delay of a system becomes important.

Certain design approaches yield much more linear phase in the pass band and through the cutoff. However, these designs have two drawbacks:

1. An increasing number of loss-versus-frequency characteristics, which is undesirable in practical transmission paths.
2. The large number of sections required for good rejection to a carrier and side bands not too remote from cutoff, leading to poor economy of design.

These considerations will yield an approximation to the circuit configuration. Assignment of circuit parameters will yield a normalized filter circuit. The normalized filter circuit is the result of a synthesis procedure for a filter using insertion parameter theory developed by Cocci,[8] Darlington,[9] Cauer,[10] and others. The Darlington reference filter was found to be quite adaptable to this design due to the arbitrariness of the possible pole location. A Cocci 5–1, 7–1, or 7–2 could also be used with success. All of these designs, as mentioned previously, must be of open-circuit variety where the open-circuit end faces the gate for sampling. This circuit will have a normalized transient response in terms of the cutoff. If this response is correct and yields a cutoff which is placed so as to allow the filter to reject the carrier and side bands, and allows room for phase linearity, the network becomes theoretically feasible.

An important consideration in the design of a resonant transfer filter is the determining of the cutoff as a result of the capacitor discharge transient. The rate of sampling in the time division system is determined by the carrier frequency used, which also determines the time which can be subdivided into the desired number of channels. The sample time is then determined by the duration of time through which the switch is closed. We shall call the sampling rate T and the sampling time τ. The duty cycle is then given by τ/T. As an example, if a 12.5 kc carrier is used, the highway time available would be 80-μsec (microseconds). This time could be subdivided into 32 time slots, each 2.5 μsec in duration. This could allow a 1.25-μsec sampling time and a 1.25-μsec guard space, which would allow 32 possible conversations on one highway. Since each time slot is sampled every 80 μsec, the voltage on the receive capacitor must be zero just prior to the closing of the switch. This is why the discharge of this capacitor must be carefully controlled. The analysis of a typical case would be as follows.

Assume a given filter configuration which must meet the transmission requirements on the system. Such a filter might look like that shown in Fig. 11.

Assume a charge of 1 on the capacitor C_R. Write the Laplace transform of this network as a function of the complex frequency variable, $S=\sigma+jw$. With the use of the inverse transform the time function of this network may be determined. If one then considers the discharge of this capacitor across terminals 1 and 2 through the filter into the load, Fig. 11, the curve might be like that in Fig. 12.

The ideal case is where zero crossings of the discharge occur as integral multiples of Wct. This would assure a zero value of charge on the capacitor each time a new sample is made. The transfer of energy from send to receive would be lossless, assuming that other matching conditions are met. The first zero crossing as a function of Wct could then make it possible to arrive at a value of Wc which corresponds to the normalizing cutoff frequency of the filter. The use of this frequency to unnormalize the filter would assure the designer of the proper transient response, if $Wc=K/T$, where K is the normalized time of zero crossing. As a matter of fact, any of the zero crossings could be used to normalize the filter. Unfortunately, a perfect integral multiple zero crossing of Wct is not practicably possible. Variation of the filter parameters will yield a good approximation of this goal.

Once the value of Wc is determined, it is compared to the requirements on the filter due to the transmission specifications. If the cutoff is in the proper location, the filter is assumed to be a good approximation to the design required.

The last requirement on the filter is that its discharge capacitor be of the proper value if an impedance match is desired, as has already been described. The value of this capacitor is $C=T/2R$, where T is the sampling interval and R is the impedance level of the filter, i.e., the send filter is driven from an R-ohm impedance generator and the receive filter is terminated in an R-ohm load. If the capacitor value is different from the prescribed value, a mismatch loss will result, as described earlier.[5]

It is possible by empirical manipulation to arrive at a set of circuit parameters which will yield a result which satisfies the simultaneous fulfillment of the requirements on both the discharge curve and the value of discharge capacity. This manipulation involves the variation of the circuit parameters such as ripple, pole location, and extraction. Once this is determined, the resonance of the transfer circuit is fixed by the sampling time. As shown in reference 1, the capacitor voltage-versus-time plot resembles that of Fig. 6.

If, then, in the example above, resonance of the transfer circuit is made to be 400 kc, the transfer of energy will be accomplished in the 1.25 μsec in which the switch is closed. The resonance could be arranged as shown in Fig. 4, where the series resonance, or C_S, C_R, and $2L$, is at 400 kc.

Conclusions

A method has been presented for the synthesis of a filter which operates from a finite source impedance into a load which is actually an electronic switch operating at a given duty cycle for use in a time division multiplex system. The method is not exact and does involve some empirical trial which is basically mathematical. Once the requisites for the efficient operation outlined are met, one may feel confident that the design will operate effectively. The resonant transfer system is an efficient and economical means of energy transfer for transmission purposes, and the design approach is mainly dependent upon this filter circuit.

An Electronic Teleprinter Distributor

N. N. BISWAS
ASSOCIATE MEMBER AIEE

H. RAKSHIT
NONMEMBER AIEE

ALTHOUGH MOST present-day teleprinters have mechanically operated cam-type distributors, which are quite satisfactory and reliable, a recent trend in the industry has been to develop electronic ones.[1,2] This paper describes an electronic distributor developed at the electrical engineering laboratory of the University of Roorkee, India. The distributor uses a ring counter consisting of cold cathode trigger tubes. The timing pulses are derived from the 50-cycle main supply. The 1.5-unit stop pulse is insured by a novel method of reversing the phase of the sinusoidal supply driving the pulse generator during the stop period of each signal train. Since no hot cathode tube is used at any stage of the distributor, it does not require any warm-up time. The distributor can be fed either directly from the keyboard or from a perforated tape. It can also be made to work from a 5- or 6-unit code by means of a code-selector switch.

The Distributor

Fig. 1 shows the block diagram of the electronic distributor. $C1$ to $C5$ are the five code contacts which are influenced either by the depression of a key bar or by the perforation of a type. These contacts are scanned by the ring counter in proper interval and sequence to transmit the mark or space as the case may be.

Ring Counter

The ring counter employs cold cathode thyratrons or trigger tubes connected in the usual 3-4 manner. To transmit a character, the distributor is required to send 7 elements: start, 5 code elements, and the stop element. At this stage let the stop element be of 2 units duration instead of the usual 1.5 unit. Fig. 2 shows that this will require 8 pulses and, therefore, 8 tubes. The sequence of operation is as follows. At the beginning of the transmission, tube T_0 is made to conduct. When the S pulse comes, tube T_S fires; when pulse 1 comes, tube T_1 fires. During the interval between the firing of tube T_S and tube T_1, the start impulse is transmitted. Then comes pulse 2 which fires tube T_2.

During this interval the first code element is transmitted. Similarly, by the time pulse M arrives, all the code elements have been transmitted. Pulse O is the last pulse for the character. This fires tube T_o, which remains conducting until the arrival of the next train of pulses for the next character. It may be seen that when two characters are transmitted one after another, as in tape transmission, the interval betwern the firing of T_o and that of T_S is 1 unit. This makes the duration of the stop element, which is the duration between the M pulse and S pulse, equal to 2 units.

It has been said that the timing pulses are derived from the main supply. When the main supply has a frequency of 50 cycles per second, the teleprinter will operate at a speed of 50 bauds. The pulse generator is so designed that, for reasonable variation of the supply voltage, there is no appreciable change in the amplitude of the output pulse. Any fluctuation of frequency will, however, affect the pulse repetition frequency. But it has been seen that if the frequency variation is limited to 4% a teleprinter receiver having a margin of 35% will function properly.

Send Relay

A high-speed polarized telegraph relay acts as the output or send relay of the distributor. The SPDT contact of the relay can be wired to provide either neutral or polar operation. Fig. 3. shows how, when tube T_1 of the ring counter conducts, the current through the send relay flows through either the 2-1 or 3-4 winding depending on the condition of the code contact $C1$. Current through the 2-1 winding makes the relay space, and current through the 3-4 winding makes the relay mark.

Before the transmission of the first code element, the start signal must be transmitted. For this reason tube T_S precedes tube T_1 in the ring counting cycle and circuit; see Fig. 4. Again, since the start signal is always a space pulse, tube T_S has been connected permanently to 1-2 winding of the send relay. For a similar reason, during the conducting period of tube T_M, the stop pulse, always marked, is transmitted. Tube T_M has been connected permanently to the 3-4 winding of the send relay immediately after tube T_5 or T_6. When the transmitter is idle, marking current should flow into the line. Hence, tube T_o, which continues to conduct during the idle period is also connected permanently to the 3-4 winding of the send relay; see Fig. 4.

Control Relay

It is clear from Fig. 2 that 8 pulses are needed to transmit a teleprinter signal for a character. The transmission of the fifth code element is over, however, when the seventh pulse comes. Therefore, up to this time it is essential that the code contacts, combination bars, and function bar are all in operation and undisturbed. This is achieved by keeping the key bar mechanically locked during this period of transmission. During this locked condition the operator is unable to depress any other key bar. As-

suming the characters are transmitted one after another without any loss of time, it is obvious that the stop signal is transmitted between the seventh and ninth pulses. During this period the keyboard should be released and a fresh combination set up. This is done by the control relay.

If the operator keeps the key depressed for a period longer than the transmission time of a signal, the transmitter should transmit the signal only once. Here also it is the control relay which prevents this undesirable repetition of the signal. Fig. 5 shows the circuit arrangement of the control relay along with the pulsing circuit. The control relay is also a high-speed polarized relay similar to the send relay, but has two changeover contacts. In Fig. 5 only the operating winding has been shown. A small biasing current always flows through the other winding, which is not shown. The contact *CR*1 is the contact of the control relay. *F*1 and *F*2 are two contacts actuated by the function bar and hence by the depression of the key.

If the operator keeps the key depressed for a period less than the transmission time, the control relay functions in the following manner. As soon as the key is depressed, the code contacts, *C*1 to *C*5 in Fig. 4, as well as the function contacts *F*1 and *F*2, are locked in the operating position mechanically. The pulsing circuit is grounded via *CR*1 and *F*1, starts generating the pulses, and transmission begins. At the end of transmission of the fifth and final code pulse, tube T_M fires and the control relay operates. Contact *CR*1 changes over and grounds the release magnet of the locking mechanism. The release magnet is very fast operating, and unlocks the locked contacts in less than 10 milliseconds. Contacts *F*1 and *F*2 come to normal position. *F*2 again grounds the pulsing circuit, and the next pulse fires tube T_o and extinguishes tube T_M. The control relay releases immediately, bringing contact *CR*1 to normal position. As a result, the ground of the pulsing circuit is removed and no further pulse is generated. Tube T_o continues to conduct, and the distributor is ready for transmission of the next signal.

On the other hand, when the key is kept depressed for a longer time than the transmission period, the code contacts and the function contacts operate and are locked in the usual way following the depressing of the key. At the end of the transmission of the fifth code element, tube T_M fires. The control relay operates, *CR*1 changes over, and the pulse generator is de-energized. Although at this instant the release magnet of the locking mechanism is energized the code contacts and the function contacts do not come to normal position as the combination and function bars remain operated by the depression of the key bar. The distributor, therefore, remains in this position as long as the key is depressed by the operator. Marking current continues to flow onto the line, since the tube T_M remains conducting. As soon as the key is released, all contacts come to normal position. Pulse generator is energized once again via *CR*1 and *F*2. The first pulse now generated fires tube T_o and extinguishes tube T_M. Consequently, the control relay releases. *CR*1 comes back to normal position, de-energizing the pulse generator. Tube T_o maintains marking current on the line, and the distributor is ready for sending the next code train.

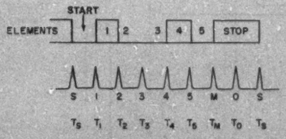

Fig. 2. Pulses and tubes required to transmit teleprinter signal

Run-out Key

In the mechanical teleprinters a special key is provided which, when depressed, sends the code of the character last transmitted over and over again. The key is known as the run-out key. Here the run-out key takes the form of a telephone key and is on the control board rather than on the keyboard. If repeated transmission of a particular character is desired, first the run-out key is operated; see Fig. 4. This operates the two contacts *RT*1 and *RT*2. Now the key for the particular character is depressed. The code contacts and the function contacts are locked. It may be seen that in spite of the operation of *CR*1, the pulse generator is working because of the ground extended by *RT*1, and the release magnet is not grounded because of *RT*2. Hence the transmission is repeated until the run-out key is brought back to normal position.

Stop Pulse

The principle by which a stop pulse of 1.5 units is obtained is shown in Fig. 6. As soon as tube T_M fires, the phase of the sinusoidal voltage driving the pulse generator is reversed. As a result the next pulse comes after 10 milliseconds and fires tube T_o. Thus, the interval between T_M and T_o is reduced to 1/2 unit instead of 1, and the stop pulse, which is the interval between the firings of tube T_M and tube T_S, now has a duration of 1.5 units. To carry out this principle two conditions are required: a means for indicating the time at which the supply is to be reversed, and a means for reversing the supply voltage at the appropriate time.

the odd and even pulse counter provides a convenient way to achieve these means. The circuitry of the odd and even pulse counter, seen in Fig. 7, is the same as that of the ring counter. The same trigger tubes with similar resistors and capacitor connections are used. The reversing relay is similar to the send relay. Its contact *R*1 reverses the phase of the sinusoidal supply driving the pulse generator; see Fig. 4.

When the control relay operates with the firing of tube T_M, contact *CR*2 seen in Fig. 7, changes over almost instantaneously, connecting the starter anodes of tube T_A and T_B to the output of the pulse generator. As a result, the same pulse which fires tube T_M makes these two tubes interchange their states. The next pulse now comes after 10 milliseconds. This pulse fires tube T_0 of the ring counter, but should not affect the states of the tubes T_A and T_B. This is accomplished by increasing the values of C_2's in the odd and even pulse counter. Because of the greater value of C_2, the charging time is increased and the voltage across R_3 which provides the positive bias to the starter anode does not rise sufficiently within 10 milliseconds. Consequently, this pulse fails to fire any tube of the odd and even pulse counter. Immediately after this pulse, *CR*2 comes back to normal; the tubes T_A and T_B interchange their states only when tube T_M fires once again. Thus the *R*1 contact of the reversing relay reverses the phase of the sinusoidal supply during the transmission of the stop pulse of each signal train. This insures a 1.5-unit stop pulse.

Fig. 8 shows the oscillograms of the sinusoidal supply, the pulses, and the output wave form when the distributor was made to transmit the code for letter D continuously with the help of the run-out key. The oscillograms were taken by feeding these three quantities simultaneously on 3 elements of a 6-element magnetic oscillograph.

START KEY

The ring counter and the odd and even pulse counter are not self-starting. That is, when power is switched on, none of the tubes in these circuits start conducting. A high voltage is applied manually by the start key shown in Fig. 4, to the starter anodes of tube T_0 and tube T_A, and then removed. These two tubes then start conducting and the distributor is ready for transmission.

TAPE TRANSMISSION

In tape transmission the distributor works continuously. During the transmission of 30-millisecond stop pulse the tape-feeding mechanism is energized. This moves the tape by one hole, presenting the code of the next character before the sensing needles. For this, an additional relay *TP* is employed. Relay *TP* is a conventional telephone relay with three contacts. This relay remains operated for the entire period of tape transmission. The circuit of this relay and its contacts are shown in Fig. 9.

In order that the distributor can work as a keyboard transmitter and as a tape transmitter, the 14 points as shown in Fig. 4 are wired into a multicontact socket. When the distributor works in conjunction with a keyboard, the code contacts, function contacts, and other points which are on the keyboard are connected to the appropriate points of the distributor by means of the plug from the keyboard. When the distributor is required to work from a tape mechanism the keyboard plug is disconnected and the plug from the tape mechanism is inserted; this brings in the code contacts and other points from the tape mechanism to the appropriate points of the distributor.

After the tape is inserted, relay *TP* operates when switch *SW* is closed. *TP*1 energizes the pulse generator by grounding it and transmission commences. At the

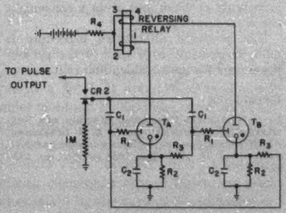

Fig. 7. Odd and even pulse counter

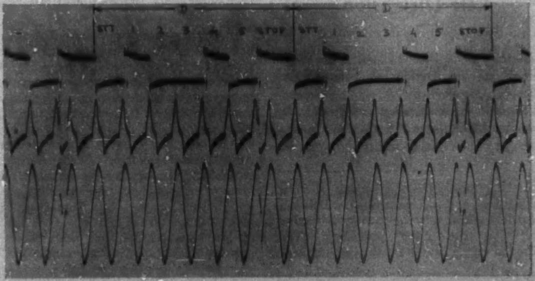

Fig. 8. Oscillograms showing phase reversal of sinusoidal supply, pulses, and output wave form

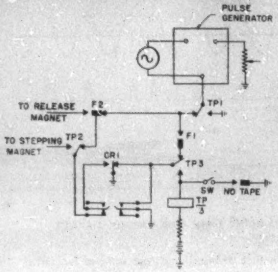

Fig. 9. Tape relay circuit

end of the transmission of the fifth element, tube T_M fires and the control relay operates. *CR*1 energizes the stepping magnet of the tape feed mechanism via *TP*2. The tape moves by one feed hole, and the code of the next character is presented before the sensing needles. This cycle is repeated for every character. At the end, when the entire tape has moved over, the switch NO TAPE releases, releasing relay *TP*. It may be seen that if relay *TP* releases at any other time than when the stop pulse is being transmitted, pulsing may stop when any of the tubes T_1 to T_5 is conducting.

Because of NO TAPE all the code contacts are in the spacing position; thus, the distributor may come to a stop with, say, tube T_3 conducting, and keeping spacing current over the line. Since this is not desirable, relay *TP* is prevented from releasing at any other time by grounding by *TP*3 and *CR*1. When tube T_M is conducting *CR*1 removes the ground and relay *TP* releases. Release lag of relay *TP* is less than 10 milliseconds. With the release of relay *TP* the pulse generator is de-energized, and tube T_M conducts. During the conducting period of T_M, there is marking current over the line, and it does not matter if it is caused by tube T_0 or tube T_M. When a new tape is inserted, *TP* relay operates once again and the transmission starts as usual. If, however, at the end of tape transmission, the distributor is required to transmit from the keyboard, the insertion of key board plug brings in the *F*2 contact of Fig. 9, and the pulse generator is energized via *CR*1, *TP*2, *F*2, and *TP*1. It sends out one pulse which fires tube T_0 and extinguishes tube T_M. The control relay releases, *CR*1 comes back to normal, and the pulse generator is de-energized.

FLEXIBILITY OF CODE INPUT

In some countries, as in India, the complexity of the language may be more than a 5-unit code can represent.[5] It is therefore desirable that the distributor work from a 6-unit code also. In the distributor that has been developed, this facility has been provided by simply having one more tube in the ring counter, as shown in Fig. 4. The circuit of this tube is essentially the same as that of any other tube of the ring counter. When the transmitter is working from a 5-unit code, the *DPDT* switch removes this tube from the ring counter. When the switch is in the 6-unit position, the tube is reinstated and the distributor then works from a 6-unit code input.

Fig. 4 gives the complete circuit of the electronic distributor.

Conclusions

The electronic distributor as described here has one important limitation, that is, it can transmit only at one speed which is 50 bauds. In the United States, where the supply frequency is 60 cycles per second, the distributor will work at a speed of 60 bauds. A flexibility of speed can, however, be obtained by incorporating a variable frequency oscillator to drive the pulse generator. The chief advantage of this design is that the timing oscillator remains free running and there is no need to double its frequency during the stop period to obtain a 1.5-unit stop pulse.

Although there are better methods of producing sharp pulses using vacuum tubes, a gas tube has been used in the distributor so that no warm-up time is necessary. A peaking transformer can also be used conveniently as a pulse generator. For a similar reason the power supply should also use a gas or a metal rectifier. The ring counter can be made more compact by using transistors or dekatron tubes.[6]

Late Discussion

Discussion of "The Numerical Graphical Method in the Design of Multiterminal Switching Circuits," by A. H. Scheinman, published in Communication and Electronics, November 1959, pages 515–19.

C. A. Stapleton (The University of New South Wales, Sydney, Australia): This is a useful extension of the author's earlier paper[1] on the same procedure. The method is very suitable for the "noncareer" switching-circuit designer who can rapidly become proficient in its use.

In neither paper does the author discuss how to weight the inputs, i.e., in what order should they be removed in the design. It is my experience that this order of removal is important in single-output problems with many inputs and I suspect that this would carry over to the method *1* of this paper; the author agrees that it affects method *2*. An alternative method of representing the switching function, by means of a transmission matrix, has been described in an unpublished paper by Stapleton. This procedure has all the features of the numerical-graphical method but adds some important advantages. For example, it enables the selection of the removal order which gives efficient results, particularly when a number of input combinations are don't-care items and permits a change in removal order after the reduction process has begun. It reduces the paper work in a large-scale problem and gives a convenient check on solutions.

The proposed alternative procedure is quite compatible with that of the present paper and is a useful addendum to it.

"WE NOW return you to our studio in New York." At this cue from the announcer the smiling face of the weather man in Chicago disappears from the screen of your television set and is replaced by that of a well-known news commentator. This change in the originating point of a television program is a familiar phenomenon to viewers and similar "switches" are performed in each television network many times each day. However, back of the ability of the various television networks to originate or receive programs almost anywhere in the United States lies a large web of intercity and local audio and video transmission and switching facilities leased by the Bell Telephone Company system to the television networks. These facilities are constantly being expanded and improved and it is the purpose of this paper to describe briefly the video switching facilities previously used and to present a more detailed description of new video switching facilities which are now being put into use.

l. 79
1
60

Intercity and Local Facilities

At the present time, three major networks, the National Broadcasting Company (NBC), American Broadcasting Company (ABC), and Columbia Broadcasting System (CBS), carry most of the television programs of the country. Programs of these networks largely originate in New York, Los Angeles, Chicago, or Washington, D.C.; but they may originate and be introduced into a network at almost any other point. The audio portion of each program is carried over facilities, built up largely or use in radiobroadcasting, which are separate from those furnished for the video portion. Fig. 1 shows a map of intercity video television facilities as they existed on January 1, 1960. These facilities comprised a total of about 85,000 channel miles of which 73,000 miles were on TD-2 (transmitter-distributor) radio relay and 13,000 miles in coaxial cable. These facilities are divided into numerous circuit elements many of which are used alternately by the various broadcasters or closed-circuit networks. This alternate use requires frequent switching of intercity circuit units as the needs of the broadcasters vary from hour to hour. In certain areas, where a number of circuits in each direction are available, the amount of switching is reduced by the use of a circuit arrangement which is termed a "round robin." As an illustration of this arrangement, the NBC television network is furnished with facilities which go west from New York through Philadelphia, Baltimore, Washington, Pittsburgh, Columbus, Dayton, and Indianapolis to Chicago and return to New York via east-bound facilities through Cleveland, Buffalo, and Albany. CBS is furnished with similar facilities which go through the same cities, but in the opposite direction. Other round robins involving other cities are gradually coming into existence. A network may wish to make any one of these cities the transmitting point for a particular program, with all others receiving; or it may wish to change transmitting points during a program as in the case cited in the opening paragraph. The television facilities of Fig. 1 must, therefore, include suitable switching gear not only to interconnect intercity circuit units but also to connect the Bell System intercity network facilities to local transmitting and receiving video circuits extending to the various studios or stations affiliated with the networks within each city. This switching gear is located in television operating centers (TOC) in most large towns and cities and also at the radio towers or coaxial terminals that serve each city.

Typical video facilities which might be furnished by the Bell System to one of the television networks within a particular city are illustrated in Fig. 2. The local video facilities furnished to a network radiate from a master-control board owned and operated by the broadcaster. To this point are brought one or more video circuits from each program originating point within the city. Some of these, from the local studios of the network, are used regularly for program origination. Others, from various local pickup points, such as the White House in Washington or Madison Square Garden in New York City, are used less frequently. One or more circuits are furnished from the master-control board to the transmitter of the local station affiliated with the network. Programs originating locally or brought in from other cities are transmitted over the air from this point. Circuits to and from the master-control board to the Bell System TOC are furnished for use on all programs which involve the use of the intercity facilities assigned to the network. The TOC has interconnecting facilities to the TD-2 radio relay tower or coaxial terminal serving the particular city.

Switching Facilities

Fig. 1 indicates that a very large percentage of the intercity routes have channels equipped for color transmission and various improvements have been introduced which have made this possible. Local video channels used to interconnect the television broadcaster's various locations within a city and to connect the broadcaster to the Bell System intercity network are being improved by the introduction of the new *A2A* video transmission system. Comparable improvements have also been made in the video switching facilities to be provided in TOC's such as the one shown in Fig. 2. The video switching arrangements provided in such a center permit switching a number of incoming intercity facilities or facilities from local network master-control boards to any one or more of a number of outgoing circuits which may also be intercity facilities or facilities to a local master-control board. The video switch originally used for this purpose is shown in Fig. 3. It employs multibutton key sets to bridge high-impedance video output circuits to incoming circuits. This type of switch required special equalization and careful limiting of the number of outputs connected to a particular video input for monochrome transmissions. Color transmission imposed even more serious limitations.

Subsequent portions of this paper will describe a new relay type of video switch which extends the bandwidth considerably beyond present color requirements and removes the limitations as to the number

of output circuits which may be connected to a particular program input. The integration of the new video switch into the over-all television network and the methods of controlling it will also be discussed.

NEW VIDEO SWITCH

The new video switch includes splitting pads, relay contacts, amplifiers, and cables so designed that any input may be connected to any output with negligible impairment of the video signal. Switching is on a 124-ohm balanced, constant-impedance basis with the inputs terminated at the switching relays when not in use. Fig. 4 illustrates the basic switching pattern for a video switch having 10 inputs and 12 outputs (10 by 12). Each input may be connected to any or all of the outputs by the operation of one or more relays in the switch. The method of controlling the operation of the switching relays will be discussed later. Each input is terminated in a splitting pad, shown in Fig. 5, having 12 output legs, there being about a 54-db (decibel) loss between any two output legs, to prevent a momentary open on one leg from producing an appreciable transmission effect on circuits connected to other legs of the pad. For each output circuit there is a 10 by 1 switch, containing 10 wire-spring relays. Two of these 10 by 1 switches are shown in Fig. 6, and each is capable of connecting any one of ten inputs to the output associated with the 10 by 1 switch. Each of the 12 legs of an input splitting pad is terminated in one relay in each of 12 different 10 by 1 switches.

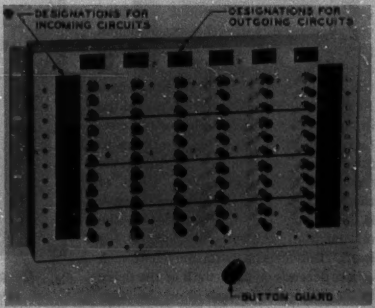
The splitting pads and 10 by 1 switches are assembled into a basic 10 by 12 switch unit as shown in Figs. 7(A) and (B). This 10 by 12 switch unit may be completely or partially equipped as required. If less than the full complement of output switches is furnished, the unused legs on the splitting pads are terminated either at the pads or on a cable terminating panel included in the 10 by 12 switch assembly. The cabling between the splitting pads and the relays of the 10 by 1 switches is illustrated in Fig. 7(C).

Fig. 8(A) illustrates how four of the 10 by 12 switch units may be combined to form a 20 by 24 video switch, such that each input may be connected to any or all of the outputs as desired. Here each input circuit enters a splitting amplifier having three identical outputs, two of which, in the case shown, are connected to two separate 10 by 12 switch units. Each output trunk circuit includes a 3 by 1 switch, containing three wire-spring relays, two of which, in the case shown, are connected to two of the 10 by 12 switch units. With the operation of a relay in a 10 by 12 switch unit and a relay in a 3 by 1 switch unit any input may be connected to any output. An amplifier is included in each output circuit, as shown in Fig. 8(A) to make up for the loss in the input splitting pad.

Fig. 8(B) illustrates how nine 10 by 12 switch units may be combined into a 30 by 36 video switch with all inputs having access to all outputs. Here the operation of a relay in a 10 by 12 switch unit and a relay in a 3 by 1 switch serves to connect any one of 30 inputs to any one of 36 outputs.

Any number of outputs may be connected to a single input, without transmission impairment, in any of these switching patterns since the operation of a video switch simply substitutes the 124-ohm input impedance of the output amplifier for the 124-ohm impedance of the termination on the video-switch contacts. The impedance which an input "sees" looking into the video switch thus remains constant no matter how many outputs are connected. However, the switching control is so designed that no two inputs may be connected to the same output.

One or more output circuits from the new video switch are reserved for monitor positions, as shown in Fig. 9, each being capable of being switched to any input circuit. Each monitor output in turn contains a splitting amplifier making it possible to receive a program simultaneously on a monochrome and a color monitor and on a waveform oscilloscope. One or two test positions are furnished, each having an input to the video switch permitting test signals to be transmitted over any outgoing circuit.



DESIGNATIONS FOR INCOMING CIRCUITS
DESIGNATIONS FOR OUTGOING CIRCUITS
BUTTON GUARD

Fig. 3. Push-button type of video switch panel

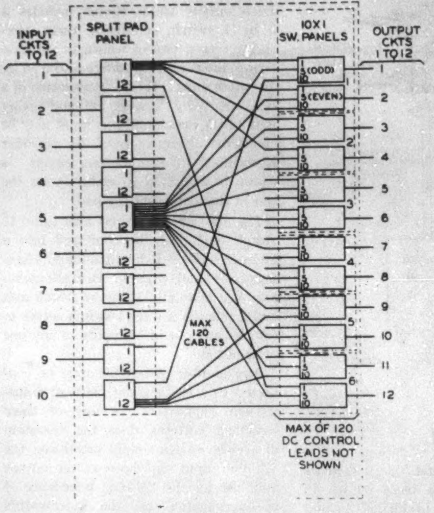


Fig. 4 (left). Switch unit, 10 inputs, 12 outputs

Fig. 5 (right). Splitting pad, 1 input, 12 outputs

Each test position also has an output circuit from the video switch permitting any incoming circuit to be connected to the receiving equipment in the test position for the reception of test signals. The improved switching flexibility and associated new testing facilities permit more rapid testing and alignment of the various components of the intercity and local video facilities.

New Video Switch Transmission Considerations

The purpose of the video switch may be stated simply as follows: to rapidly connect any incoming circuit to any one or more outgoing circuits with little or no distortion in the video signal or opportunity for error in switching. This results in each input circuit having as many branches as there are output circuits, if simple remote switching operation is desired, rather than manual plug and jack patching. For example, in a small 10 by 10 video switch each of the ten inputs would have ten branches. Each branch, including the cable from the input junction point to the switch contacts, may introduce slight echoes due to mismatches between the cable and the terminating impedance. The effect of these echoes on the wanted signal path is determined by the amount of the mismatch and the value of the leg-to-leg loss. The television distortion due to such echoes depends on the length of the delay in the echo paths as well as on the magnitude of the echo. Accordingly, in the new switch the connection from the junction point is kept electrically short and is terminated in the high-frequency image impedance of the cable. Also, the junction point and branch circuits terminate the incoming circuit in its characteristic impedance. A constant impedance splitting pad, shown in outline form in Fig. 10, is the most economical junction which meets these requirements. The attenuation requirements for the splitting pad may be stated as follows:

1. The attenuation from one output to another must be large enough to reduce the echo from the switch to negligible proportions. The requirement for this attenuation increases as 20 log N if the echoes from each branch are similar, or as 10 log N if they are random.
2. The attenuation between outputs should be at least 46 db to permit momentary removal of the termination on one leg during switch operation without noticeable change on the other outputs.
3. The attenuation from input to output should not be so great that noise in succeeding amplifiers becomes objectionable.

Noise considerations indicated that the through attenuation of the pad should not exceed about 28 db and operating features indicated the desirability of 12 outputs. Computations based on the use of a conventional H-type splitting pad illustrated in Fig. 10 indicated an echo magnitude about 55 db below the signal. This was considered to be excessive. Accordingly, a splitting pad was designed for sufficient loss between outputs where each output leg, as shown in Fig. 10,

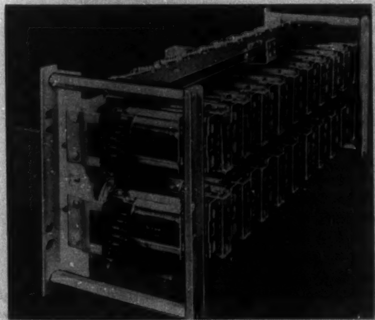

Fig. 6. Relay-type video switch panel

Vol.
Pt. I
196

contains a rectangular pad whose input shunt is the impedance of the other legs. This resulted in a further reduction of 21.5 db in echo magnitude which was considered to be adequate.

Balanced rather than coaxial circuits are used throughout the video switch because many of the TOC's are in locations where differences in ground potentials are to be expected due to nearby power, lighting, or contact making equipment; and coaxial circuits are more sensitive to these disturbances.

Each incoming or outgoing circuit in a TOC includes numerous components such as lengths of cable, splitting pads, switches, and amplifiers that require equalization. In order that one equalizer per incoming or outgoing circuit will suffice, each component is so designed that the residual distortion has a cable or "square root of frequency" shape. Typical values are as follows:

10-by-12 switch, 25 feet.
3-by-1 switch, 12 feet.
1-by-3 amplifier, 10 to 30 feet.
Output amplifier, 10 to 50 feet.

It is interesting to note that the amplifier equivalents change with vacuum-tube characteristics.

In a large video switch each input circuit and output circuit includes several lengths of cable. Since the number of lengths of cable to be equalized is large and the tolerances on equalization are severe, it is impracticable to provide individual equalizers for each length of cable or to adjust them to the necessary precision. Accordingly, the components of the video switch are equalized by variable equalizers in each incoming or outgoing connected facility. In each case, one equalizer adjustment serves for numerous cables and associated components under service conditions; therefore, the equalizer steps need not be as small as they would have to be if each of the numerous parts were equalized separately.

This method of equalization and the objective that all paths through the switch be equalized alike impose strict requirements on certain cable lengths. For example, the three cables from the output of a 1 by 3 splitting amplifier to the associated splitting pads must have the same length within a few inches. The three cables from a 3 by 1 switch to the 10 by 1 switch outputs have similar requirements.

Each incoming or outgoing facility is equalized to or from the input to a 10 by 12 switch unit, i.e., as near as feasible to the actual switch contacts. This, for discussion purposes, is referred to as point *X* and the general equalization procedure as 1-point equalization. Each incoming facility, equalized to point *X* encounters, when switched, an outgoing facility equalized from that point. In addition to the advantages discussed, this arrangement simplifies testing. Access through the video switch to connected facilities for testing purposes is obtained by means of transmitting and receiving testing facilities, which are themselves equalized to point *X*. The test equipment, therefore, functions as though it were located at the input to the 10 by 12 switch unit and terminated at the connected facility in the same impedance which a through connection encounters. Fig. 9 illustrates this arrangement. Patching facilities, using test connecting circuits having carefully cut cable lengths, are used to permit transmitting or receiving test gear to be quickly connected through the video switch to any service facility. Monitor and oscilloscope connecting circuits are also available for observing incoming signals or test patterns.

Design Considerations of New Video Switch

inputs to as many as 36 outputs, requires a large number of switching elements. Several different types were studied for use as a video switch and certain of them were found either to be too expensive or did not meet the attenuation and bandwidth requirements expected of such a switching element.

A general-purpose switching relay designed to satisfy automation manufacturing processes has recently been produced by the Bell System. This relay has wire springs in a molded assembly with precious-metal double contacts welded on the ends of the springs. This relay is faster and requires less power than the older flat spring types and, because of its basic design, has closely controlled characteristics which permit it to be incorporated into the video-switch design. The relays used in the video switch are standard wire-spring relays, no structural changes having been made other than to ground the noncircuit metallic parts. In order to reduce crosstalk, the link between the input and output on each relay is grounded when through connec-

tion is not desired. Further crosstalk reduction is obtained by using two sets of transfer springs as a ground plane between the input and the output, as shown in Fig. 11. Since all switching is on a balanced basis, two leads may be switched through each relay, one lead connecting to the upper printed circuit panel of the associated 10 by 1 switch unit and the other to the lower. Fig. 12 shows a view of the printed circuit multiple wiring. The two printed circuit multiple panels of a 10 by 1 switch unit are accurately spaced with respect to each other and permit reproducing with considerable accuracy the same impedance in the multiple wiring of all 10 by 1 switch units. It will be noted that each input has a different length of printed wiring to the common output. This produces a variation in impedance which is compensated for by series inductances of differing values. Common output coils assist in compensating for the capacitance to ground of springs on the associated wire-spring relay video switches. The series inductances make each circuit through the switch closely similar to each other circuit and provide a transmission characteristic through the switch which has a cable or square root of frequency shape. For the 10 by 12 switching unit, the transmission from any input to any output matches about 25 feet of video cable to ±0.02 db or better and up to 10 mc (megacycles).

Amplifiers

The splitting pads, described previously, introduce approximately 27-db loss into each connection between an input and an output. To make up for this loss a receiving terminal amplifier, a component of the *A2A* video systems, is introduced into each video switch output trunk circuit. This is a 3-stage video amplifier which for this application is connected so that both input and output are balanced 124 ohms. It provides about 27-db gain with a nominal bandwidth of 4.5 mc. The gain-frequency characteristic matches 10 to 50 feet of cable within 0.06 db to 4.5 mc.

The balanced amplifier stages have several advantages, the most important of which are the reduction in distortion due to balancing out the even-order distortion products of the electron tubes, and the reduction of longitudinal disturbances at the input of the amplifier.

As shown in Figs. 8(A) and (B), whenever the number of output trunk circuits exceeds 10, a 1 by 3 splitting amplifier with balanced input and output is provided in each input trunk circuit. In a video switch, a 1 by 3 splitting amplifier provides one input circuit with simultaneous access to two or three

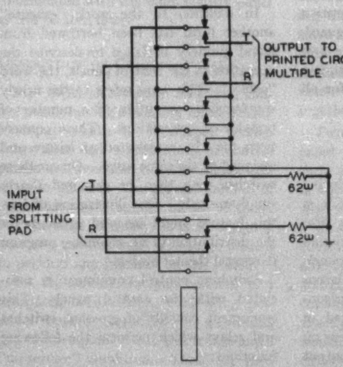

Fig. 11 (left). Method of wiring video relays of 10-input 1-output switch

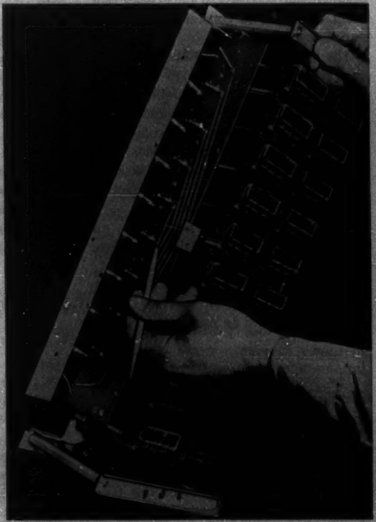

Fig. 12. (right) Video switch multiple wiring for 10 inputs, 1 output

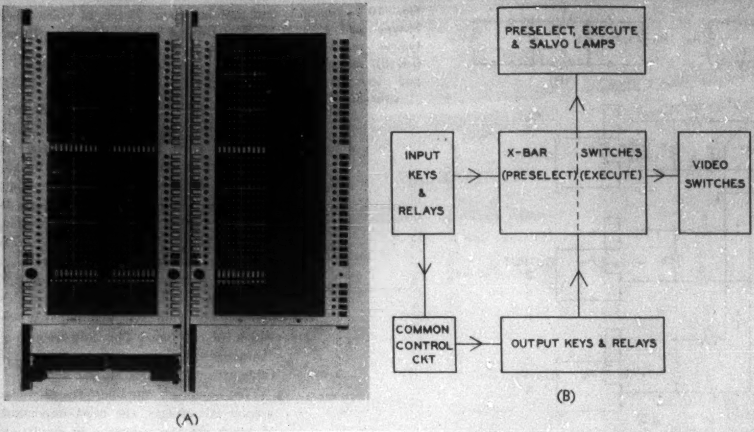

Fig. 13. Switching control panel (A) and block diagram (B)

10 by 12 switching units, each serving 12 or less outgoing trunks. The output circuit of this 2-stage balanced amplifier includes a 1 by 3 splitting pad affording 20-db loss from output to output and no net gain or loss from amplifier input to pad output. The two vacuum tubes in the output stage are so connected that the plate of one and the cathode of the other feed one side of the balanced output and vice versa. This symmetrical arrangement not only balances out even-order distortion but also effect a large saving in output power at the expense of a small reduction in constancy of output impedance.

The somewhat variable output impedance and the relatively low leg-to-leg attenuation are not objectionable for this amplifier because the three outputs are permanently terminated in accurate terminations (1 by 12 splitting pads) and the connecting cables are short (35 feet). This amplifier matches 10 to 30 feet of cable within 0.06 db to 8 mc.

The same amplifier, except with an unbalanced output, is used in the new television monitoring bay and test-monitor bay to provide simultaneous operation of a monochrome monitor, a color monitor, and an oscilloscope.

Switching Control

The older type of video switches described earlier were contacts on multi-button keys as illustrated in Fig. 3. The operation of a single button served to connect the input of the associated horizontal row of buttons to the output of the associated vertical row. Since this type of switch had no indicating lamps, the position of an operated switch was indicated by a green plastic guard ring which was placed over the operated button and flush with the top of the button. An unoperated button was protected against accidental operation by a white guard ring. The switches to be operated next were indicated by red guard rings placed over the buttons to be pushed. These are referred to as "preselected" switches. Leisurely preselection in advance of actual switching to reduce operating errors.

In addition to video switching, a TOC has control over remotely located i-f (intermediate-frequency) switches at TD radio rooms or towers and switches in coaxial terminals. Buttons to operate these switches over remote-control systems are located on monitor positions in the TOC. Each button, when operated, causes an "order" to be sent over the remote-control system for the operation of the selected switch. As a safeguard, it is usually necessary to operate two buttons for each order, one of which is a master button, used in common for all orders.

New Switching Control System

As part of the plan for introducing improved video switching in TOC's, a new switching control system is also being furnished. The video switches are operated through main control panels having a co-ordinate pattern of lamps and associated keys arranged in horizontal and vertical rows as illustrated in Fig. 13(A). The input trunks appear on the horizontal rows and the output trunks on the vertical. The intersection of a horizontal row with a vertical row represents a switching connection from the associated input to the corresponding output. A switching connection from an input to an output may be "preselected" prior to the time the switch is actually operated. A white preselect lamp and a red "execute" lamp are furnished at each co-ordinate point on the panel. The condition of each lamp of the pair describes the various states in which the possible connection between the input and the output represented may be. These states are as follows: (1) neither lamp lighted, no connection between input and output and none immediately expected; (2) white lamp lighted, connection preselected but not yet executed; (3) red lamp lighted, connection existing between the input and the output represented.

In addition to the work "execute" another term has been borrowed from naval gunnery parlance to describe the operation of the control panels, the word "salvo." This term refers to the nearly simultaneous execution of a number of preselected connections. These connections may be preselected at leisure and assigned to the same salvo. On cue these switches may then be executed nearly simultaneously. One illustration of how this feature might be used would be in the distribution of an incoming program to several theater outlets.

Switching control equipment is associated with the control panels. This equipment consists of crossbar switches and relays which perform the following functions:

1. Provide "memory" for retaining information concerning preselected switching connections.
2. Furnish salvo memory to which more than one switching connection may be assigned for simultaneous execution. (The executions assigned to a salvo are performed sequentially over a period of approximately 1 second.)
3. Provide the operating circuits for switches and for lighting lamps on the control panel to indicate both preselected and switched connections.
4. Provide safeguards against the selection of unwanted connections and against failures of portions of the common control equipment.

This equipment is illustrated in block diagram form in Fig. 13(B). The input and output keys, in association with a common control circuit, cause crossbar switches to perform both preselect and execute functions. The control circuits are furnished in duplicate to lessen the possibility of failure.

To correspond to each co-ordinate point on the control panel there are two crossbar switch "cross points," one of which furnishes preselection memory and the other an operating circuit for the associated switch and the corresponding red execute lamp. This switching control system, in addition to its use for operating video switches, may be used to operate remotely located i-f or coaxial switches over present remote-control systems. It may also be used for audio program switching control.

Monitor and test positions in the TOC are furnished with keys with which they may operate video switches to select incoming trunks for monitoring or testing on incoming circuits. Test positions have additional keys which permit selection of outgoing circuits for transmitting tests. The operation of these keys is co-ordinated with the main control panel as will be seen later.

Description of Control Panel

Fig. 13(A) shows main switching control panels having a capacity for switching 30 input trunks to 30 output trunks. Other sizes and combinations of control panels are available but this figure will serve to illustrate the general method of operation which applies to all of them. For the sake of safety, it is so designed that two buttons must always be pushed to perform any function on the panel.

On the left of the panels there is a maximum of 31 black, nonlocking preselect buttons arranged in a vertical row to correspond to 30 input trunks and a "no-service" condition. These are used in making preselections. On the right-hand side of the panel 31 similar push buttons are provided. These cause a duplicate common control circuit to function which is independent of the one controlled by the buttons on the left side so that preselections may be made from either side of the panel, in case of circuit failure.

Near the bottom of the panels there is a row of white nonlocking "output" buttons, each corresponding to an output trunk. These buttons are also used in making preselections, it being necessary to press an input and an output button simultaneously in order to preselect the associated connection. Suitable designation strips are furnished to indicate the associated video circuits for both the preselect and the output buttons.

A red master button is furnished at each side of the panel for use in the execution of preselected connections. In the lower portion of each panel are located five orange colored salvo buttons and associated amber salvo lamps, there being one amber lamp per output trunk in each salvo row. As each connection is preselected on the panel, it is automatically assigned to the top salvo and the amber lamp corresponding to the associated output is lighted in that row. A preselected connection may be assigned to another salvo row by pressing the associated output button and the button of the desired salvo simultaneously. The amber lamp corresponding to the output will go out in the top salvo row and a new lamp corresponding to the output will be lighted in the new salvo row. Any switch may be individually executed from any salvo row by pressing the master button and the associated output button simultaneously. All the switches assigned to any salvo may be executed nearly simultaneously by pressing the master button and the desired salvo button simultaneously. Two or more salvos may be executed nearly simultaneously if desired by pressing the master button and the associated buttons together.

Two green "annul" buttons are located at the bottom of the panel and these are wired in parallel for convenience in operation. If, through error or otherwise, a line preselection is made such that a white preselect lamp is lighted at the co-ordinate point where a red lamp is already lighted, meaning that this outgoing line is to be switched to the incoming line it was connected to previously, it should be noted that there would be a momentary opening of this circuit as the control circuit functions. At the time of a network break this may not be of any concern. However, if this program is a continuing one while other programs are being switched, this particular switch should not be executed. This undesired white lamp and its associated amber lamp in the salvo bank can be extinguished and the preselection nullified by holding in operation the green annul button and pushing the associated white outgoing line button.

In order to release outputs from service and make them available for testing, the lowest horizontal row of preselect and execute buttons on the main control panel is designated as a no-service row. The execute lamps in this row are green. When an output circuit is not in use, it may be preselected and executed to this row in the same manner as to any one of the 30 regular input rows. As soon as the execute or green lamp corresponding to an output circuit lights in the no-service row, an "available" lamp corresponding to the output circuit will light in each test position. The output circuit may now be selected by either of the test positions but control of it remains at the main control panel so that it may be reseized for program service at any time. The operation of an output selection key on the test position also lights a "test in progress" lamp corresponding to the output circuit on the main control panel. These lamps have novelty caps and are located on the main control panel in a horizontal row just below the no-service lamps. One of these lamps lights at any time the associated key in any test position is operated so that, in addition to indicating an output circuit under test, it may be used to indicate that the test position wishes to obtain an output circuit not yet released for test.

Remote Switching Control Equipment

As explained earlier, there are many instances where a TOC in order to establish a particular connection, is required to operate one or more i-f switches in a remote radio tower or coaxial terminal as well as video switches in the TOC. Where this type of operation is required, one portion of the control panel can be assigned to the operation of the i-f or coaxial switches over a remote-control system and another portion to the local video switches. Either switching system can be operated independently on an "individual execute" basis or switches of both systems may be operated simultaneously as part of the same salvo.

The new switching control panel has been arranged to work either with existing remote switching control systems or with a new remote-control switching system designed especially to function with the new control panel. The existing systems operate the remotely located switches either over direct-current circuits or by means of sequential signaling over a voice-frequency circuit such as a call wire. No indication is given to the control center as to whether the correct switch has been operated. The new remote-control system not only orders the operation of a remotely located switch, but checks to see that the proper switch has been selected and acknowledges its operation by the lighting of associated lights at the control TOC.

The new remote-control arrangement uses a pulse-length code frequency shift system employing *43A1* carrier telegraph terminals at the transmitting, or control, end of the system and at each receiving point. The incoming and outgoing circuits at each remote point are represented by horizontals and verticals on the main control panel at the TOC and are preselected by the operation of the proper buttons, in the manner described earlier The operation of these buttons results in sending pulse-length code orders to each remote point. Only one remote station accepts a particular set of preselection orders, however, depending on the code sent. At this station the preselection is made and checked, and if the received order has been correctly handled, an acknowledgment signal is sent back to the TOC. When this acknowledgment order has been received, the lamps at the coordinate point, represented by the operated input and output buttons, light. This may be as long as 2 seconds after the buttons are pushed initially.

At the remote point, crossbar switch equipment is provided, which, under the control of the orders from the remote system, furnishes the operating paths for the remote i-f switches. A control panel at each remote point permits local control in case of emergency. Normally, this panel is not in use and its lamps do not light as remote orders are received. When switched to local control, however, the lamps on the remote panel indicate preselections and executions in the usual manner. Any order sent from the control panel at the TOC will automatically restore the local panel to remote operation.

Conclusions

The new video switching equipment together with the associated new monitoring and testing facilities are part of an over-all integrated plan for furnishing broad-band transmission facilities. These may be improved, in accordance with the requirements of future developments in the color and theater television fields, up to bandwidths of 0–10 mc. The new switching control equipment offers safer and more flexible control of switching facilities, and it is expected that these will be widely used for television network services furnished by the Bell System.

Radio-Frequency Transmission Line Engineering

R. F. LEWIS
NONMEMBER AIEE

IN THE development of a transmission line, the engineer attempts to establish a criterion for minimum attenuation; minimum discontinuities, or minimum VSWR (voltage standing wave ratio); maximum power handling capability; maximum frequency range; ease of manufacture; and the ability to attach connectors having consistent and reliable electrical and mechanical qualities. This paper will discuss the development of a semiflexible, semisolid dielectric coaxial transmission line and its associated connectors, with particular reference to obtaining minimum discontinuities. A cycling method of measurement is used to ensure complete frequency coverage as well as to distinguish discontinuities between connectors and those inherent in the coaxial transmission line. The first part of the paper will consider the general aspects of the coaxial transmission line and its associated connectors; the second part will discuss a specific consideration of the problem of analyzing cycling traces in determining over-all discontinuity effects.

General Considerations

The general axiom accepted in the development of semiflexible semisolid dielectric transmission line is that the metals have excellent conductivity qualities and that they be sufficiently malleable to allow bending to a given minimum radius. The dielectric also must have good mechanical and electrical qualities; mechanically, it must support the inner conductor in a concentric position in any configuration, at least to the minimum bending radius. The problem is to choose sufficient dielectric material to keep the inner conductor concentric with the outer for all permissible configurations, yet not to the extent of causing excessive attenuation due to the dielectric. A desirable feature is to have all sizes of cable for a given characteristic impedance designed in the same manner. This feature adds to the ease of manufacture, and in particular it eases the problem of preparing the transmission line for low VSWR connectors.

In designing transmission lines for maximum frequency response, experience has shown that minimum discontinuities can be obtained from the solid-dielectric or continuous-dielectric contact type of transmission lines at the expense of high attenuation; and that minimum attenuation is obtained in discrete insulator-supported air dielectric transmission line at the expense of large discontinuities over relatively narrow frequency bands. The characteristics of semisolid transmission line places it between the solid and air dielectric types.

Spir-O-Line is a semiflexible semisolid dielectric transmission line developed and marketed by the company with which the author is associated. It is composed of a copper inner conductor and aluminum outer conductor. Six high-density polyethylene tubes are symmetrically placed about the inner conductor to make it concentric with the outer conductor. Sufficient pressure results from the sinking-down process of the outer conductor to ensure constant and consistent contact of the dielectric tubes on both inner and outer conductors. Fig. 1 shows a cross section of the 1/2-, 7/8-, $1^5/_8$-, and $3^1/_8$-

inch 50-ohm Spir-O-Line. It is felt that this construction is a very close approach to a continuous dielectric wherein all portions of the transmission line have the same velocity of propagation. This type of construction permits all sizes to be made in the same manner; thus all sizes have the same capacity per unit length, and therefore the same phase velocity. This feature aids in the ability to design connectors since the dielectric interface effect will be the same for all cable sizes.

A further advantage of this type of construction is that it permits Teflon tubes to be used as the dielectric, whereby temperature rating is increased approximately two and one half times.

The transmission line should be so designed that standard hardware tools can be employed in preparing the ends for various connectors. Certainly, if such is the case only the knowledge of such tools is required to dress the line for connectors. Further, it is desirable to be able to cut the dielectric perpendicular to the axis of the conductors. The tools for trimming the transmission line are shown in Fig. 2, where it may be seen that the only tools necessary are tube cutter, razor knife, measuring tape, file, and wrenches. The feature of cutting the dielectric perpendicular to the axis is particularly desirable in eliminating discontinuities in the high-frequency spectrum, or in the event that it is desired to have many lengths where each length shall have the same electrical characteristics.

All connectors developed for use with Spir-O-Line have the same basic grip design where they couple to the sheath, and are known commercially as Spir-O-Lok connectors. A typical cutaway of a Spir-O-Lok connector is shown in Fig. 3.

Two mating tapered sleeves achieve a positive grip. The holding sleeve has grooves machined at an angle designed to shear into the cable sheath to a predetermined depth. This depth multi-

plied by the number of grooves will equal the thickness of the sheath; thus a Spir-O-Line connector when properly attached to the outer sheath causes no distortion to it, and the connector has a tensile strength equal to the sheath itself.

All Spir-O-Line connectors have Teflon insulation, thereby eliminating confusion in their use with low-temperature or high-temperature cables.

Fig. 7. Test equipment

There is always a great deal of interest in how the different parameters of a transmission line and its associated connectors are determined at radio frequencies. A brief description of a cycling method over a limited frequency range will be given.

When a radio wave is passed through a directional coupler, the directional coupler will sample the forward wave as well as a reflected wave, if present. If, now, a given length of transmission line is connected to the directional coupler where the far end is terminated in the characteristic impedance of the transmission line, then, under ideal conditions there should be no reflected component. If, however, there are discontinuities or mismatches either at the terminal, or within the transmission line there will be a reflected component in the directional coupler. If the radio frequency is allowed to be continuously swept over a given range, then discontinuities due to the terminal end will produce a periodic response. It is evident that many combinations of discontinuities and transmission line lengths can be arranged to give periodic cycling. For example, with matched connectors, and a good terminal load equal to the characteristic impedance of the transmission line, there should be evidence of the cycling rate due only to small discontinuities at the input and terminal ends with perhaps some evidence of random cycling due to the transmission line. Fig. 4 is a schematic diagram of the equipment used in recording the VSWR cycling of Spir-O-Line transmission line and connector assemblies.

Figs. 5(A), (B), and (C) indicate the magnitude of the VSWR, and the cycling rate of representative samples of 1/2-, 7/8-, and $1^5/_8$-inch Spir-O-Line. Since the velocity of propagation of the different diameter lines is equal, the cycling rates of equal lengths are the same. It is important to observe that the magnitude of the VSWR is fairly constant, and the cycling is due to the ends of the transmission line or the end connector and load. This type of cycling indicates that the transmission line is free from internal discontinuities.

Accurate measurements of the cycling rate are useful in determining the electrical length of a transmission line, and also its effective dielectric constant. Fig. 6 shows a cycling trace of a 20-ft (foot) sample of $1^5/_8$-inch Spir-O-Line. Note that the cycling rate is now well defined, but the peaks of the VSWR are higher than those shown in Fig. 5(C). This is due to reduced attenuation in the shorter length, thereby allowing a greater amount of the reflected component at the terminal to appear at the directional coupler.

This suggests a convenient method for testing connectors. Let us select a length of transmission line sufficiently short to reduce the attenuation to a negligible quantity, but a length to produce a convenient cycling rate. Suppose that a long length of transmission line is used which masks the terminal discontinuities as a load for a short length of transmission line of the same size. If the same input and output connections are maintained, and the short length with the sample connectors are placed in series with the long length, effects should be seen of the long-length cycling superimposed on the

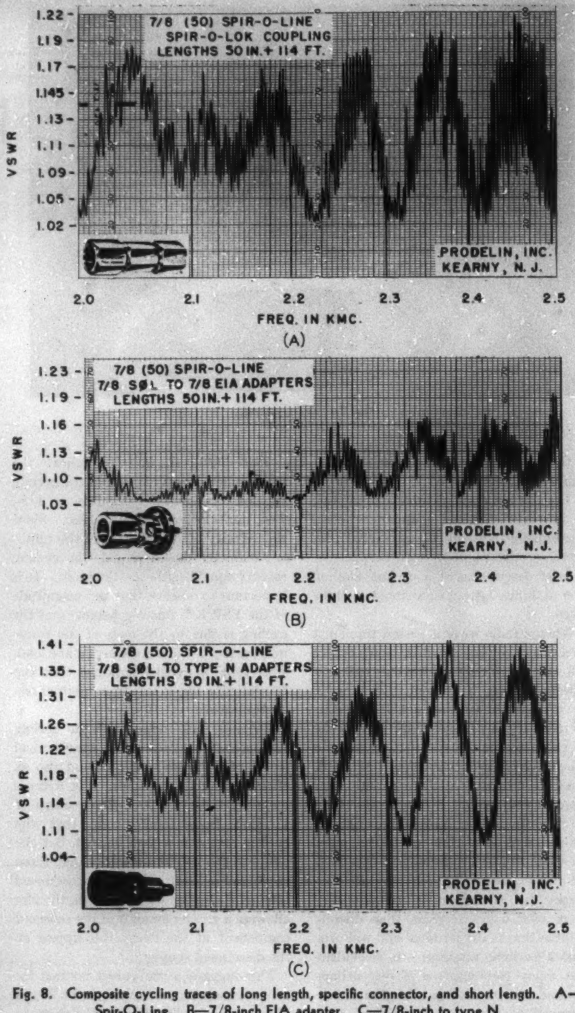

Fig. 8. Composite cycling traces of long length, specific connector, and short length. A—Spir-O-Line. B—7/8-inch EIA adapter. C—7/8-inch to type N

short-length cycling. The test arrangement for the long length, sample connectors, and short length is shown in Fig. 7. Figs. 8(A), (B), and (C) show the result of tests performed on 7/8-inch cables for a 7/8-inch Spir-O-Line coupling, two 7/8-inch Spir-O-Line to 7/8-inch *EIA*, and two 7/8-inch Spir-O-Line to type *N* connectors respectively.

In the foregoing is presented a method with rapid continuous frequency coverage for observing discontinuities in either the coaxial transmission line, the connectors, or both.

Specific Considerations

The development of Spir-O-Line presented the usual headaches. A description of one of these difficulties may be of interest as to how the condition arose, and what was done to remedy it. In the early stages of Spir-O-Line development the measurements extended up to 1,000 mc (megacycles). Above 1,000-mc measurements seemed to be somewhat erratic, and were passed over as experimental errors in measurement. However, as our measuring techniques improved, we were soon able to determine that in one particular size some of the erratic measurements were occurring with a regularity which demanded attention. Our observations showed that cycling could not be due to the load or connectors since the length of the transmission line had sufficient loss to mask their discontinuities. We were left with the rather disturbing fact that we might have the problem of manufacturing tolerance. Or had some manufacturing procedure been introduced which could cause the observed discontinuities? If the load should be eliminated, the discontinuities must exist due to some variables within the line itself. The first variable generally associated with discontinuities is the change in capacity in portions of line. Another variable that cannot be neglected is that of attenuation. Let us see if these variables are dependent on each other, and if possible to what extent they are dependent to the extent of causing troublesome cycling.

Table I. Transfer Parameters

Transmission Line	Noise
x = meter	t = time, sec
$C(x)$ = farad	$I(t)$ = amplitude
S = cycles per meter, "sinuosity"	f = frequency in cycles/sec
$w(s)$ = power spectrum	$w(f)$ = power spectrum
Mean square deviation, farads²	mean square deviation, amperes²
$(\overline{C}(x))^2=\int_0^\infty w(s)ds$	$(\overline{I}(t))^2=\int_0^\infty w(f)df$
$C(x)=\sum_{n=1}^{\infty} C_n \cos(2\pi S_n x+\phi_n)$	$I(t)=\sum_{n=1}^{\infty} C_n \cos(2\pi f_n t+\phi_n)$
$\overline{C}_n^2=2w(S_n)\Delta s$	$\overline{C}_n^2=2w(f_n)\Delta f$
$S_n=n\Delta s$	$f_n=n\Delta f$

It seems convenient to borrow part of the work of Rice[1] on the problem of random noise and attempt to convert a few of the noise parameters to fit present needs. Rather than carry through all of the derivations, we will simply state the change in parameters, and show the end result. Since the work of Rice was carried through from a power spectrum basis, the same will be done here; see Table I, a table of transfer parameters. When these transfer parameters are inserted, the following equation results:

$$|(I_r)^2|=\frac{\pi}{16}\frac{1}{\lambda_0}\left(\frac{f_0}{f_b-f_a}\right)\left(\frac{C(x)}{C}\right)^2\frac{1}{\alpha}$$

Vol.
Pt. 1
1960

where

I_r = reflected current due to discontinuities expressed as 100% of incident current

λ_0 = wavelength at center band of discontinuities, meters

f_0 = frequency at center band of discontinuities, mc/sec (mc per second)

$f_b - f_a$ = frequency range of discontinuities, mc/sec

$C(x)$ = capacity discontinuity, farads/meter

C = capacity between inner and outer conductor under ideal conditions, farads/meter

α = attenuation, nepers/meter

In this equation such terms as $(1-\epsilon^{-4\alpha l})$ were allowed to approach unity, which is permissible when long lengths in the microwave spectrum are considered.

After reviewing some of our observations, the question will be considered as to how to use the equation to determine such quantities as $[C(x)/C]^2$ and I_r. Fig. 9(A) shows a 20-ft section cut from sample *A* and cycled over a range from 2.0 to 2.5 kmc (kilomegacycles). Note a slight peak at 2.05 kmc having a VSWR of 1.19, and another slight peak at 2.35 kmc of some 1.13 VSWR. Consider the first peak. The following quantities are known:

f_0 = 2,050 mc/sec
λ_0 = 0.146 meters
$f_b - f_a$ = 25 mc/sec
$C = 77.3 \times 10^{-12}$ *fd/m*, a measured value
$1/\alpha = 1.28 \times 10^3$, a measured value taken on 100-ft sample
VSWR = 1.19
I_r = 0.0825

Inserting these values in the equation and determining the ratio $[C(x)/C]^2$ yields

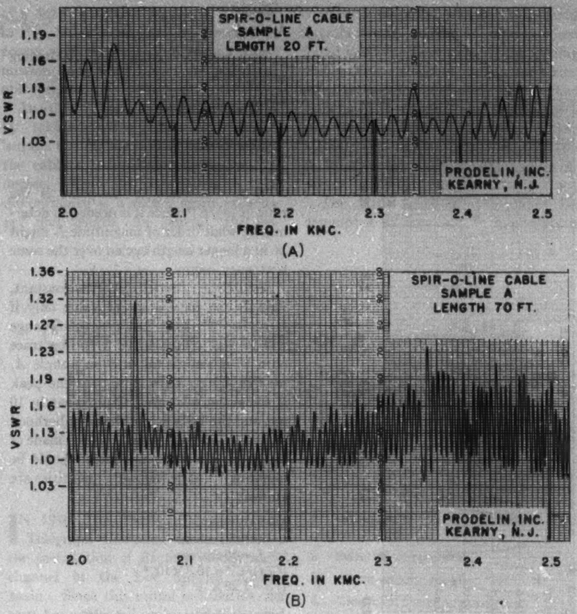

Fig. 9. Sections cut from sample A and cycled from 2.0 to 2.5 kmc. A—20-ft section. B—70-ft section

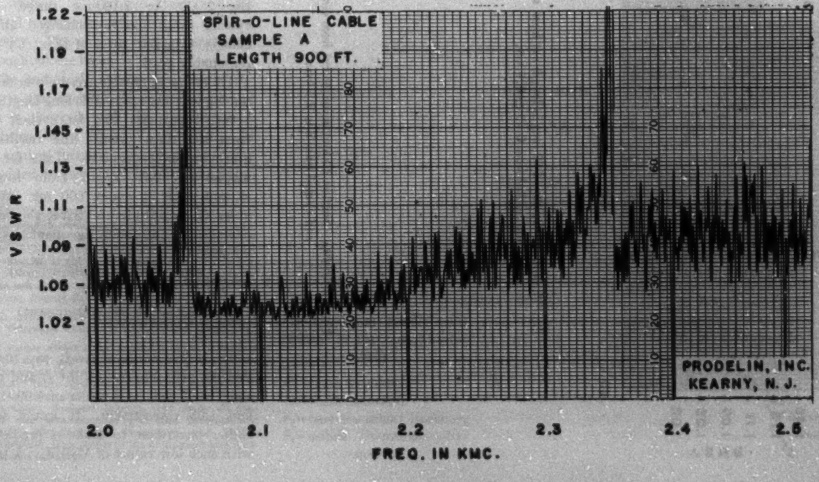
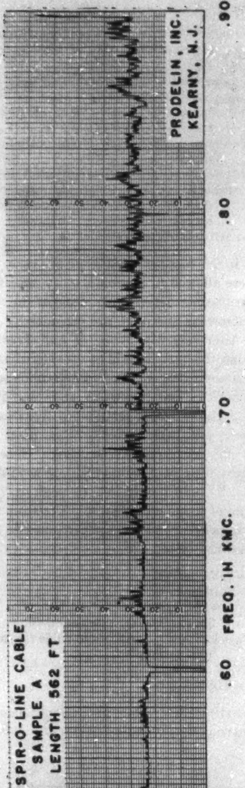
Fig. 10 (below). Section 900 feet in length cut from sample A and cycled from 2.0 to 2.5 kmc





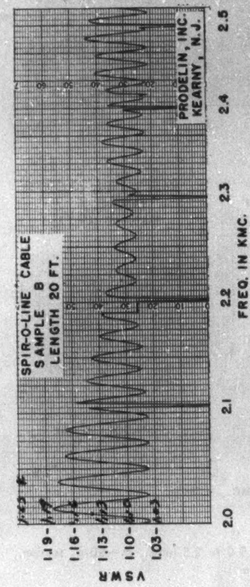


Fig. 11 (above). Section 562 feet in length cut from sample A and cycled from 0.45 to 0.9 kmc

Fig. 12 (right). Section 20 feet in length cut from sample B and cycled from 2 to 2.5 kmc

$$\left(\frac{C(x)}{C}\right)^2=16.3\times10^{-8}$$

Reducing the equation and substituting for C yields

$$\frac{C(x)}{C}=4.02\times10^{-4}$$

$$C(x)=4.02\times10^{-4}\times77.3\times10^{-12}$$

$$C(x)=0.031\times10^{-12}\ fd/m$$

Of more interest at this point is the ratio $[C(x)/C]^2$, since it is needed in determining what order of magnitude I_r might be in a longer length cycled over the same frequency range.

Should the ratio $[C(x)/C]^2$ be constant, then I_r can have a larger value only if f_b-f_a becomes less; i.e., the cycling range will be less. To observe a cycling trace on a 70-ft sample taken from sample A, see Fig. 9(B). Here, note that the peak is somewhat narrower, approximately 10 mc, and the VSWR is in the neighborhood of 1.32. If a good guess has been made of the ratio $[C(x)/C]^2$, agreement should be found in I_r. The following quantities are known:

$f_0=2{,}050$ mc/sec
$\lambda_0=0.146$ meters
$f_b-f_a=10$ mc/sec
$[C(x)/C]^2=16.3\times10^{-8}$
$1/\alpha=1.28\times10^{-3}$

Putting these values in the equation yields $I_r=0.131$, or a VSWR of 1.32. This seems too good to be true!

If lengths much greater than 70 ft are cycled, and the cycling range of the peak remains close to 10 mc, can we feel reasonably sure that we have made a good guess of the ratio $[C(x)/C]^2$? Fig. 10 shows a trace of 900 feet of sample A including the 2,000- to 2,100-mc range. The cycling range has not changed appreciably; thus our guess of $[C(x)/C]^2$ was reasonably good.

This same approach may help in determining whether reasonable long lengths at lower frequencies can be cycled, and from the trace predict the results at much higher frequencies. Take for example a 562-ft length from sample A and cycle it about 500 mc. What order of magnitude of VSWR should be observed? The following quantities are known:

$f_0=500$ mc/sec
$\lambda_0=0.6$ meters
$1/\alpha=2.64\times10^3$ (from measurement)
$[C(x)/C]^2=16.3\times10^{-8}$

Try a few values of f_b-f_a, say 10, 20, and 40 mc. The values for I_r and thus the VSWR will be in order of 1.09, 1.07, and 1.05 respectively. It would seem rather hazardous to make a prediction with such low values of VSWR. A trace of a 562-ft length of sample *A* is shown in Fig. 11, and one may be tempted to accept such a trace as indicating a transmission line as not possessing objectionable peaks.

An attempt has been made to show that by taking cycling traces on various lengths the capacity discontinuity within the cable can be determined to a fair degree. It has also been shown that the discontinuity is a rather small capacity per unit length. In general, the discontinuity discussed was due to a small manufacturing tolerance which, when found and remedied, reduced the cycling within the transmission line to a minimum. After proper manufacturing changes had been made, cycling traces were taken on a new production sample, *B*. Figs. 12 and 5(B) show such traces on a 20-ft and a 114-ft length. No cycling peaks were observed in either section.

The latter part of the paper has attempted to show how it is possible to overlook troublesome discontinuities in samples of short lengths at high frequencies, or in long sample lengths at lower frequencies. The theory was injected to show order of magnitudes which might be expected for the various dependent variables.

Centralized Testing of a Very-High-Frequency Mobile Radio System

D. L. MacDONALD
ASSOCIATE MEMBER AIEE

In 1946 The Pacific Telephone and Telegraph Company made plans for the installation of its first mobile radio channel in the Los Angeles (Calif.) basin. Since this initial installation the area has evidenced an insatiable demand for this type of service. By the end of 1960 the telephone companies serving the area plan to have all available channels in service. Fig. 1 is a block schematic of a typical channel in the Los Angeles area.

In the company's Los Angeles System, all base transmitters are located either at Mt. Wilson or Verdugo Peak and all control terminals are located in Los Angeles. The receiver sites are scattered throughout the basin.

The technical operator for these channels is stationed at the control terminal and is charged with the usual responsibilities of a licensed operator. In the control terminal equipment has been provided to perform the following functions:

1. Off-on switching of the remote transmitter.
2. Selection of receivers.
3. Alarm circuits for the transmitter.
4. Control of the test transmitter.
5. Audio level control for transmitter and receiver.

In the initial design of these channels, a frequency monitor was provided which continuously monitored the transmitter. This device gave an alarm and connected the transmitter to a dummy load whenever the transmitter drifted too far off frequency. One major trouble developed immediately. The monitors were less stable than the transmitters. As the stability of transmitters improved rapidly the need for monitors apparently disappeared and they were no longer installed. In retrospect, it is evident that some means of monitoring other than aural should have been retained.

The problem which now arises is that of a radio spectrum crowded beyond anything believable 10 years ago. Errors in operation which could be accepted then are intolerable today. Portable frequency meters now have a precision that 10 years ago could only be achieved in laboratory instruments, and still they are not good enough.

In Los Angeles this problem is further complicated by the topography of the area. Mt. Wilson has a height above average terrain of 2,800 feet as defined

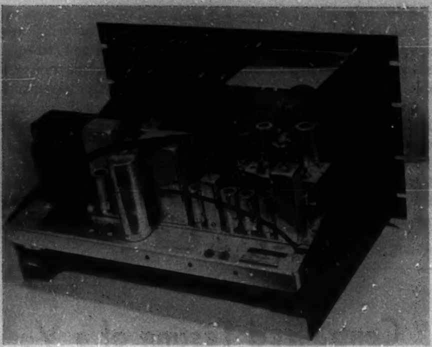

Fig. 3. Crystal turret mounted in receiver

by Federal Communications Commission rules.[1] From this standpoint it is an ideal site for the location of radio transmitting and receiving equipment. However, the same natural laws which govern site selection for mobile radio also apply to site selection for frequency-modulation and television entertainment broadcast purposes. Consequently, most major frequency-modulation and all television stations have located their transmitters on Mt. Wilson. The Pacific Telephone and Telegraph Company therefore finds it necessary to operate and maintain mobile radio equipment consisting of transmitters with comparatively modest power output and receivers of high sensitivity in a radio-frequency (r-f) field of high intensity.

In view of the increased demand for accuracy in measurement of frequency and deviation and the high r-f levels existing on Mt. Wilson and Verdugo Peak, a decision was made to attempt no more of these measurements at the transmitter or receiver sites, but to use centralized measuring techniques for maintenance. By making these measurements at a single location, they can be made by one set of instruments. This eliminates one source of error and allows intensive training to be given a few technicians who, through daily practice, will develop a high degree of proficiency.

Following a review of commercial equipment, it was apparent that no single "package" could be purchased which would satisfy all requirements and the design of a complete installation was begun.

To develop the program in an orderly way, the following general specifications were set up:

1. The design of the installation must be such that it could be readily changed.
2. A means of calibrating all instruments must be included.
3. Making the measurements must require a minimum of time.
4. Frequency measurements are required in the 35-, 43-, 152-, 157-, 454-, and 459-mc (megacycle) range.
5. Measurement must be made on transmitters in the same room as well as those 25 to 30 miles away.
6. Measurement of the frequency modulation (deviation) of the transmitters is required.
7. Initially, only base station equipment will be measured; eventually, mobile units will also be measured from this point.
8. Since a consistent, usable signal from stations *WWV* or *WWVH* cannot be received during normal working hours in downtown Los Angeles, any instrument requiring reception of *WWV* at the time the measurement is made cannot be considered.

The test bay and methods to be described are suitable for use in any frequency-modulation mobile radio system. They are economical only when applied to systems having a comparatively large number of transmitters and which are closely integrated or where access to the transmitter is difficult. The bay itself contains equipment to make frequency and deviation measurements on remote transmitters with an accuracy which exceeds Federal Communications Commission requirements by better than 100%. It contains all equipment necessary to calibrate the instruments. In addition, aural and visual means may be employed to obtain an estimate of the quality of the output of the remote transmitters.

Test Bay Equipment

The heart of the system consists of three communication receivers modified to permit reception of as many as 12 crystal-controlled channels on any one receiver. Thus, by using only three receivers 36 crystal-controlled channels are available.

The device that makes this possible is a 12-position crystal turret designed and manufactured by International Crystal Manufacturing Company. The specifications for the turret as drawn up by The Pacific Telephone and Telegraph Company impose the following requirements:

1. There must be provision for 12 crystal-controlled channels.
2. A minimum modification of the receiver should be necessary.
3. It should be as nearly a plug-in unit as possible.
4. A front panel control should be provided to shift the frequency of the selected crystal channel.
5. The stability and sensitivity of the receiver using this unit should approximate that of the standard communication receiver.

A second modification of these receivers consists of the addition of a 390-kc oscillator and mixer. This is used in making measurements of the frequency modulation (deviation) of the remote transmitters. It is also manufactured by International Crystal Manufacturing Company. Its use is discussed in the paragraphs on deviation measurement.

The first of the crystal turrets to be delivered, shown in Fig. 2, is for use in a 450-mc General Electric Company receiver. A padder control visible on the front panel allows the discriminator of

the receiver to be "zeroed" on a carrier that is displaced ±1.5 kc from the center crystal frequency. While this range is sufficient to allow the device to be used, its usefulness would be much greater if the range were extended.

Fig. 3 shows the turret installed in a receiver. Also visible are two meters mounted on the front panel.

The first of these meters, a conventional 0–500 microammeter, is connected to the first limiter test jack and to the last intermediate-frequency (i-f) output. With this arrangement it is possible to obtain a relative indication of the output of the remote transmitter. This is not an absolute indication of power out, but by noting the first limiter reading when the transmitter is putting out its rated power and the reading when the power is reduced 3 decibels, a useful indication of the power output is available, provided the sensitivity of the receiver remains constant. A means of checking this is provided in the test bay.

The second of the two meters, a 50–0–50 microammeter connected to the discriminator test jack, is used when making frequency checks.

Frequency measurements of the remote transmitter are made using one of the receivers described and an *FM-6* Gertsch frequency meter. The *FM-6* has been modified by substituting a new type of crystal oven which is expected to substantially improve the already excellent performance of the instrument. The primary advantage of the new oven is the elimination of the off-on effect of the oven thermostat. The new oven has a proportional control.

The third major item of equipment included in the test bay is a standard oscilloscope. The only major requirement is that the oscilloscope have a d-c input. There is no requirement for wide-band operation. The instrument selected for this installation is manufactured by the Hewlett-Packard Corporation and is used with no modification.

A *WWV* receiver is provided in the bay for calibration of the *FM-6*. Several methods of obtaining a "zero beat" indication are available. There is a meter in the receiver which can be used, the beat may be checked audibly, or an oscilloscope presentation may be used.

A standard signal generator manufactured by Marconi is included in the package. It is used for servicing and as a means of measuring the sensitivity of the receivers. The remaining items of equipment in the test bay consist of several attenuators and coaxial switches which are all of a standard design.

In order to allow flexibility in the use of the bay, the inputs and outputs of all equipments are jack-terminated. This will permit the addition of other items of test equipment which may become necessary in the future.

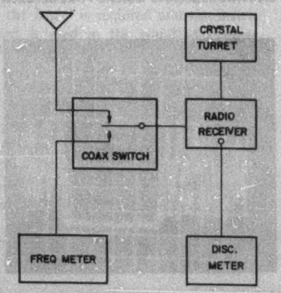

Fig. 4. Block schematic of interconnections for frequency measurement using discriminator

Operations

The frequency measurements are made by using the appropriate receiver and the *FM-6*. The block schematic of the connections is shown in Fig. 4. In operation the input of the receiver is connected through a coaxial switch to an antenna. The switch on the crystal selector is then set to the correct channel. By means of the padder the crystal frequency is adjusted until the discriminator meter reads zero when receiving a signal from the transmitter which is to be measured. The *FM-6* is then connected to the input of the receiver and adjusted until the discriminator meter again reads zero. The frequency may then be read from the *FM-6* after using the proper multiplier.

To avoid the necessity of the operating forces performing any computation, tables similar to Table I have been prepared for all channel frequencies.

Inasmuch as this method is a signal substitution method, the receiver has no influence upon the accuracy of the measurement and it is not necessary to calibrate it in any way.

The first method of deviation measurement to be described has been known for several years but not widely used for several reasons.[2] Since use is made of a receiver discriminator the possibility of the presence of amplitude modulation (AM) cannot be disregarded. With modern high-quality design of limiter and discriminator circuits, the AM suppression of the receiver becomes high enough to permit their use in this way,

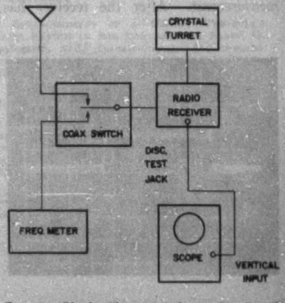

Fig. 5. Block schematic of interconnection for deviation and frequency measurements using oscilloscope

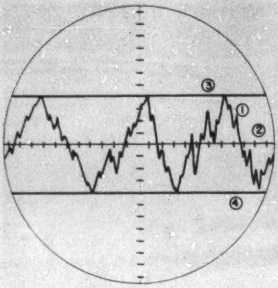

Fig. 6. Typical display of discriminator voltages

1—Modulated r-f signal
2—Unmodulated signal from FM-6 at center frequency
3—Unmodulated signal from FM-6 adjusted to measure upward peak deviation
4—Unmodulated signal from FM-6 adjusted to measure downward peak deviation

if the receiver limiters and discriminator are properly maintained, and a signal level high enough to saturate both limiters can be received.[3] The connections required for this method of deviation measurement are shown in Fig. 5.

Fig. 6 presents a display which is typical of the traces observed when an oscilloscope is connected as in Fig. 5. Line *1* is the trace which represents the modulated signal. Line *2* is the straight line produced by an unmodulated signal from the *FM-6*. Lines *3* and *4* are the traces obtained from the *FM-6* when its frequency has been adjusted to measure the peak deviation.

The initial steps in making the deviation measurement are identical with those taken in making a frequency measurement. After the receiver has been adjusted to give zero discriminator on the unmodulated signal from the transmitter, the controls of the oscilloscope are adjusted to center the straight line on the oscilloscope tube. The input of the receiver is then shifted from the antenna to the *FM-6* and the *FM-6* adjusted to give a straight line at the center of the oscilloscope tube. The input of the receiver is again shifted to the antenna, modulation applied to the transmitter, and the peaks of the voltage display marked on the cathode-ray tube. The input of the receiver is then moved to the *FM-6* and the output of the *FM-6* shifted in frequency until the line from the *FM-6* coincides with the previously marked peaks. At this time the frequency of the *FM-6* is read. The difference between this frequency and the center frequency is the instantaneous deviation of the transmitter.

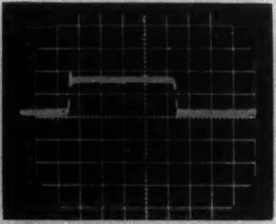

Fig. 7. Center trace from FM-6 adjusted to produce 454.750 mc. Outside trace from transmitter is 1.97 kc low in frequency

A more refined method would be to drive the coaxial switch at a 60-cycle rate, thus displaying the trace from the remote transmitter and the *FM-6* simultaneously. This is the method which is used in the installation being described. Both positive and negative modulation peaks may be measured.

The accuracy of this method was established by making comparisons with measurements made using the Bessel function method of measurement.[4] These measurements indicate that in actual performance on fixed transmitters an accuracy of 7 to 8% can be achieved at the frequencies and deviations being measured.

Figs. 7–11 are oscillograms taken at the test bay. The transmitter being observed was located at Mt. Wilson and operated on an assigned carrier frequency of 454.75 mc. In these figures the trace in the center is from the *FM-6*. The trace at either side is that from the remote transmitter. The vertical distance between the two traces represents the frequency difference between the *FM-6* and the transmitter.

Fig. 7 is the oscillogram obtained when making a frequency measurement. The connections are as shown in Fig. 5. In this specific case the transmitter was 1.97 kc off frequency. Fig. 8 is the oscillogram obtained when the transmitter was adjusted to the correct frequency. This adjustment was confirmed by simultaneous measurement made at the transmitter site. The difference between the two measurements was less than 0.0001%.

with the trace from the *FM-6*. The *FM-6* is displaced 11 kc from the transmitter center frequency. This is the desired deviation. Fig. 11 shows the transmitter after being adjusted to give the desired 11-kc deviation.

A second method of measuring deviation has been provided which makes use of the Gertsch *DM-3* modulation meter and the appropriate one of the receivers mentioned previously. These receivers have been equipped with an additional crystal oscillator manufactured to company specifications which, when mixed with the 290-kc intermediate frequency of the receivers, gives an output at 100 kc. This may be fed directly into the Gertsch *DM-3*. Since this instrument is essentially a 100-kc receiver no modification of the *DM-3* is required and the instrument is used in the standard manner. The frequency of the difference oscillator in the receiver may be shifted as required to satisfy the "frequency set" instructions of the *DM-3*. This equipment has an accuracy of ±5% of the full-scale induction.

The *DM-3* was originally provided to enable measurements to be made on the test transmitters which are located on the same floor as the test bay. To enable frequency and deviation measurements to be made on these transmitters, the r-f transmission line to the antenna is tapped and the branch circuit run through a Dumont attenuator to a jack in the test bay. A patch connection can be made between this jack and the *FM-6* and *DM-3* to allow frequency and deviation measurements to be made on the test transmitters. These measurements are all made in the standard manner.

A third method of measuring deviation of the remote transmitters has recently been suggested and is being given consideration. The proposed method will achieve an accuracy of about ±3% regardless of the frequency band. This method consists of shifting the frequency of the low i-f oscillator. An oscilloscope is connected to the discriminator output as in the first method described. The rest of the procedure is similar to that of the first method with the exception of the point of injection of the variable frequency. If the need for further improvement in accuracy is required, this method will be investigated.

One common defect in a phase-modulated transmitter is the presence of an excessive amount of amplitude modulation of the carrier. This is easily detected by reducing the signal strength of the incoming carrier until it is well below the saturation point of the first limiter. If the oscilloscope is connected to the first limiter jack, any amplitude modulation which may be present is readily detected.

Other tests of the remote and local transmitters will undoubtedly be developed as experience is gained with the equipment.

Fig. 12 is the complete installation, and Fig. 13 shows test bay in operation.

Interstitial Channels for Doubling TD-2 Radio System Capacity

H. E. CURTIS
NONMEMBER AIEE

T. R. D. COLLINS

B. C. JAMISON
ASSOCIATE MEMBER AIEE

THE TD-2 microwave radio relay system at present provides six broad-band channels in each direction of transmission in the frequency band between 3,700 and 4,200 mc (megacycles), each channel being capable of transmitting several hundred voice circuits.[1] This paper describes arrangements and some of the technical problems involved whereby the number of broad-band channels can be doubled with no significant penalty to the existing channels.

Use and Growth of TD-2 Systems

TD-2 routes were installed at a rapid rate after the first *TD-2* system was placed in service between New York and Chicago in September 1950. During the following 8 years there was a large demand for additional intercity television, message, and private line circuits to meet the expanding business requirements. Because the *TD-2* system gives excellent transmission performance and also has economic advantages over other systems, especially where new routes are needed, a large part of the additional Bell System intercity facilities provided during the 8-year period consisted of *TD-2* channels.

Long video network circuits were obtained almost entirely from *TD-2* channels, and side connections to the backbone video networks were usually *TD-2* facilities. These channels were also widely used to obtain intercity voice and private line circuits. By using the type *L* carrier terminal equipment, up to 600-voice circuits were assigned to one *TD-2* radio channel. This technique uses base-band frequencies only up to about 3 mc for the 600-voice circuits, although the base-band capability of the *TD-2* channel is considerably higher. It was found, however, that when the *TD-2* channel was loaded with more than 600-voice circuits, the noise and intermodulation distortion on the voice circuits were often too high to meet circuit objectives.

By the end of 1958 a microwave network had been established which connected together most of the large cities in the United States and Canada, as shown in Fig. 1. This network was comprised of over 30,000 *TD-2* route miles between some 1,300 individual stations scattered throughout the country. These routes provided about 67,000 miles of intercity television circuits and about 20 million telephone circuit miles. The *TD-2* radio channels installed over the approximately 8-year period comprised about 80% of all intercity video and about 35% of all long-distance telephone circuit mileage in the Bell System plant.

Need for Additional TD-2 Channels

Before 1958, many of the existing backbone routes had all six channels in at least one direction of transmission either in service or planned for service; it was becoming increasingly apparent that six radio channels would not be adequate to take care of the wide-band channel needs and that construction of parallel backbone routes would be necessary.

Television requirements for circuits resulted in some routes with more channels in service in one direction of transmission than in the other. These unbalanced requirements, together with other needs for 2-way circuits, resulted in a number of routes soon reaching their capacities in at least one direction of transmission.

By constructing new *TD-2* routes, additional *TD-2* channels could be obtained in some circumstances, and this was done where practicable. Such new routes required new radio towers and buildings to house the equipment and power plants, which proved to be expensive, particularly where the geographical length of the routes had to be increased in order to avoid interference with regard to existing routes.

Other radio systems which would use frequencies in other common carrier bands and which would give high-quality circuits meeting long-distance transmission requirements were not yet available. The new *TH* microwave system is expected to be available for service about the end of 1960, and each individual *TH* broad-band channel will provide about three times the circuit capacity of a *TD-2* channel.[2] The *TH* channels will usually be installed along routes where their high telephone circuit capacity is needed and where higher costs per radio channel will be justified.

The possibility of adding interstitial channels between the regular *TD-2* channels had been considered in view of the unused 20-mc interstitial frequency space available between channels, but a study revealed that it was not practicable with the delay lens antenna and associated rectangular waveguide system.[3] Starting in 1955, the horn-reflector antenna with the associated circular waveguide system became standard for all new installations, and it then became possible to cross-polarize signals between adjacent *TD-2* channels to obtain additional discrimination between adjacent channel signals.[4] By the beginning of 1958, the necessity of providing more circuits along fully loaded *TD-2* routes resulted in the investigation of the feasibility of adding interstitial channels on these routes.

The TD-2 System

The *TD-2* system has been described extensively in the literature, but for the purpose of this paper, certain features will be reviewed briefly.[5] Each base-band channel has a frequency capacity extending from about 30 cycles to 6 to 10 mc per second depending on the length of the system. Frequency modulation is employed to raise each channel to an intermediate frequency (i-f) of 70 mc, from which each is shifted to its proper location in the microwave frequency spectrum. The frequency plan for a typical repeater point is shown in Fig. 2.

Channels are so assigned that there is always a spacing of 40 mc between the carrier of any transmitter operating in a given direction and the carrier of the nearest receiver operating in the same direction. Since each frequency modulation (FM) channel potentially occupies a total band of 20 mc, there is a total of six interstitial bands of 20 mc each in each direction in which no significant quantity of energy is present.

Successful operation of the *TD-2* system requires freedom from interference between microwave channels under all reasonable conditions. The potential interference which does exist arises from radio-frequency (r-f) coupling paths.

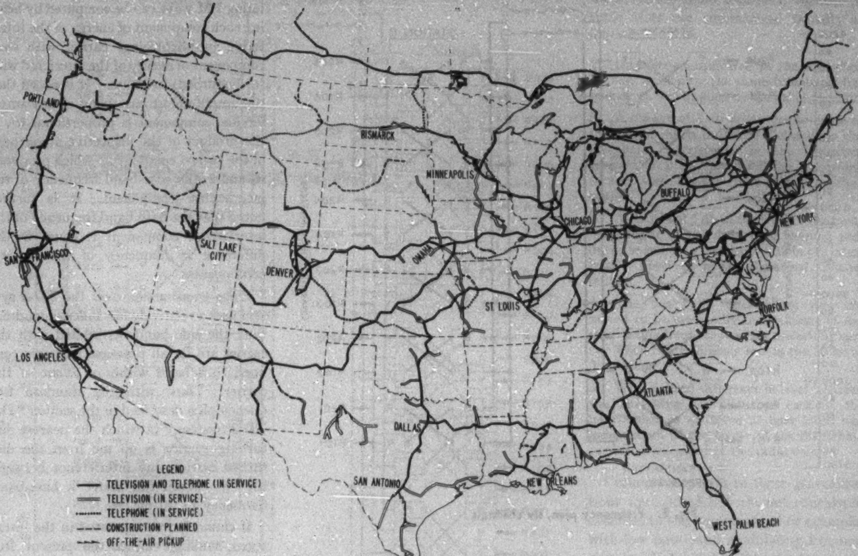

Fig. 1. TD-2 routes, 1958

These couplings may for convenience be separated into two types. The first, called near-end, is due to high-level energy radiated from one antenna on a tower falling into receivers connected to the receiving antenna on the same tower. In the frequency plan of Fig. 2, the significant interferences of this type are 40 mc removed from the center of the band of the disturbed channel. The effect of this r-f interference is minimized by:

1. Transmission loss between the two antennas.
2. Selectivity of the r-f channel-dropping filters and image suppression filters.
3. Discrimination of the i-f amplifiers.

The net loss, including antenna gains between horn-reflector antennas side by side and pointed in the same direction, is in excess of 95 decibels (db) in the absence of foreground reflections. However, measurements at a large number of locations show that the effect of foreground reflections is to distribute the loss over a wide range of values. Fig. 3 shows a cumulative probability distribution curve of 97 measurements of side-to-side coupling loss between horn-reflector antennas. Even 61 db, the poorest value shown, is adequate for 6-channel operation. The r-f filters offer about a 16-db loss at frequencies 40 mc removed from the center of the channel band. The main i-f amplifier, however, provides about 60 db of discrimination at 30 and 110 mc relative to 70 mc.

Since the normal transmitting power as measured at the input to the transmitting waveguide is approximately 0.5 watt, or +27 db below one milliwatt, and the received carrier power at the converter during nonfading conditions is 35 db below one milliwatt for the average path, the level difference between these two points on the same tower is 62 db. However, the sum of the losses above enumerated, together with those in the i-f preamplifier, the transmitter modulator, and the first stage of the transmitting r-f amplifier, insures complete freedom from near-end interference between microwave channels under all normal conditions.

The second type of r-f interference, called far-end, is the result of energy intended for one receiver at a particular point falling into another receiver at the same point. In this case the nearest disturbing channel is 80 mc removed from the center of any particular disturbed channel. For example, at station *B* in Fig. 2 the carrier from station *A* at 4,090 mc may, potentially at least, interfere with the similarly directed channels at 4,170 and 4,010 mc. R-f filters are used which provide about 50 db of loss to frequencies 80 mc removed from the channel-operating frequency; here again the sum of all the circuit losses at side frequencies is sufficient to insure freedom from far-end interference.

Interstitial Channels

Six additional 2-way microwave channels may be derived by utilizing the interstitial bands mentioned above. A frequency plan for such operation is shown in Fig. 4 in which the six additional channels are shown as dashed lines. It will be noted that here adjacent receiving channels are only 20 mc apart, and furthermore that the minimum difference in frequency between transmitters and receivers on the same tower is also 20 mc.

Inasmuch as the total discrimination of the repeater to frequencies 20 mc from mid-band is not great, supplementary means had to be found for improving the discrimination between such closely spaced channels. For far-end interference between similarly directed channels only 20 mc apart, additional discrimination may be obtained by transmitting one set of six channels with vertical polariza-

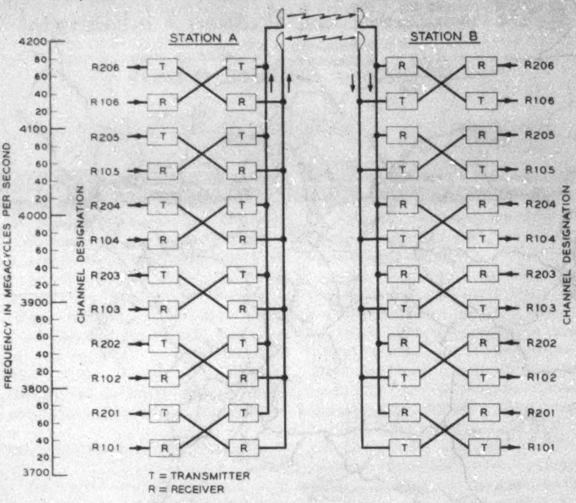

Fig. 2. Frequency plan, six channels

tion, and the other set of six channels with horizontal polarization, as shown symbolically in Fig. 4. The two sets of oppositely polarized channels are separated at the receiving waveguide by means of a suitable network.

It is essential that during fading the amplitude of the vertical component of any particular horizontally polarized carrier shall not become excessive relative to the amplitude of the vertically polarized carrier located 20 mc away, and vice versa. Cross-polarization during fading periods was studied experimentally on a 23-mile path between Murray Hill and Holmdel, N. J. The experimental work was carried out by G. M. Snow, formerly of Bell Telephone Laboratories. This was done by transmitting a vertically polarized carrier at 4,008 mc and a horizontally polarized carrier at 3,980 mc, and observing them with a receiver tuned to each but with both receivers arranged to accept only vertically polarized waves. Fig. 5 is a cumulative distribution curve of the instantaneous difference in level between the two received components obtained during September 1954.

It should be pointed out that by the nature of the recording means, there is an inherent uncertainty of ±5 db in the observed values of discrimination. Fig. 5 shows that during this period the cross-polarization discrimination was poorer than 20±5 db for only about 0.002% of the time.

While the use of cross-polarization materially improves the interference from far-end couplings, it does not appreciably increase the side-to-side coupling loss between antennas; consequently, near-end crosstalk becomes an important consideration in interstitial channel operation.

Interchannel Interference, Theory

In an ideal FM system, the base-band interference due to a relatively weak interfering FM wave can be computed by beating each component of energy of the interfering (or disturbing) carrier with each component of energy of the interfered with (or disturbed) fm wave. It is noted that the amplitude at base band of any interference component is proportional to: 1. the product of the respective amplitudes of the two r-f components which produced it, and 2. the base-band frequency of the interference component. It is further noted that the base-band frequency of the interference component is equal to the difference in frequency of the two r-f components.

Since transmission over the *TD-2* system uses a relatively low index of modulation, the side bands associated with the carrier are for all practical purposes confined to a band within ±10 mc of the carrier. Thus, with the standard frequency plan described in the section "The *TD-2* System," in which the nearest disturbing carrier is 40 mc from the disturbed carrier, any interference between the two would fall above a base-band frequency of 20 mc.

If channels were operated in the interstices available under the present frequency plan, potential interference would extend from zero base-band frequency upward, having maximum power at 20 mc. A quantitative analysis using this theory shows that, for the types of base-band signals normally transmitted over the *TD-2* system, the interference falling in the useful base-band frequency range of the *TD-2* system would be expected to be negligible if the disturbing carrier at the FM detector is always at least 6 to 10 db below the disturbed carrier.

Preliminary laboratory studies and pub-

lished information indicate that the interference at baseband was far higher than expected, and that it did not obey the laws indicated by ideal, simple fm theory.[6] For this reason a detailed investigation to establish the feasibility of interstitial operation was implemented in the laboratory and continued in the field.

Laboratory Study

Some of the characteristics of direct adjacent channel interference between *TD-2* channels 20 mc apart had been studied briefly in the laboratory as early as 1952. The desire to operate the *TD-2* system as a 12-channel system making use of this spacing made it necessary to extend the previous work and to produce an engineering plan for successful operation of the 12-channel system.

A typical laboratory circuit arrangement for testing such a proposal is shown in Fig. 6 in block schematic form. The upper left-hand part of the figure shows the disturbing channel, operating at 3,830 mc and modulated by a signal from a baseband signal generator. The equipment in the lower left section provides the 3,810-mc carrier which represents the disturbed channel.

In the early part of the studies this carrier was unmodulated, as indicated in the figure. The two microwave carriers are combined in the hybrid junction and delivered to the radio receiver which is tuned to the carrier frequency of the disturbed channel. The 70-mc output of the radio receiver is passed to the fm receiver, which is in turn followed by baseband measuring equipment of appropriate type. The variable attenuator *AT1* is used to adjust the 3,810-mc carrier power at the input to the radio receiver to any desired value. Similarly, *AT2* is used to adjust the received power of the 3,830-mc disturbing carrier. The difference between the decibel settings of the two attenuators represents the cross-polarization discrimination, which proved to be the significant parameter in many of the tests.

Tests were made using single-frequency base-band tones to modulate the disturbing channel, while interference in the disturbed channel was observed at the output of the FM receiver connected to the 3,810-mc radio receiver. Results of these tests are summarized broadly as follows:

1. Interference appeared in the disturbed channel at exactly the same base-band frequency as was applied to the other channel.
2. A change of 1 db in the carrier ratio of the two channels produced a change in the base-band interference in the disturbed channel of 2 db, provided the disturbing carrier was weaker than the disturbed carrier.
3. A change of 1 db in the level of the base-band input to the disturbing channel produced in general a change of 1 db in the interference observed in the disturbed channel output.
4. The base-band interference was observed to be essentially independent of the modulation frequency on the disturbing carrier when this frequency was in the 50-kc to 5-mc range.
5. With a fixed difference in level between the disturbing and disturbed carriers, the interference as observed at base band was independent of the power of the disturbing carrier at the input of the radio receiver.

Certain exceptions to these generalizations were noted but are not considered essential to the argument. For example, with low base-band modulating frequencies, i.e., 50 kc, a change in the frequency deviation from ±4 to ±0.4 mc produced a change in interference in the disturbed channel of 26 rather than 20 db.

Fig. 7 shows some of the characteristic relations between the FM carrier ratios and the base-band interference. The abscissa is the ratio in decibels of the two carrier powers as measured in the receiving waveguide. The ordinate is the observed base-band interference in decibels on an equal level crosstalk scale.* Over a considerable range of carrier ratios the slope of the curves is essentially 2 to 1. However, as the carrier ratio begins to approach unity, the slope is considerably greater. Since a working system will not be satisfactory when the interference is large, the region where the disturbing carrier is stronger than the disturbed carrier is only of academic interest.

While the shapes of the curves were almost the same over the region of interest, the position of the curves with respect to the carrier ratio depended upon the discrimination against the disturbing channel that was provided by the frequency characteristic of the receiver in the disturbed channel. The experimental work indicated that the crosstalk mechanism which is characteristic of adjacent channel interference existed in the limiter of the

---

* On this scale the number −40 means that the measured interference at base band is 40 db below the value of the base-band tone which would be measured at the output of an FM receiver on the disturbing channel.

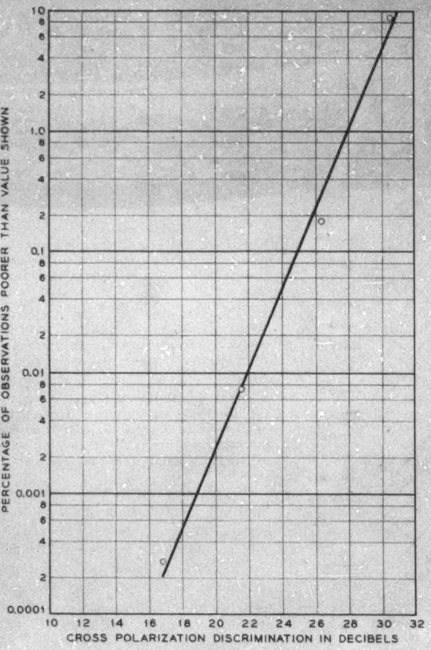

Fig. 5. Cross-polarization discrimination

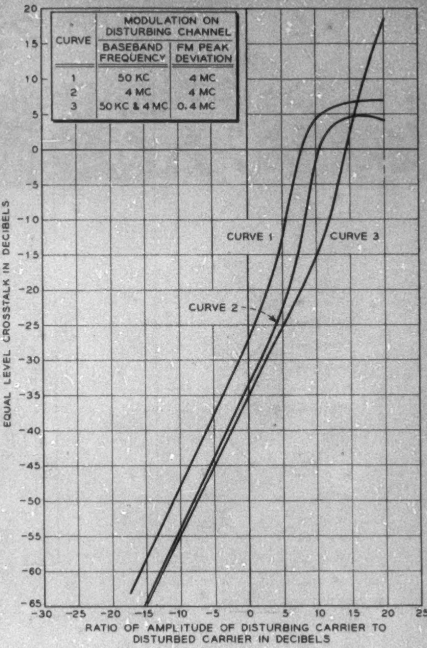

Fig. 7. Crosstalk between microwave channels, laboratory measurements

fm receiver, and also at any point in the system where there was a pronounced tendency to compress the signal.

Such a mechanism has been suggested in an unpublished memorandum by W. R. Bennett of the Bell Telephone Laboratories. This mathematical work shows that when an unmodulated FM carrier and a weaker sinusoidally modulated FM wave are passed through an ideal clipper limiter, distortion is introduced on the stronger FM carrier, some of which appears at base-band frequencies as interference having the same frequency as that of the modulation on the weaker carrier. The amplitude of this interference varies in two ways: as the square of the ratio of the amplitude of the two carriers, and as the square of the ratio of the voltage at which the limiter clips to the signal voltage impressed upon it.

The next series of experiments was undertaken to determine how the frequency discrimination at the edges of the channel pass band might be changed to hold the interchannel interference to tolerable limits in the presence of a limited amount of cross-polarization discrimination. It was found that sufficient improvement could be obtained if the frequency discrimination of the disturbed channel was increased in the region of the disturbing carrier and its signal side bands. Since the strength of these side bands usually decreases as their frequency spacing from the carrier increases beyond

the peak frequency deviation, and since the peak deviation is 4 mc in the *TD-2* system, an i-f filter which would increase the discrimination markedly in the range 16 to 24 mc from the disturbed carrier, and somewhat less strongly in the region 10 to 16 mc removed, should be effective. Laboratory models of such a filter were made. The filter was placed in the receiver at a point between the i-f preamplifier and the i-f main amplifier. This arrangement was also tested in field trials, and both laboratory and field results were encouraging. Fig. 8 shows the shape of the pass band of a receiver before and after adding an experimental i-f filter. The disturbed carrier will be located at 70 mc and the disturbing signal will be centered either at 50 or 90 mc. In many cases disturbing signals will be located on both sides.

Since the *TD-2* system normally operates with compression in the final stage of the microwave transmitting amplifier, this i-f filter, for the reason described above, must be applied at each repeater point, and must be located between the point of exposure and the transmitting r-f amplifier.

Another part of the general interference problem involves the condition in which the carrier of the disturbing channel has been severely faded or actually lost at some preceding section. In the latter case, the gain of the system is sufficient to amplify the noise originating in the converters until the transmitter output consists of a broad band of noise whose total power is substantially that of the carrier it replaces. In this situation the energy density at the edge of the band is greater than it is when a carrier with its normal side-band distribution is present. The tendency to interfere or "spill over" into the adjacent channel is greatly increased.

The automatic switching system for *TD-2* operates when the high-frequency noise in a broad-band channel reaches a predetermined level as a result of a fade or loss of carrier in a preceding section of the system.[7] If spillover from a failed interstitial channel occurs, a nominally good channel may be impaired and an unnecessary switch will ensue. The filter is not adequate to cope with this situation, and consequently during such periods the repeater gain must be reduced.

The elements of the engineering plan for interstitial operation may be found in the preceding discussion. A new i-f filter and means for reducing the repeater gain during deep fades must be provided at each repeater on an interstitial route. Cross-polarization discrimination is available in the form of a polarization-sensitive 4-kilomegacycle (kmc) microwave network which connects the rectangular waveguide into the round waveguide leading to the antenna. This network had been developed as part of the equipment necessary to permit systems operating at 4, 6, and 11 kmc to be simultaneously connected to one horn-reflector antenna.[8]

Field tests of various aspects of the engineering plan were carried out from time to time. Before discussing these tests, it seems worth while to discuss the objectives against which the results of the field tests were evaluated.

Objectives

The objective for satisfactory interstitial operation is based on the philosophy that the speech crosstalk from an adjacent channel during a fade should be well masked by the first circuit noise simultaneously present. For system engineering purposes, this objective must be interpreted in terms of a required ratio of disturbed carrier to disturbing carrier.

In the case of near-end crosstalk as defined above, the desired received carrier is subject to normal fading, whereas the disturbing carrier is not. For this condition it has been determined experimentally that without the special i-f filter, if the disturbing carrier is 35 db or more below the disturbed carrier during conditions of free space transmission, then during fading, the base-band interference from the interstitial channel into the disturbed channel will always be below the noise in the disturbed channel.

In the case of far-end crosstalk, fading of the disturbing carrier is correlated to a

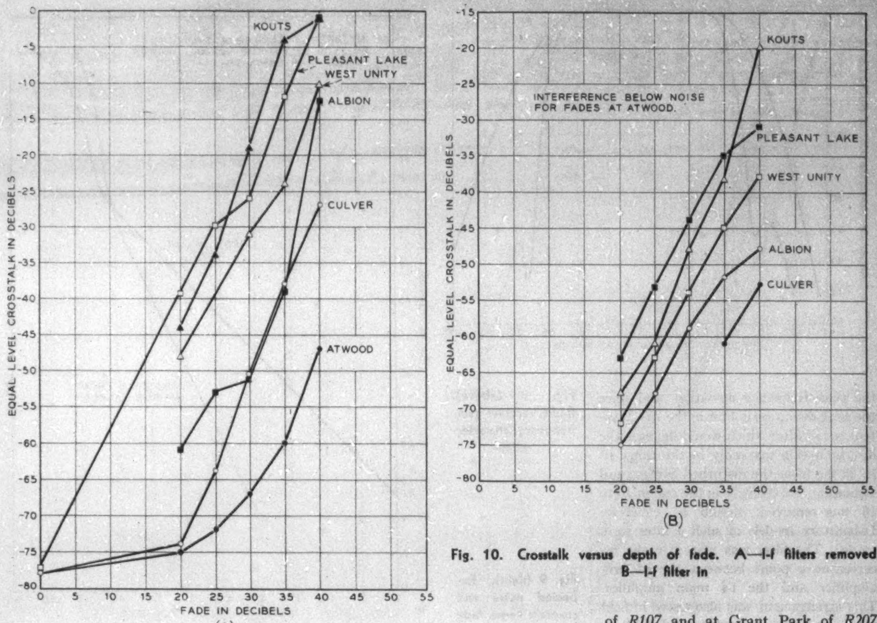

Fig. 10. Crosstalk versus depth of fade. A—I-f filters removed. B—I-f filter in

degree with fading of the disturbed carrier, and this in turn leads to an objective somewhat less than 35 db. The limited amount of data at hand indicates that for this case a ratio of about 20 db is adequate. If the fading on the two channels is uncorrelated, the objective will be 35 db for far-end as well as for near-end crosstalk.

Fig. 9, taken from reference 9, shows how the fluctuation noise and speech crosstalk contributions of one repeater may be expected to increase with depth of fade. Talker volumes are distributed over a wide range, and the volume assumed here is sometimes referred to as the volume of the "rms" talker; this is approximately 10 db below the loudest talker. At a 35-db fade, the point at which service is normally transferred to a nonfaded channel, the speech crosstalk is 7 db below the noise power.

It is also convenient for some purposes to specify the above objective in terms of equal level crosstalk at base-band frequencies. The conversion can readily be made by means of the experimental relationship shown in Fig. 7. Thus, if the 35-db objective were met, then under free space conditions the equal level crosstalk would be completely negligible. For a 35-db fade, the carrier ratio would be 0 db and the corresponding equal level crosstalk objective would be −35 db.

Field Tests

In the six repeater sections between West Unity, Ohio, and Grant Park, Ill., interstitial channels had already been installed, thus providing a suitable location for feasibility field tests. Channels *R201* and *R207* in the east-to-west direction and *R101* and *R107* in the opposite direction (see Fig. 4 for channel nomenclature and frequencies) were used for the tests since *R101* could interfere with *R107* and, produce far-end crosstalk and similarly, for example, it could couple into *R207* and produce near-end crosstalk. Both crosstalk paths involve a spacing of 20 mc. The following basic tests were among those made:

Sine Wave Crosstalk

As an example, a sine wave of suitable power was applied to the base-band input of *R201*, and the magnitude of the crosstalk at this same frequency was observed at West Unity at the base-band outputs of *R107* and at Grant Park of *R207*. This was carried out for various values of simulated r-f fades at each repeater section on *R107* and *R207*.

Video Crosstalk

The test detailed in test 1 was repeated using a video signal. In this case the outputs of *R107* and *R207* were examined on a video monitor for evidence of picture crosstalk for simulated fades, as described above.

Noise Spillover

The carrier was removed from one radio channel at the head end of the system, the gain of the subsequent repeaters thereby rising, as described previously, until the repeater output consisted of a broad band of noise. The magnitude of the spillover of this noise into the adjacent channel was observed for various depths of fades.

Fading Margin Loss From Noise Spillover

In a *TD-2* system, one channel out of six is normally set aside as a protection channel. In each operating channel, noise is sensed at a base-band frequency of about 9 mc, and if the noise is excessive a switch is made to the protection channel when available. Noise spillover increases the noise at the upper video frequencies and hence causes a faded circuit to ask for the protection channel sooner than it otherwise would. This, in turn, ties up the protection channel longer than is actually necessary, and as a result increases the amount of time in which a switch cannot be made, because the protection channel is unavailable.

Fig. 10(A) shows typical results of sine wave crosstalk measurements in which the modulating tone on the interfering channel is 3.59 mc and various repeater sections are faded. The coupling path in this case is between similarly directed channels, and it generates far-end crosstalk. The results are plotted in terms of equal level crosstalk.

Using the more severe of the two objectives suggested previously for far-end crosstalk, it was shown that this led to an objective of −35-db for equal-level crosstalk loss for a 35-db fade. It is apparent, then, that three out of the six far-end coupling paths failed to meet this requirement.

The addition of the supplementary i-f filter substantially reduced the magnitude of the crosstalk, as shown in Fig. 10(B). In this case the poorest equal level cross-value for a 35-db fade was −35 db, which meets the stated objective.

Observations showed video crosstalk mixed with the noise for deep fades, but this was eliminated by the application of the supplementary i-f filter.

Figs. 11(A) and (B) show the effect of noise spillover from channel *R201* into *R207* as the latter is artificially faded at Kouts: (A) shows the measured noise spectrum on *R207* with *R201* operating in normal fashion. These curves exhibit satisfactorily the expected 6-db-per-octave increase of noise with base-band frequency. Fig. 11(B), however, shows the effect of removing the carrier from *R201* at West Unity. The effect of noise spillover from *R201* is most marked in the region above 6 mc.

Application to Existing Routes

The application of interstitial channels to an existing *TD-2* route requires the use of the horn-reflector type of antenna and associated circular waveguide system in order to permit the cross polarization of the radio signals for channels having 20-mc frequency separation. The field tests confirmed the results expected from the laboratory measurements and indicated that the discrimination obtained from cross polarization and i-f filters would provide satisfactory discrimination against adjacent channel signals. Existing delay lens antennas with their associated rectangular waveguides must be replaced, and coupling networks must be installed at the bottom of the tower for combining the cross-polarized signals. Temporary arrangements, such as parabolic antennas, may be necessary in order to keep in service the circuits assigned to the existing *TD-2* channels and to avoid interruptions during the cutover.

It is planned to operate the interstitial channels added to a route as a system separate from the existing regular channels. The interstitial channels will have their own protection channels because adjacent channels 20 mc apart will frequently fade at the same time, and would simultaneously need the same protection channel. Building additions, particularly at auxiliary repeater stations, and increased power plant capacity will usually be required for the additional channels. In all other respects *TD-2* channels on interstitial routes will operate in a normal manner since the i-f filter and the gain-reducing means mentioned previously are essentially the only additional circuit arrangement required on an interstitial channel route.

Some of the factors affecting the decision as to application of interstitial channels to an existing *TD-2* route are the circuit growth needed, the freedom from interferences arising from parallel or branching routes using the same interstitial channel frequencies, and the type of antennas already installed. In some cases there may be interference from

1. 79
1
60

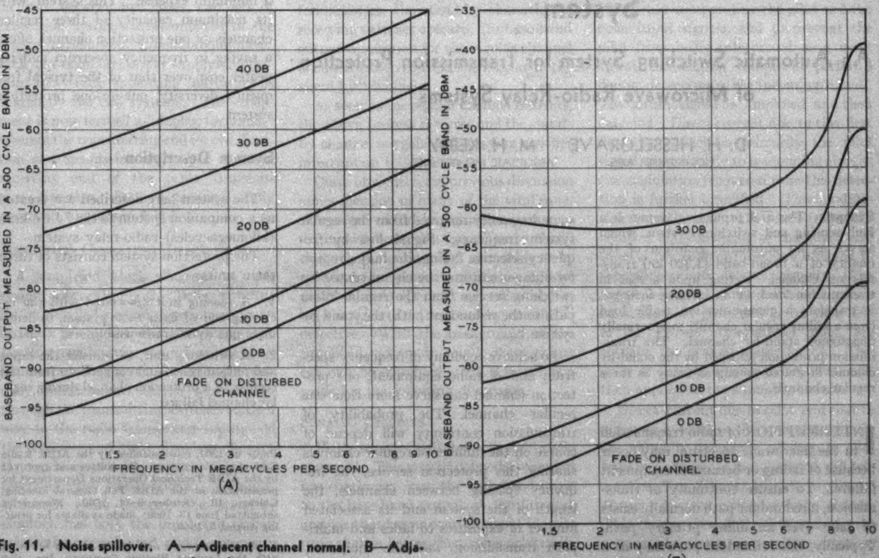

Fig. 11. Noise spillover. A—Adjacent channel normal. B—Adjacent channel open

other radio routes such as side legs or converging routes which might limit the number of interstitial channels which could be added.[9]

TD-2 routes having horn-reflector antennas are particularly attractive candidates for interstitial channel applications from an economic standpoint. The cost of replacing the delay lens antennas and rectangular waveguides by horn-reflector antennas and circular waveguides, and at the same time maintaining existing service, is substantial.

In general, the same factors apply for side-leg routes as for main through routes. However, in side-leg route cases it will be necessary to make sure that the addition of interstitial channels on the side legs will not restrict the number of such channels which could be added on main routes because of possible frequency interferences.

Conclusions

It appears that widespread use of *TD-2* interstitial channels is possible since the results of the field trial indicate that the interference between nearby and branching *TD-2* routes would in general be sufficiently low to permit the use of the same channel frequencies on different routes. In a few cases, however, it is expected that interroute interference might be severe enough to prevent using these channels on more than one route unless remedial measures are taken, such as the construction of new route for short distances.

The results from the field tests and from experience with interstitial channels placed in service in the Chicago-Mishawaka, Indianapolis–Terre Haute, and Troy Hill–Hopedale sections subsequent to the field trial, indicate that both the regular and interstitial channels have transmission characteristics practically the same as those of *TD-2* channels on noninterstitial routes. In view of these satisfactory results, plans are being made for the installation of interstitial channels on *TD-2* routes in many portions of the United States. It appears that nearly all the main *TD-2* routes will have interstitial channels added during the next few years.

The 57A Microwave Path Protection System

An Automatic Switching System for Transmission Protection of Microwave Radio-Relay Systems

D. H. HESSELGRAVE
NONMEMBER AIEE

M. H. KEBBY
ASSOCIATE MEMBER AIEE

Synopsis: The 57*A* protection system is a fault-sensing and switching system, which serves as an automatic guardian of the quality of a broad-band (1,300 kc) transmission channel. Acting upon a loss in transmission level, or an increase in noise, it transfers a communication traffic load from a failing regular channel to a normally unassigned stand-by channel. The transmission protection afforded by the stand-by channel is shared among as many as three regular channels.

INTERRUPTION of radio transmission in the microwave spectrum may occur because of fading or because of equipment failure. To ensure continuity of transmission, a redundant path normally exists to take over an ailing primary path. Typically, this redundant path may be a parallel radio-relay system, operating at some frequency removed from the regular system frequency. Signal loss by frequency-selective fading, the major reason for outage, can now be circumvented by switching service from the regular radio path to the redundant path, the stand-by system.

To achieve economy of frequency spectrum and of radio equipment, one protection channel can serve more than one regular channel. The probability of transmission continuity will depend of course on the number of regular channels sharing this protection service, the frequency spacing between channels, the length of the system and its associated number of exposures to fades and multipath transmission, and the equipment reliability.

The *57A* microwave path protection system permits an orderly expansion of microwave path transmission capacity at a minimum expense. This system, with its maximum capacity of three regular channels for one protection channel, offers a saving in frequency spectrum and repeater cost over that of the typical frequency diversity, one-for-one protection system.

System Description

The system here described was created as a companion system to the *74A* 6-kmc (kilomegacycles) radio-relay system.

The protection system consists of three main units:

1. A sensing unit associated with the receiving end of each radio system, to determine quality of transmission.
2. A switching unit, to transfer the input and output base-band connections from the regular to a protection channel during regular channel failure.

Paper 60-1207, recommended by the AIEE Radio Communication Systems Committee and approved by the AIEE Technical Operations Department for presentation at the AIEE Fall General Meeting, Chicago, Ill., October 9–14, 1960. Manuscript submitted June 13, 1960; made available for printing August 5, 1960.

D. H. HESSELGRAVE and M. H. KEBBY are both with the Lenkurt Electric Company, Inc., San Carlos, Calif.

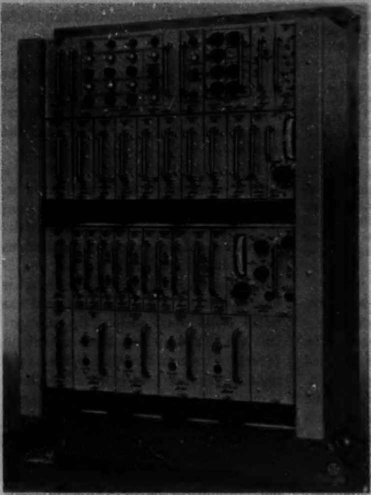

Fig. 1. Fully equipped duplex terminal (transmitting and receiving ends) of a 57A protection system

3. A supervisory control path between the sensing unit at the receiving end and the switch elements at the transmitting end of the radio system.

This equipment protects a unilateral transmission path. Since most of the practical applications are on a bilateral transmission path, such as the telephone facilities between two cities, two sets of protection systems are combined in the typical installation. Common equipment, such as a regulated power supply and certain relay-rack mounting hardware is shared by the two systems. The equipment is now termed a "duplex terminal," wherein the transmitting end for one direction of transmission is grouped with the receiving end of the other transmission direction. Such a terminal, fully equipped, appears in Fig. 1.

SIMPLIFIED OPERATING DESCRIPTION

A simplified block diagram of this system appears in Fig. 2. Before entering into a detailed system description, let us consider briefly how the system operates. Under normal service conditions, the base-band inputs for the regular channels, typically, multichannel carrier systems, go through the transmitting switches on their way to the radio transmitter input. At the receiving end, these signals go through the receiving switches on their way to the receiving drop terminations. Normally, a fourth radio system, the stand-by channel, has both the input and output connections terminated, and is not carrying any service.

When a sensing circuit recognizes a failure of its associated regular channel, a command signal is sent to the transmitting end; the base-band input bridges the stand-by channel, and the base-band signal now rides on two radio paths. When the receiving end of the switching system recognizes regular channel information on the stand-by channel, the receiving switches operate; the base-band output connection for the regular channel is now transferred from the regular to the stand-by channel.

As soon as the regular channel recovers, the above process reverses and the stand-by channel is again idle, waiting another interruption to service.

Quite obviously, the previous discussion omits mention of many of the vital functions required for the protection system to distinguish between a "good" and a "bad" channel, to decide which channel is to be switched, to prevent multiple or false switches, and to prevent any switches during the time that the stand-by channel is defective. With the background of the simplified system in mind, these points can now be examined. Fig. 3 serves as a guide for the following discussion.

SENSING CIRCUITS

First, what constitutes a "good" radio channel? This may be defined as one that has continuity from the base-band input to the base-band output at the far end, and one that has an over-all signal-to-noise ratio that is better than some arbitrarily chosen figure.

To establish continuity, the protection system monitors a pilot which is injected at the transmitting end of the system. This pilot lies above the commercially usable toll telephone base-band spectrum, at a frequency of about 1,600 kc. Its transmission level is a compromise between one that would be so high as to load the radio system, and one that is so low that the superimposed modulating tones could not be recovered in the presence of system noise. This compromise level is about 12 db (decibel) below that of a single v-f (voice-frequency) channel test tone, as applied from a 264-channel carrier system.

So that the receiving end of the system can determine if the stand-by channel is connected to a regular channel input or is merely idle, only the regular channel pilots carry a superimposed 4-kc modulation; the presence of this modulating tone at the stand-by channel sensing equipment signifies that a transmitting-end switch has been completed.

In addition to the pilot, the protection system also monitors the noise lying in a broad slot surrounding the pilot. Although this part of the radio base-band lies above the commercially used spectrum, the noise characteristic is closely related to that within the commercial band; furthermore, the transmission roll-off is not of sufficient magnitude appreciably to alter the received signal level over normal length radio systems.

For ease in separating the pilot and the noise input signals, and to prevent the pilot from being interpreted as a noise signal, the sensing equipment performs double-detection on the incoming signals. The entire signal is amplified and then detected. Direct current due to this first detection, which is primarily the pilot signal, goes directly to a summing circuit; the modulation recovered from this detection is further amplified. This modulation must be split; the lower-frequency components, consisting of the guard and supervisory control tones, are directed to the appropriate control circuits. The higher-frequency components, lying in a band of about 30 to 100 kc on each side of the 1.57-mc (megacycle) pilot, are actually the system noise signals. This noise is further amplified, rectified, and then applied to the summing circuit.

Direct current due to pilot and that to noise, as applied to the summing circuit, are mutually opposing. A drop in pilot level or an increase in noise level will trip a "slicer," or Schmitt trigger, to give an abrupt, discrete control-voltage change. This change sets off the first event in the sequence leading to a complete protection switch.

The noise signals previously mentioned result either from radio transmitter failure or atmospheric fading. In either event, the gain of the radio receiver will rise seeking an r-f (radio-frequency) signal. In doing this, it of course increases the base-band output level of the Johnson noise arising in the front end of the radio receiver. The system may be operated to switch at noise levels ranging between 20 dba (decibels adjusted) minimum to about 55 dba maximum (as measured with a telephone-type noise measuring test set on the v-f drop referred to 0-db transmission level point). The pilot threshold is set so that a 3- to 4-db loss in pilot level will initiate a switch. In both the pilot and noise recognition circuits a fair degree of inertia or hysteresis must exist to prevent jittering between a switch and no-switch condition right at the threshold point.

First Phase of Switch Sequence: Request for Switch Protection

A discrete voltage resulting from either low pilot or high noise is applied to the input of the receiving-end logic circuit. This circuit has three distinct functions as follows:

1. It must initiate a transmitting-end switch request, but only if no other regular channel has already called for a protection switch.

2. It must order the completion of a receiving-end switch (the last event in the switch sequence), but only after the stand-by channel has bridged onto the regular channel at the transmitting end.

3. In the event of simultaneous failure of more than one channel and subsequent return to normal of a switched channel, it must delay the switch sequence to the second channel until the entire switch sequence from the first channel has been restored to normal.

At this stage of the switch sequence, only the first function is of importance.

The d-c output current from each of the radio channel sensing circuits is assigned to an input of the receiving logic circuit. These four inputs feed reverse-biased d-c amplifiers which, for the regular channels only, are interconnected. A request for switch protection on any one of the inputs will drive the associated amplifier into saturation; the output of this amplifier, through the interconnection, immediately clamps the other two regular channel amplifiers in a cut-off condition. Because of the electrical "over-center," bistable, nature of these interconnected amplifiers, only one of the three can ever conduct at one time.

No order of preference exists for the regular inputs. They operate on a "first come, first served" basis, with the fastest sensing chain seizing the stand-by channel service.

The conducting amplifier turns on a regular channel control tone oscillator, operating in the voice frequency region; its assigned frequency tells the transmitting end of the switch section which channel is calling for a switch.

The first phase of the switch sequence is now complete. The regular channel has failed, calling for a switch; the logic circuit has locked up the other channels to prevent a concurrent switch request; the regular channel control tone oscillator is energized and is transmitting a signal back to the transmitting end of the protection system.

The regular channel control tone, accompanied by a guard tone (for monitoring continuity of the control line) proceeds back to the transmitting end of the switch section via a common-carrier facility. This may be a wire line paralleling the radio route, for unidirectional radio

systems. However, in the general case of the two-way radio system, these control tones ride back as additional modulation on the protection system pilot for the opposite-direction radio system. It is important to recognize here that the *57A* path protection system has two functions, first, that of maintaining system continuity by switching the failed channel to the stand-by channel when necessary, and second, that of serving as a common carrier for the control tones of the complementary, opposite-direction path protection system.

Since there is no more certainty of transmission continuity on this common-carrier path than there is on the forward transmission path, the control tones are multipled to every radio channel for transmission back to the transmitting end. At the far end of the switch section, these tones are demodulated from the separate 1.57-mc pilots, added, and applied to the control tone receiving circuits. Should any return channel fail, its demodulated tone output is removed from the common line to prevent noise or false signal interference.

SECOND PHASE OF SWITCH SEQUENCE: TRANSMITTING-END SWITCH OPERATION

The output of the common-carrier control tone system at the transmitting end of the section is applied to the control circuit receivers. Each of these receivers consists of a band-pass filter, an amplifier, and a rectifier. Just as in the case of the receiving-end sensing circuits, the outputs of these control tone receivers are connected to a logic unit; in this case, it is the transmitting-end logic circuit.

This latter logic circuit has a simpler mission than that of its counterpart at the receiving end. It merely performs the following functions:

1. Permits transmitting-end bridging switches only during the presence of the common-carrier guard tone.
2. Initiates a transmitting-end switch, and concurrently locks up the other two regular channels to prevent any other switch.

Because of the marked similarity in function between the receiving-end and the transmitting-end logic circuits, it was possible to use the receiving-end package, with a few components removed, at the transmitting end.

If the necessary conditions for a transmitting-end switch are fulfilled, a d-c output is delivered from the logic unit to an amplifier which drives a transmitting-end switching relay. This relay bridges the regular channel to the input of the stand-by channel. As a result of this switch, the stand-by pilot is removed and the regular channel pilot appears on the stand-by channel. The regular channel information now leaves the transmitting end of the switching system on two paths, that of its assigned channel and that of the stand-by channel. The second phase of the switching sequence is now complete.

FINAL PHASE OF SWITCH SEQUENCE: RECEIVING-END SWITCH OPERATION

The appearance of regular channel pilot signal, with its accompanying 4-kc modulation, on the stand-by channel is the last "fact" necessary for the receiving logic circuit to order a receiving-end switch. The logical process is: a regular channel has failed and the stand-by channel is bridged to a regular channel at the transmitting end—the failed channel output should now be transferred from the regular to the stand-by channel. Notice that the logic unit does not verify *which* regular channel has been bridged to the stand-by channel. In view of the lock-out features at both the receiving and transmitting ends of the circuit, this refinement and additional safeguard is unnecessary.

The protection switch, as established in the previous sequence, will hold until the regular channel is restored to a "good" condition again. At that time, the entire switch sequence will progressively restore to normal.

SIGNAL SWITCHES

All base-band switching is performed by quick acting, short frame, telephone-type relays with multiple-spring pile-ups. To reduce crosstalk between channels through the relay contacts, additional isolation is

Table I. Performance Characteristics of the Microwave Path Protection System

Base band transmission frequency	12 kc to 1.3 mc
Pilot frequency	1.57 mc
Time required for a complete switch from the moment of failure	approximately 70 milliseconds
Level change during switch interval*	None
Transmission interruption during switch interval*	None
Insertion loss (overall)	4 db
Power input, all channels normal	21 watts
Power input: maximum alarm and failure	50 watts

* This assumes a switch due so a typical fade, or a relatively flow equipment failure. In either of these cases, full level base-band output must appear at the failing channel output from the moment that the failure is recognized until the switching is completed

obtained by an arrangement of grounded relay springs.

The sequence of relay operations provides for the transfer of a failing channel to the stand-by channel with no level change or interruption of transmission during the switching interval.

OPERATING CONTROLS AND INDICATIONS

To avoid any ambiguity, all control functions appear only at the receiving end of the section; each of these operating controls has an associated guard lamp to serve as a reminder of its operation. Two sets of controls are deemed necessary:

1. A control to lock out, or disable, the automatic function of any one, or of all, the channels.
2. A control to switch manually any regular channel to the stand-by channel.

The guard lamps associated with these controls, along with a second set of indicator lamps, tell a complete story on the condition of the protection system. These lamps show which channels have failed, which are locked out; and they indicate that a switch sequence has been completed, or that it failed to complete.

In addition to the receiving-end controls and indications, one set of indicator lamps is also located at the transmitting end of the switch section. These lamps show when a transmitting-end bridging switch has been made to a regular channel. The full set of lamps will indicate the steps in the switch sequence as outlined above, to simplify trouble-shooting.

INTEGRAL TEST EQUIPMENT

A built-in metering panel at the transmitting and at the receiving end of the system reads more than 30 different d-c functions. The progress of the switch sequence can be traced, step by step, with the aid of these meters. Additionally, the receiving-end test set includes a pilot and noise generator, to facilitate lineup procedure. The complete lineup and adjustment of the entire *57A* protection system is accomplished with the use of these integral test sets, supplemented by a high-frequency a-c vacuum-tube voltmeter. The use of the lockout controls, plus a TEST-NORMAL switch at the receiving end, permits complete system lineup without disconnecting the *57A* system from the radio channels. Of course, during this lineup interval, the automatic protection service is disabled.

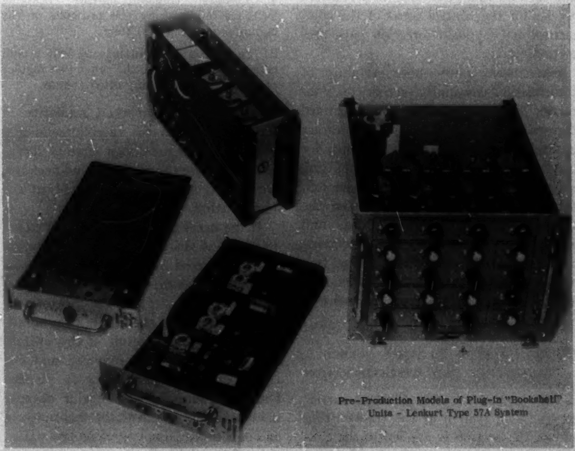
ELECTRICAL AND MECHANICAL FEATURES

The *57A* system is completely transistorized, using 103 transistors and 88 diodes in the fully-equipped version. It operates from a −48-volt unregulated source, a voltage supply common to the typical telephone office. The entire system is built up on a modular series of 30 plug-in units occupying four shelves in a standard relay rack. With no change in common wiring, the system may be expanded from a one-for-one (one stand-by channel to protect one regular channel) up to a one-for-three system, by removing a few plug-in bypass units and plugging in the regular equipped units.

Those units containing circuits common to all channels have an interlock jumper, which removes operating voltage from the system when they are unplugged. The removal, or the failure, of operating voltage causes all circuits to return to the normal, unswitched condition. A total of eight units, those carrying the switches at the transmitting and at the receiving ends, carry the transmission path and may not be unplugged without first patching out the channels affected. All other units may be removed with no risk other than having any automatic switch fall back to normal. The eight units contain only relays and passive elements, to minimize the necessity for their removal. For maintenance purposes, any unit can be extended out of the shelf, with both sides exposed, by interposing an extension unit. A set of parallel-connected bridging jacks at each end of the system permits either the patching out of a channel, or cross-patching of the carrier channels to different radio channels. These patches, which can parallel the normal path through the switch system, can be executed with no breaks or outages.

All units are wired following the Lenkurt-developed stitched-wiring process. This process, adaptable to any circuit consisting of components assembled on a flat dielectric mounting sheet, uses machine-driven staples on a grid pattern to support pigtail components. Wiring between components may either be by hand or on an automated basis. Fig. 4 illustrates the typical unit wiring.

The complete *57A* microwave path protection system, shown in Fig. 1, occupies a total of 14 relay rack spaces, 24.5 inches.



Pre-Production Models of Plug-in "Bookshelf" Units - Lenkurt Type 57A System

Fig. 4. Typical plug-in unit assembly and wiring

Conclusions

The *57A* system permits an orderly expansion of microwave path transmission facilities, at a minimum expense. This system, with its maximum capacity of three regular channels for one protection channel, offers a saving in frequency spectrum and repeater cost over that of the typical frequency diversity, one-for-one protection system. Application of the *57A* system, although discussed here in relation to radio systems, is also feasible for use in connection with a cable or wire line.

Telephone Influence Factor (TIF) and Its Measurement

W. C. BALL
MEMBER AIEE

C. K. POARCH
ASSOCIATE MEMBER AIEE

FROM the earliest days of telephony the evaluation of message circuit noise has been an important problem. Of particular interest has been the evaluation of noise originating from harmonic components present in power system voltages and currents. Magnetic fields set up by power currents, and electric fields set up by power voltages, tend to induce voltages in nearby telephone conductors. Even a small transfer of power at harmonic frequencies in the voice band can cause trouble. For example an input of 400 $\mu\mu$watts (micromicrowatts), or 26 db (decibels) above reference noise, into a telephone set at 1,000 cps (cycles per second) will give an audible tone. To put such a tone on all of the 60 million telephones in the United States at once would require just 24 milliwatts, transmission losses neglected.

If telephone circuits could be perfectly balanced or shielded, the transfer of power at voice frequencies would not be of concern. However, since such perfection is impracticable it is the practice for telephone and power companies to co-ordinate and determine the best engineeering solution to keep power line noise at tolerable levels. For several decades the Joint Subcommittee for Development and Research, of the Edision Electric Institute and Bell Telphone System, has been active in this endeavor.

While the joint co-ordination of systems is a field of considerable scope, the basic yardstick for gaging a particular power circuit as a potential noise source is the telephone influence factor (TIF). This factor is dimensionless and provides an index of the inductive influence of a power system wave shape. It takes into account the relative interfering effect of various frequencies of noise on a telephone circuit (message weighting) and the variations in coupling between power and telephone systems with respect to frequency.

With the introduction of new telephones having improved response characteristics, the relative interfering effects of frequencies in the voice band are changed. Such changes occurred recently with the introduction of the "500-type" telephone set. Thus both the message weighting and the related TIF characteristic have had to be re-examined and brought up to date. The work on the new TIF weighting was done by a Task Force on TIF Revision, set up by the joint subcommittee mentioned above. The revision of the message weighting and the development of a new noise-measuring set incorporating this message weighting was undertaken by the Bell Telephone Laboratories. The set is manufactured by Western Electric Company, Inc., and is coded as the *3A* noise measuring set.

Inductive Co-ordination

The need for inductive co-ordination arises from the basic fact that power system influence is a potential source of telephone noise. If power circuits could be built and operated so as to produce a pure 60-cps sine wave or to prevent any external voice-frequency fields, or if telephone systems were not susceptive to such fields, there would be no need for inductive co-ordination.

There are three basic factors in inductive co-ordination work: the *inductive influence* of the power system, the electric and magnetic *coupling* between power and telephone systems, and the *susceptiveness* of the telephone plant.

The inductive influence of a power system is dependent upon the TIF of the voltage or current and on the voltage or current magnitudes. Voltage TIF affects electric induction which usually is a problem only with open-wire telephone lines. Current TIF is important in cases of magnetic induction. Except for very close separations, such as on joint-use poles, the induced voltage is essentially longitudinal and is due chiefly to the residual current in the power line. Residual current is the vector sum of the phase currents and its TIF may be quite different from that of the phase currents. If the series and shunt unbalances in the telephone circuit are both small, longitudinal induction will cause little current to circulate in the telephone loop and no noise will result.

Although current TIF, and especially residual current TIF, is usually more important in inductive co-ordination, open-circuit voltage TIF limits usually are specified for rotating machines. This is because significant current TIF measurements are not feasible at the factory, and it is assumed that a machine with a low open-circuit voltage TIF will not tend to produce troublesome harmonic currents on a power system.

Susceptiveness, as used in telephony, is essentially a measure of the vulnerability of the telephone plant to outside interference. This is largely a matter of longitudinal balance (as distinguished from return loss balance) and shielding.

TIF, I·T, and Kv·T

The contribution of a given harmonic current (or voltage) to the total noise influence of a disturbing circuit is the product of that current (or voltage) and the appropriate TIF weighting for its frequency. It is designated I·T (or V·T). More often the voltage is expressed in kilovolts and the product is written Kv·T.

Paper 60-1195, recommended by the AIEE Wire Communication Systems Committee and approved by the AIEE Technical Operations Department for presentation at the AIEE Fall General Meeting, Chicago, Ill., October 9–14, 1960. Manuscript submitted June 10, 1960; made available for printing August 2, 1960.

W. C. BALL is with the Bell Telephone Laboratories, Murray Hill, N. J., and C. K. POARCH is with the Edison Electric Institute, New York, N. Y. Members of the Task Force on TIF Revision were A. J. Aikens, O. H. Coolidge, M. D. Fagen, H. A. Gauper, Jr., W. W. Holloway, W. R. Hyatt, Jr., C. K. Poarch, L. T. Rosenberg, D. F. Shankle, H. P. St. Clair, T. J. Talley, and M. D. Westrate.

Of the many individuals who have contributed to the development of the new weighting and the new noise measuring set, the authors are particularly indebted to A. J. Aikens, W. T. Cochran, and D. A. Lewinski of the Bell Laboratories, in connection with the 3A set.

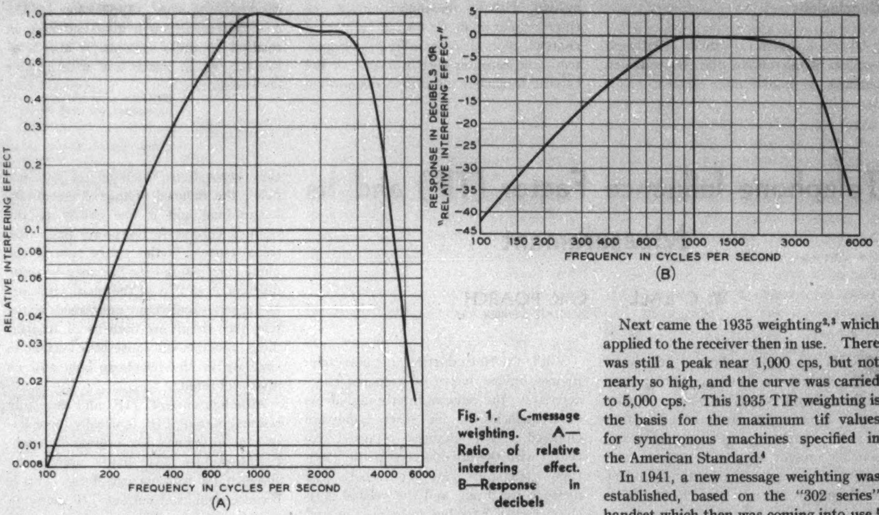


Fig. 1. C-message weighting. A—Ratio of relative interfering effect. B—Response in decibels

The I·T (or Kv·T) of a complete current (or voltage) wave is defined as the square root of the sum of the squares of all of the I·T (or Kv·T) products of the wave's components, including the fundamental.

The current or voltage TIF of the complete wave is the ratio of the I·T or Kv·T value to the total rms value of the wave.

To make TIF a meaningful measure requires that the TIF weighting (TIF_f) account for:

1. The relative subjective effect of frequency f in the message circuit, as heard in the telephone (message weighting).
2. The coupling between the power and telephone circuits, assumed to be directly proportional to f.

Thus

$$TIF = K p_f \frac{f}{1{,}000} \qquad (1)$$

where p_f is the relative interfering effect at f, such that p_f is equal to 1 at 1,000 cps, and K is a constant.

The factor p_f is the ordinate of the message-weighting characteristic. The message weighting characterizes the interfering effect relative to 1,000 cps, as determined by subjective tests. It may be expressed as a decimal fraction of the interfering effect at 1,000 cps or as decibels down from that value. The value at 1,000 cps is therefore 1.0 in the first case and zero db in the second. The newest Bell System noise weighting, called "*C*-message," is shown as a ratio in Fig. 1(A) and in decibels in Fig. 1(B). In equation 1 the ratio is used.

In deriving the *C*-message weighting, two types of tests were conducted using 500-type telephone sets, one in the absence and one in the presence of speech.[1] In the absence of speech a group of observers were asked to adjust the loudness of 14 different frequencies until the sound of each was judged to be equally as annoying as a −59 db below one milliwatt 1,000-cps reference tone. Then, in the presence of the average level of received speech volume, the same observers were asked to adjust the level of each of these frequencies so that the impairment in the received speech was judged to be equivalent to that produced by the 1,000-cps reference tone. Other tests took into account the interfering effects of combinations of single frequencies and of different bands of thermal noise.

TIF Weighting Curves

Figure 2(A) and Table I show comparisons of the several TIF weighting curves which have been used. The first one, published in 1919, applied to the telephone instruments in use at that time. This curve has a high peak near 1,000 cps, indicating a resonance of the telephone receiver at that frequency. It was not carried above 2,100 cps because the telephone of that day was rather insensitive at higher frequencies.

Next came the 1935 weighting[2,3] which applied to the receiver then in use. There was still a peak near 1,000 cps, but not nearly so high, and the curve was carried to 5,000 cps. This 1935 TIF weighting is the basis for the maximum tif values for synchronous machines specified in the American Standard.[4]

In 1941, a new message weighting was established, based on the "302 series" handset which then was coming into use.[5] The resonant peak at 1,000 cps has disappeared but the weightings above 1,400 cps are higher than before, reflecting the improved transmission characteristics of the instrument. Work on a companion TIF weighting was initiated but not completed. One version of a revised TIF weighting under consideration at that time, usually referred to as the "tentative 1941" TIF weighting, has been used to a considerable extent by the Bell System.

The new 1960 TIF curve is based on *C*-message weighting which was derived from tests on the 500-series telephone sets. It is felt that the response of these sets is such that the weighting is largely controlled by the characteristics of the listeners, and that it is unlikely that such changes as may be made in future types of telephones will require a re-evaluation of TIF.

The original scale of values of TIF was related to weighted receiver μamperes per rms ampere in the power line. With each succeeding revision an attempt has been made to adjust the level of the curve (by adjusting the constant factor of the TIF formula) so that readings on typical power circuits or machines would average approximately the same on the new basis as on the preceding one. This generally has made it unnecessary to adopt radically new figures for TIF objectives for apparatus and circuits.

Improvements in the telephone plant over the years have allowed some relaxation in TIF weighting in the lower part of the voice frequency range. This is because the improved transmission has raised the average received speech volume, and because the flatter frequency response of the receiver has improved understandability. Conversely, the TIF weighting in the upper part of the voice frequency range has been raised because of the increased response of the receiver at these higher frequencies.

When a trial TIF weighting characteristic was computed from the *C*-message weighting with $K=6{,}000$, the constant used in the tentative 1941 TIF weighting, the resulting TIF values computed from analyses on many generators and power lines appeared too high, compared with 1935 weightings. The Subcommittee therefore agreed to reduce K to 5,000, and the resulting characteristic has been accepted as the 1960 TIF weighting. With $K=5{,}000$, equation 1 becomes

$$\text{TIF}_f = 5p_f f \qquad (2)$$

The 1960 TIF curve and a table of values for harmonics of 60 cps are shown in Fig. 2(B). The specified TIF of 0.5 at 60 cps (Table I) is nominal and not computed from the *C*-message weighting curve, which has no value specified for 60 cps.

Measurement of 1960 TIF

TIF always can be computed by making a harmonic analysis of the voltage or current wave and then applying the individual frequency TIF weightings to the various harmonic components. Such harmonic analyses can be made with any of a number of suitable harmonic analyzers, including the Western Electric *2B* noise-measuring set with the *10A* noise analyzer attachment or the newer Western Electric *4A* noise analyzer.

Less accurate but much more convenient single over-all measurements of voltage or current waves according to the 1960 TIF weighting can be obtained with a Western Electric *3A* noise measuring set and a suitable coupler. The *3A* set includes a *C*-message weighting network. When used with a voltage or current coupler which introduces a multiplier of f, the set readings become proportional to the product of frequency, the relative interfering effect in accordance with the *C*-message weighting, and the magnitude of the voltage or current. Therefore, the measurement is equal to a constant times V·T or I·T. Multiplying the set reading by a suitable constant and dividing by the rms value of the power circuit voltage or current then gives the TIF of the waveform applied to the coupler.

The schematic circuit of a voltage TIF coupling unit as used with the Western Electric *3A* noise-measuring set is shown in Fig. 3(A). The resistor is used to match the input impedance of the set. The accuracy of the readings is directly dependent upon the precision of the 0.01-μfarad capacitor because of its use as a multiplier. The factor for converting a reading to Kv·T is computed by assuming an input of one volt at 1,000 cps. Since the 1960 TIF weighting at 1,000 cps is 5,000, the V·T product of this input is 5,000 and the Kv·T product is 5.

The input impedance of the voltage TIF coupling unit and noise set is $300 - j15{,}900$ ohms at 1,000 cps. With a

1-volt input to the coupler the voltage across the set input is $300/(300-j15,900)=18,900\times10^{-6}$ volts. Reference noise voltage for the new set is 24.5×10^{-6} volts. (This is equivalent to 10^{-12} watts dissipated in 600 ohms, i.e., zero dbrn.) Thus the set will read $20\log_{10}(18,900/24.5)$ or 57.8 dbrn (reference noise in decibels). This is for an input where $Kv{\cdot}T=5$. For $Kv{\cdot}T=1$ the reading will be $57.8-14=43.8$ dbrn. The conversion chart, Fig. 4(A), therefore has an ordinate of 43.8 at $Kv{\cdot}T=1$, and a slope of 20 dbrn per decade.

A similar computation made for any other frequency using the appropriate coupler impedance, TIF weighting and message weighting, will give the same factor of 43.8 dbrn for $Kv{\cdot}T=1$.

The coupler may be connected directly to a low-voltage power secondary or to a potential transformer secondary. The TIF of the voltage is found by dividing the measured Kv·T by the rms voltage in kilovolts. TIF is the same on the primary and the secondary of the potential transformer. Kv·T on the primary, however, is equal to the secondary Kv·T times the transformer ratio.

Current TIF is measured by placing a current TIF coupling unit in the power circuit, as shown schematically in Fig. 3(B). It may be placed directly in a low-voltage circuit carrying 5 amperes or less, but it is usually placed in a current transformer secondary circuit. Its impedance at 60 cps is about $0.1+j0.15$ ohm so that it does not imposed a serious burden upon the current transformer. The conversion factor is computed in a manner analogous to that described above for the voltage coupler, assuming one ampere at 1,000 cps. The set reading is 20.2 for $I{\cdot}T=1$, and the chart in Fig. 4(B) is plotted accordingly.

The TIF of the current in the coupler is the I·T divided by the rms value of that current, and the TIF of the primary current is the same. The primary I·T is equal to the secondary I·T times the current transformer ratio.

Residual component voltage TIF of a 3-phase machine is measured by connecting the windings in delta with one corner open and measuring across the open corner. One third of the Kv·T product so measured, divided by the phase-to-neutral rms voltage in kilovolts, gives the residual component voltage TIF.

Residual current TIF is measured by paralleling the secondaries of the current transformers on the three phases, thus giving the vector sum of the three currents.

Table III. Harmonic Currents in Supply to 24-Phase Rectifier

Frequency	Line Current, Amperes	I·T

Comparison of Actual TIFs

Some comparisons of TIF computed from analyses of power system voltages and currents using the 1935 and 1960 TIF weightings are shown in the tables. Table II compares the open-circuit voltage TIF of several synchronous generators of various sizes and current design. It will be noted that use of the 1960 weighting increases the TIF in some cases and reduces it in others, depending on the particular distribution of the various harmonics involved.

Table III compares the I·T of a 13,200-kw 24-phase rectifier as measured

in the 13.8-kv supply line. Table IV compares the I·T of one of the eight 6-phase elements comprising the same 24-phase rectifier. As might be expected, use of the 1960 weighting increases the I·T of the entire 24-phase rectifier because the 1960 weighting is greater in the region of the 23rd and 25th harmonics, which predominate in a 24-phase rectifier. Conversely, use of the 1960 weighting decreases the I·T of the 6-phase unit because the 1960 weighting is smaller in the region of the lower-order harmonics, which predominate in a 6-phase rectifier.

The 3A Noise-Measuring Set

The Western Electric *3A* noise measuring set is the only set at present available for measuring the 1960 TIF values, but other manufacturers may adopt the new weighting in the future.

Since the set was designed to be useful as a general noise-measuring instrument, a brief description of some of its features may be of interest.

The basic requirement is that it give approximately the same reading on any two different noises which are judged to be equally interfering when heard over a 500-type telephone set. This is accomplished by means of its *C*-message weighting network, its detector (approximately square law), and dynamic response.

The appearance of the *3A* set is shown in Fig. 5. Its dimensions are approximately 8 by 11 by 7 inches and its weight about 15 pounds. This represents a considerable reduction in size and weight over previous noise-measuring sets; it was accomplished through the use of transistors and other miniature components.

An important physical innovation in the *3A* set is the plug-in arrangement for weighting networks. Two networks are packaged in a rectangular unit which may be inserted into a well in the panel in either of two ways, so as to use either network at will. The usual unit for general noise purposes and TIF contains *C*-message weighting and 3-kc flat weighting. An optional unit has 5-kc program weighting and 15-kc flat weighting. The meter has the same response at 1,000 cps with all four networks, and the set may therefore be calibrated with any network in position.

The *3A* set is powered by a small 45-volt battery. The battery life is expected to be 100 hours with 2 hours of steady operation per day.

Two separate single-tip and ring jacks afford access respectively to the monitor circuit which is the a-c output, and to the d-c output. When the a-c output is operated into 5,000 ohms or a higher impedance, no voltage clipping will take place until the peak output is 15 db higher than that corresponding to full-scale meter reading. The a-c output may be monitored with the special monitoring receiver furnished with the set. The noise being monitored may be heard at clearly audible volumes in the receiver for all meter readings from full scale down to zero db.

The d-c output may be used for oper-

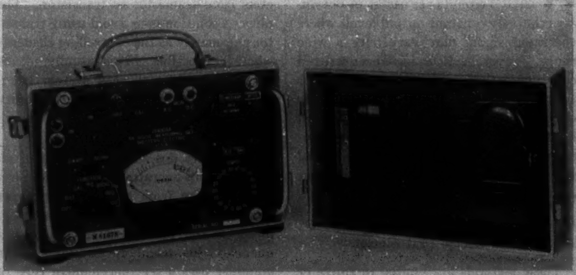

Fig. 5. The 3A noise-measuring set

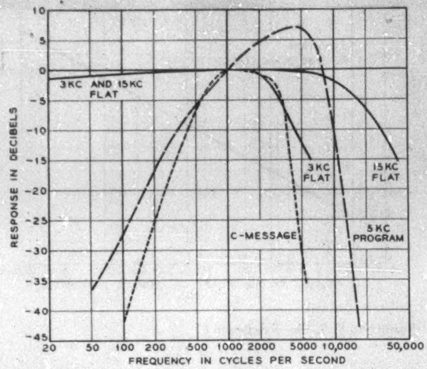

Fig. 6. Characteristics of weighting networks

ating a recording meter. The d-c voltage does not suffer compression up to a value of 1.4 volts across a load impedance of 1,100 ohms.

The sensitivity of the new set is −90 db below one milliwatt (10^{-12} watts or 24.5 μvolts across 600 ohms), and 90 db of amplification is provided. An internal oscillator gives one milliwatt at 1,000 cps for convenient calibration. The frequency characteristics of the weighting networks are shown in Fig. 6. The accuracy of response of the networks varies over the frequency range from ±0.1 db at 1,000 cps to as much as ±2 db on the steeper parts of the curves. The average on *C*-message weighting may be taken as about ±0.5 db, and the over-all accuracy of the *3A* set is about ±1 db.

Operation

The input of the set (see Fig. 5) may be connected to a telephone circuit or to a TIF coupling unit by means of a telephone plug, a banana plug, or an open-end pair of leads. The desired weighting network and the monitoring receiver are plugged in. The function switch is then turned through the BAT and CAL positions (assuring that the set is in proper working order) to one of the four input impedances. The attenuator switch (marked DBRN) is turned until a suitable meter indication is observed. The noise set reading is then established as the sum of the dbrn indication and the meter reading in dbrn.

A Transistor Automatic Gain Control System for Audio Frequencies

J. SHIRMAN
ASSOCIATE MEMBER AIEE

AUTOMATIC GAIN CONTROL (AGC) circuits are useful in obtaining relatively constant output levels where the input signal may vary over a wide range. Several articles have been written covering methods of controlling transistor gain in intermediate radio-frequency circuits.[1,2] The usual method employed is to change one of the transistor parameters by the application of an external signal. The two basic methods of gain control indicated are:

1. Emitter current (I_e) control.
2. Collector voltage (V_c) control.

These methods are limited in range of control and stability of output level because of inherent differences in parameters from transistor to transistor. The obvious solution is to avoid using transistor parameters as the controlling elements wherever possible. This usually means that a more complicated system is required. However, when good stability and wide operating range are required, no other solution exists.

This paper describes the design of an AGC system operating in the audio-frequency range from 300 cps (cycles per second) to 3,500 cps. This will be recognized as the pass band for audio frequencies in telephone systems. The amplifier uses a servomechanism type of closed loop feedback network to give a stable output level. One of the main advantages of this system is its ability to compensate internally for transistor parameter variations and supply voltage fluctuations in the amplifier section.

Circuit Description

This particular system was designed to compensate for input variations from −30 dbm (decibels referred to 1 milliwatt) to 0 dbm while maintaining the output at about +1 dbm. This system is used between an electronic field telephone and its associated mobile electronic dial switching system. All signaling is done with multifrequency tones

originating in the telephone. These frequencies all fall within the audio spectrum. Signaling tones and voice could be received at the switching center at any level from 0 dbm to −30 dbm depending on the condition of the telephone and the connecting line length (up to 8 miles). Operation of subsequent logic functions in the switchboard require a +1.5 dbm level ±1.5 db over wide environmental and component ranges. These are as follows:

1. Battery voltage variable from ±10.0 volts to ±14.5 volts.
2. Temperature range from 30 F (degrees Fahrenheit) to 130 F.
3. A predicted beta variation from 20 to 200 which included aging over a 200,000-hour (20-year) life and the temperature range indicated above.

A complete circuit diagram is given in Fig. 1, while Fig. 2 gives a simplified block diagram indicating the main sections of the system. The a-c amplifier is a fixed gain 3-stage circuit containing loop feedback to aid in gain stabilization. The output of this amplifier is fed back to a peak rectifier comprised of a transistor and diode. This voltage is then converted to a current in the d-c amplifier stage which supplies the current to the variable impedance Z_1. Two silicon diodes are used with a wide dynamic impedance range in the forward biased direction. The two diodes are in parallel when viewed in an a-c equivalent circuit. The use of two diodes extends the range of operation and helps stabilize against diode variations from unit to unit. The input signal is attenuated by the variable L pad comprising the fixed resistor R_2 and the variable Z_1. The operation of this pad is such that the voltage at point A in Fig. 2 is always constant over the control range of the diodes.

With proper adjustment of circuit parameters operation is as follows:

When a signal at −30 dbm is applied at the input it is amplified by the a-c amplifier and arrives at the output at the +1-dbm level desired. This output is fed back through the rectifier and d-c amplifier which, due to its low level, delivers a small current to Z_1. This results in a high diode impedance and no attenuation of the input signal. The output therefore remains at +1 dbm. If an input signal is applied at a 0 dbm level, the output attempts to go to a very high level and actually does for a short time. This large signal is fed back around the loop, and a large current is delivered to the diodes. This results in a low diode impedance and a resultant large attenuation of the input signal. By proper adjustment of the d-c amplifier again a +1 dbm output can be obtained. The time it takes for the servo loop to operate and pull down the level at point A is referred to as the attack time of the AGC system. For this circuit the attack time is on the order of 5–8 ms (milliseconds). The release time is, however, on the order of several hundred milliseconds.

This system is by no means limited to these points of operation. Resistor R_2 determines the output level at which the circuit operates, while R_{30} regulates the minimum and maximum inputs at which regulation is obtained. By judicious adjustment of R_{30}, R_2, and the gain of the d-c amplifier, the system can be made very flexible with regard to output level and range of input level which can be controlled.

Circuit Analysis and Design

In order to allow for output level variations resulting from beta changes and battery fluctuations it was decided to design the AGC system with an allowable variation in output of 0.5 db for a 30-db change in input. This means that the stiffness ratio is:

$$\frac{dP_o}{dP_i}=\frac{1}{60} \tag{1}$$

For instance, for a 1-db change in the input there is a change in output of 1/60 db. If the amplifier gains can be assumed to be constant, the simple block diagram of Fig. 3 may be drawn from which a mathematical analysis of the system can be made.[3] From the diagram it can be seen that the relationship between input power, output power, and attenuation in db is as follows:

$$P_o=P_i-X \tag{2}$$

where X is the variable attenuation, x, less the fixed gain of the a-c amplifier, k (i.e., $X = x - k$). Also, since the diodes are current controlled devices, the output of the rectifier is some function of the output power level:

$$I=f_1(P_o) \tag{3}$$

and the attenuation is a function of the current through the diodes:

$$X=f_2(I) \tag{4}$$

By differentiation and combination of the preceding equations:

$$\left(\frac{\partial I}{\partial P_o}\right)\left(\frac{\partial X}{\partial I}\right)=59 \tag{5}$$

which is the basic design equation for the AGC system. The first term on the left side of the equation is the slope of the bias current versus output power curve in relative db, while the second term is the slope of attenuation versus bias current. The product of these two terms is a constant. For perfect AGC action (as given by equation 1), this value must be maintained at every point along the re-

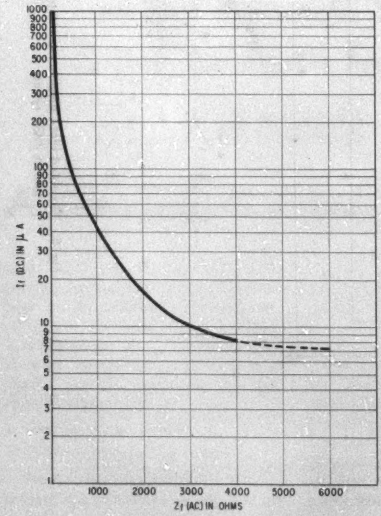

Fig. 4 (left). Bias current versus forward impedance (a-c) of 689 silicon diode at 25 C

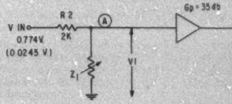

Fig. 5 (right). Equivalent circuit for calculating diode impedance

quired operating range. As will be shown later, experimental results are very close to the desired ideal values.

Diode Operation

The first step in the design procedure was to find a diode with a sufficiently wide dynamic impedance range in the forward biased direction. The plot of Fig. 4 shows bias current versus forward impedance of the silicon diode selected. Due to the interdependence of various sections of this system, considerable empirical work was necessary in selecting the value of fixed resistance to use in the *L* pad. It was found that a value of 2,000 ohms for R_2 gave the best results over the desired range of operation. However, in order to get sufficient attenuation of the input at the 0-dbm level, it was necessary to use two diodes. Diodes *CR1* and *CR2* are connected in a-c parallel but in a series d-c circuit. This gives the benefit of a lower a-c impedance at a given current level. At the same time, by feeding direct current in series, differences between the two diodes are balanced out.

Before deciding over what range of bias current the diodes must operate, it was necessary to investigate the gain requirements of the a-c amplifier. It is obvious that the minimum gain must be 30 db since that is the lowest input level requiring control. In order to get rapid AGC action at the low end, it was necessary to have several db of attenuation present in the *L* pad. This meant that at the minimum input level some current was already being delivered to the diodes. It was decided to have 4 db of attenuation present at the −30-dbm input level. This then required an amplifier with about 35 db of gain. The next step was to calculate the required *L* pad needed to give +1 dbm output for a 0-dbm input signal (0.774 volt). Fig. 5 gives the equivalent circuit and necessary data used in the calculations.

It is seen that V_1 must be 0.0155 volt at this input. This means that Z_1 must be about 40 ohms. Therefore, each diode should present an impedance of about 80 ohms. Looking again at Fig. 4, it was seen that the required bias current for this value of forward impedance is 750 μa (microamperes). In the same manner the value of Z_1 required for an input of −30 dbm (0.0245 volt) was calculated. In this case the output level could drop to +0.5 dbm (0.825 volt). This gave a value for Z_1 of about 3,000 ohms or an individual diode impedance of 6,000 ohms and bias current of 7.5 μa. These two bias currents gave the range of currents required from the d-c amplifier. This amplifier is strictly a linear device, that is, the output current is a linear function of the input. In order to get rapid AGC action it was necessary to have a nonlinear resistance as the variable element.[4] The silicon diodes used in this circuit act as linear to logarithmic converters by converting a linear input current change to a logarithmic variation in dynamic impedance. The ideal relationship for the conversion is given by:

$$A=\epsilon^{CB} \tag{6}$$

where *A* and *B* are variables and *C* is a constant. The current voltage relationship for a diode is given by:

$$I=I_s(\epsilon^{qv/kt}-1) \tag{7}$$

neglecting the *IR* drop of the diode. At room temperature q/kt is a constant. Also, at the normal voltages encountered across a diode:

$$\epsilon^{qv/kt}\gg 1 \tag{8}$$

which means that equation 7 reduces to

$$I=I_s\epsilon^{Cv} \tag{9}$$

where I_s (the saturation current) and *C* are constants. This equation is now in the form of equation 6. Fig. 6 is the well-known *V-I* diode curve for the *689*-type used over the range where equation 9 holds. The linear to logarithmic conversion is seen to be about 0.1 volt/decade and to be constant over the range of currents required for this AGC system.

Rectifier and D-C Amplifier

The main problem in designing these two circuits was stabilization of the output with changes in the environmental conditions specified at the beginning of the paper. The output level of the rectifier varied considerably as a result of the indicated battery fluctuations. This problem was solved by Zener regulation of the collector and base voltages. A 7.5 ±5% Zener (*CR4*) was used which guaranteed regulation over all battery conditions.

The main difficulty with the d-c amplifier resulted from shifts in operating point with temperature. The use of a special low I_{co} transistor helped considerably. By placing a forward biased silicon diode in the emitter further stabilization of the operating point was achieved.

A-C Amplifier

Once the gain requirements of the a-c amplifier were determined the design procedure was quite straightforward. The amplifier consists of three stages, each

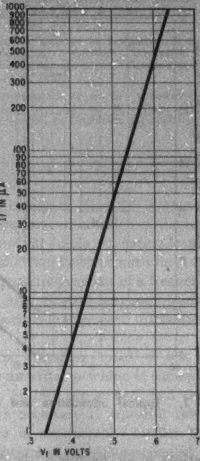

Fig. 6. Forward voltage versus forward current curve for 689 silicon diode at 25 C

containing emitter degeneration. All three stages are designed with d-c operating point stabilization through the use of base biasing resistors. Over-all loop feedback of about 10 db around the a-c amplifier is also included. Each stage has about the same gain, approximately 12 db. The amplifier alone exhibited a stability of better than ±0.4 db over all the beta and battery conditions indicated before.

When connected in the AGC system a very important and interesting result was noted. Due to AGC action, the variation in gain indicated above was almost completely eliminated. Changing the three transistors from betas of 20 to 150 (the highest available) the output level changed less than 0.1 db. This resulted from the operation of the AGC loop in maintaining the output at a fixed level. The high beta transistors acted in the same way as a higher amplitude signal resulting in greater attenuation in the AGC loop. The converse is true in the case of the low beta units. For this reason the AGC system is quite insensitive to beta variation, the only transistors having any effect being the two in the AGC feedback loop.

Experimental Results

In testing the system it was found that the variations in dynamic impedance of the diodes had serious effects on the operation of the a-c amplifier. Also

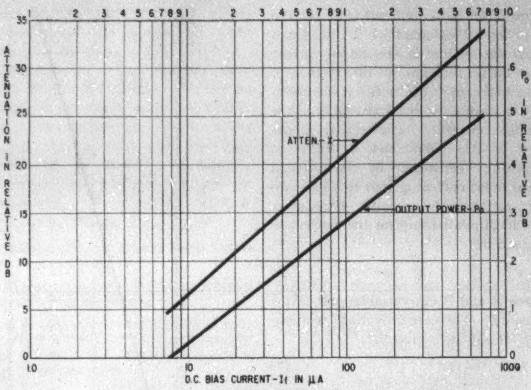

Fig. 7. Typical attenuation and output power versus bias current curves found during development

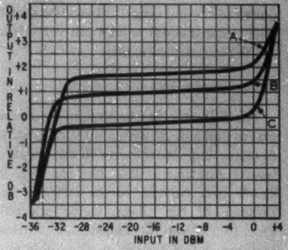

Fig. 8. Input versus output for complete AGC system

A—Volts: ±14.5; B maximum = 150; T_A = 135 F
B—Volts: ±12.3; B nominal = 60; T_A = 75 F
C—Volts: ±10; B minimum = 20; T_A = 20 F

variations in a-c loading of the AGC affected the operating range of the circuit. In order to eliminate these effects emitter follower circuits were included at the input and output of the a-c amplifier to isolate it from impedance variations at its terminals. The emitter follower output means that the system has a very low output impedance. However, due to loading effects, the minimum load resistance before serious distortion occurs is about 1,000 ohms. On the input side, the 620-ohm shunting resistor, R_1, has the effect of stabilizing the input impedance variation due to the variable *L* pad. For a 30-db input voltage change the input impedance varies from about 450 ohms to 580 ohms or a total of about 25%.

Fig. 7 shows typical curves of attenuation and output power versus diode bias current. It is the slope of these curves which must satisfy equation 5. A check will show that correlation is quite close over most of the operating range.

One factor which tends to limit the usefulness of the circuit is distortion. Due to the fact that the diodes are used over a wide dynamic range they tend to introduce distortion at the higher input levels. Distortion at −30 dbm input is about 5%. However, at an input of 0 dbm the total rms distortion increases to a value of 10% to 15%. No simple solution to this problem has been found. It is believed that a bridge diode network instead of the parallel connection would be a considerable improvement.

Fig. 8 is a set of curves of input versus output for the complete AGC system. The *A* and *C* curves are "worst condition" results and show that the design requirements were easily met. It was found that variations in the output level occurring with differences in beta and temperature were almost exclusively the result of effects of those conditions on the rectifier and d-c amplifier circuits. It was also noted that if the minimum beta was increased from 20 to 60 (the nominal value indicated), curve *C* is almost equal to curve *B*. This shows that the greatest variation in output level is due to the spread in transistor beta, particularly in the feedback loop. By raising the minimum beta requirements it is possible to design this system with a total output variation of less than 1.0 db. It should also be noted that temperature has some effect on the range in which the diodes act as good logarithmic converters. This can be noted in Fig. 8 at the lower end of the operating range. The operating range at 20 F is about 2 db more than at 135 F.

The frequency response of the system is flat, ±0.5 db from 400 cycles to 10 kc. Fig. 9 shows a nominal frequency response curve. The curve shows that the system displays a 3-db peak at about 150 cycles. This peak results from some of the *R-C* time constants in the system. Since this system was intended for use primarily over the telephone audio band of 300 to 3,500 cps, this was not considered a problem.

Some low-frequency oscillations were encountered along with feedback of pulses through the battery supply from other circuits. To eliminate these problems, four decoupling circuits were used as indicated in Fig. 1. These solved all the problems of intercircuit interference as well as preventing any oscillations due to mutual feedback between various parts of the AGC system.

Conclusions

Although this paper outlines the design of a particular AGC system it is evident that the procedure and block diagram configuration are applicable to a wide range of design requirements. The principal problem centers on finding the proper diodes to do the job. This is not always easy, but considerable help can usually be obtained from diode

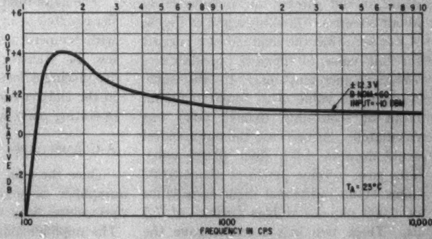

Fig. 9. Frequency response of agc system

manufacturers. Wider ranges of operation should be possible by using diodes in series or bridge arrangements.

Datacom Unit—An Experimental Data Transmission Subset

R. E. STOFFELS
ASSOCIATE MEMBER AIEE

THE NUMBER of miles of telephone wire in the United States today runs well over the 240 million mark. This is enough to run 1,000 wires between here and the moon, or, if extended as a single pair, enough to carry on a telephone conversation with the sun. Also there are in use today, in this country alone, well over 60 million telephone instruments.

The almost unbelievable magnitude of these figures suggests that future growth in the telephone industry will be mainly horizontal rather than vertical. That is, the growth will be more in usage than in number of miles of wire, or number of telephone instruments. One field which promises to provide such expansion is that of data transmission. Data that were formerly collected with paper and pencil, acted upon by trained personnel, and transmitted by mail or by hand, are now being collected and acted upon automatically, and, as a matter of course, must be transmitted automatically.

Transmission

The transmission of digital data over telephone lines is not new; in fact, the world's vast teletypewriter networks use, for the most part, existing telephone lines. In order to make this transmission possible, however, a language translation is necessary. This is because of the basic characteristics of a telephone line, or, to be more precise, a telephone channel.

A telephone channel is not capable of transmitting all frequencies from 0 cps (cycles per second) up; if it could it would not be economical, for a telephone channel was designed to carry a human voice, and in order to do this only those frequencies from approximately 250 cps to 3,000 cps have to be reliably transmitted. Consequently, a telephone channel is essentially a band-pass filter which severely attenuates those frequencies below approximately 250 cps and above 3,000 cps. (These cutoff frequencies will vary from circuit to circuit.) Because of the low-frequency limitation of the telephone channel all pulses emanating from a data transmitting machine must be in the form of alternating current of a frequency over 250 cps. Several language translations, commercially employed, will be mentioned later.

The operating speed of the popular teletypewriter machine is somewhat less than 80 bits per second, and the bandwidth necessary to transmit this intelligence is considerably smaller than the bandwidth of a telephone channel. Other business machines, which transmit data at higher speeds, require proportionately larger bandwidths. The maximum speed attainable, however, is limited by such factors as impulse noise, frequency band shift, and delay distortion.

There are two types of data transmission systems in common usage today; the synchronous system and the start-stop system.

In the synchronous system the re-

Paper 60-790, recommended by the AIEE Data Communication Committee and approved by the AIEE Technical Operations Department for presentation at the AIEE Summer General Meeting, Atlantic City, N. J., June 19–24, 1960, and represented for discussion only at the Fall General Meeting, Chicago, Ill., October 9–14, 1960. Manuscript submitted April 5, 1960; made available for printing August 15, 1960.

R. E. Stoffels is with Automatic Electric Laboratories, Inc., Northlake, Ill.

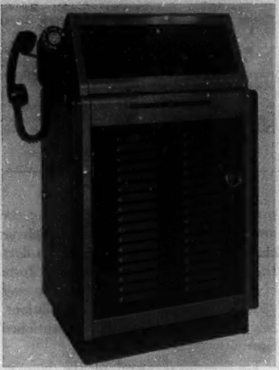

Fig. 2. Datacom unit

ceiving business machine is, in some manner, made to run at exactly the same speed as the transmitting business machine; often two stable oscillators are used.

In the start-stop system the receiver is allowed to run at a speed slightly faster than that of the transmitter. It comes to a complete stop every so often (usually once each character) and waits for the next signal from the distant transmitter. Because the transmitted signal must contain a START and a STOP pulse carrying no intelligence, this system is quite wasteful of time.

Briefly consider the schemes in popular usage for making the language of the business machine compatible with the language of the telephone channel;[1] see Fig. 1.

The system first used in the transmission of teletypewriter information was the on-off scheme. In this system a "yes," or mark, was represented by a voice-frequency tone, and a "no," or space, was represented by the absence of this tone. In the true sense, therefore, this is an amplitude modulation (AM) scheme, since there is either no modulation at all or the modulation is complete. Because the signal is absent approximately half the time this system is quite susceptible to noise.

In the vestigial sideband system, filters eliminate one sideband and a portion of the carrier. The small portion of the carrier allowed to remain is amplified in the receiver and mixed with the received sideband prior to detection.

The system which is often used to replace AM is the frequency shift, or frequency modulation (FM) system. In this scheme a "yes," or mark, is represented by one frequency and a "no," or space, is represented by a second frequency. The technical considerations of this system are very similar to that of the AM system, except that the FM scheme is considerably less vulnerable to noise.

The latest modulation scheme, and one which appears to have a great future, is phase modulation. In this scheme a continuous carrier wave is transmitted, but its phase is shifted depending upon whether the intelligence bit is a mark or a space.

Terminal Devices

The devices which will take intelligence and transmit it over a telephone channel and receive this intelligence at the distant station have been mentioned and also the speed capabilities of the telephone channel, the problems encountered in transmitting intelligence, and the modulation schemes which are commonly used. A brief investigation follows of the type of machines which are used to generate this intelligence at one end and to present it, at the other end, in a usable manner.

There are in use today thousands upon thousands of teletypewriter machines. These machines normally use a start-stop code, with the stop pulse either exactly as long as an intelligence pulse, or, more commonly, 1.42 times as long. These machines usually use five-channel paper tape; that is, each character consists of five bits. In the binary system this permits the use of 32 characters ($2^5=32$). If more possible combinations are required a sixth channel is added. If, in addition, a parity check is required of each character, then an additional channel is added. Very often, in fact, eight channels are used in transmitting data.

Magnetic tape is coming into wide usage today, and the type of tape used varies considerably, both as to the number of intelligence channels and the bit spacing. Punched cards are used by several companies, and both the physical dimensions and the number of holes varies considerably from one to the other.

This is mentioned to point out that the companies in the data field, the codes used for transmitting data, and the means used for recording this data vary enormously. It becomes quite apparent that any device used by the telephone company to transmit data must not try to replace these business machines, but rather must accept data from them at one end and present data to them at the other end. It must perform a translation from the language of the business machine to a language capable of being transmitted over telephone channels and back again to the language of the business machine.

Datacom Unit

In designing a data transmission device it was recognized that no one unit would work with all business machines; for instance, simple circuits adequate for slow-speed operation would be completely unsatisfactory for use with high-speed machines.

Because of the large number of teletypewriter machines in general use it was this machine which was considered in our design program. It was felt that as many special features as possible should be included with the device, even though in most applications many would not be useful.

The result of this design effort was the "Datacom" digital data communication set, a unit which we feel is a big step forward in meeting the requirements for data transmission; see Fig. 2.

The Datacom unit is a transmission device; it accepts information from a business machine and does not try to replace the machine; see Fig. 3.

In the Datacom unit an FM modulation system is used; equipment utilizing FM modulation is commercially available and has been perfected by manufacturers to a high degree.

Telephone lines are used on a demand basis; thus leased lines associated with the equipment on a permanent basis are unnecessary. Data are accepted from the associated business machine in a sequential form; therefore, the number of intelligence channels used by that business machine is immaterial. The sys-

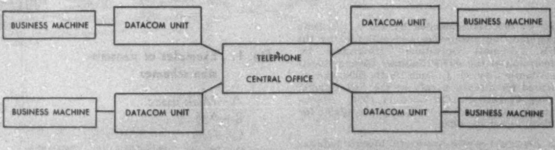

Fig. 3. Block diagram showing Datacom units in relation to central office

Vol.
Pt. 1
196

tem is nonsynchronous and the expense of local controlled oscillators is eliminated.

The Datacom unit consists of: tone equipment and equipment required to convert the data communication language of the business machine into a "tone" language compatible with the voice-frequency telephone lines; control equipment required for the necessary dialing, automatic answering, switching from voice communication to data communication, and resetting of equipment; and loop equipment which serves to connect the particular business machine to the Datacom unit.

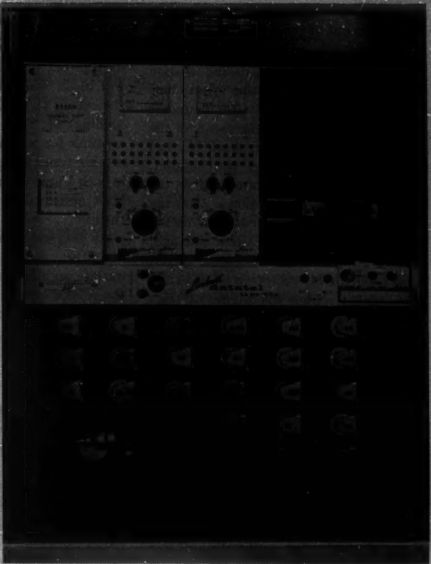

Fig. 4. Inside view of Datacom unit showing tone and control equipment

TONE EQUIPMENT, FIG. 4

The tone equipment used is standard Lenkurt type *23A* telegraph carrier equipment[2] and is entirely transistorized, operating on a FM basis. The carrier frequency used is 1,955 cps, and the mark and space frequencies are formed by shifting the carrier frequency between values which are 35 cycles above and below the nominal midband frequency. Consequently the midband frequency of 1,955 cps never actually appears. Both levels may range from +6 dbm (decibels referred to 1 milliwatt) to −40 dbm. The equipment is designed for a line impedance of 600 ohms.

TRANSMITTING EQUIPMENT

In the transmitting equipment, a diode modulator is used to insert or remove a shift capacitor from the oscillator tank circuit, thus minimizing the effect of the line to the business machine. The oscillator can best be described as a regenerative flip-flop whose oscillations are limited by clipping in both transistors. This stage feeds a buffer amplifier; the output is fed through a 2-transistor amplifier, and an output transformer feeds the transmission line.

RECEIVING EQUIPMENT

In the receiving equipment, the signal is fed through a pad, if required, then through a band-pass filter and a single stage of amplification. It is then severely clipped and fed through a transformer to a push-pull stage. The output of this stage feeds a discriminator of the double tuned series-resonant type. One mesh is tuned to a frequency close to the mark frequency, and the other mesh is tuned to a frequency close to the space frequency. The output of each mesh is bridge-rectified and two currents are combined differentially. The resultant signal then feeds two power transistors connected as d-c amplifiers, and this final output drives a polar relay. The polar relay is used to operate the receiving portion of the business machine.

CONTROL EQUIPMENT, FIG. 4

The function of the control equipment begins when a call is initiated and ends when the line is released. It includes the initiation of a call from a standard telephone dial, automatic answering of the distant station in response to ringing current, and control of the tone equipment. The equipment consists of a control panel from which all operations are performed, control relays, transistor circuits used for timing purposes, and a telephone with means for automatically cutting the handset transmitter in and out of the circuit at the proper time. Thus it is possible at all times to monitor the voice-frequency signals being transmitted and received and, in certain instances, to carry on voice communication.

Because this system provides unattended service, certain additional equipment had to be added to replace the spoken "hello" of a normal telephone conversation with an electronic "hello" or "go ahead." This additional equipment consists of a unit of FM tone equipment, thus providing two additional tones for supervisory functions. The second of these tones is used to indicate an alarm condition, and will sound a buzzer to call the operator at the distant station. Voice communication can then be carried on.

LOOP EQUIPMENT

Since all business machines do not put out the same kind of signal, there must be some means for permitting the tone equipment to accept the specific signal being used. Very often a neutral signal is used; that is, current is present for the mark, and absent for the space. This current varies from 20 ma (milliamperes) to 60 ma. Occasionally a polar signal is used; current is sent in one direction to indicate a mark and in the other direction to indicate a space. Again the current can vary between several values. A strapping block is provided in the loop equipment to make several of these options possible.

Operation

Let us trace the transmission of a message from one station to another. To make this situation a little more complete, assume that the called station also has a message for the calling station.

For the purpose of discussion also assume that the business machine used is a teletypewriter machine which contains a page printer to receive data and a tape transmitter for transmission purposes. The tape transmitter is equipped with a "tape-out" pin, which indicates when the machine is out of tape, that is, a message has ended.

The operator at the calling station momentarily depresses the START button, thus applying power to the electronic equipment and starting the motor of the associated teletypewriter machine, and listens for dial tone on the handset. Upon hearing the dial tone he dials the number of the distant station. After the central office has selected this distant station, ringing current is sent out and, instead of operating a telephone ringer, it operates a relay receptive to this ringing current. The operation of this relay applies power to the tone equipment and turns on the motor of the teletypewriter machine.

When the called Datacom unit is ready for operation it sends a go-ahead tone. The Datacom unit at the calling station receives the tone and automatically starts the teletypewriter tape transmitter. The tape passing through the transmitter, with the aid of the loop equipment, modulates the FM tone equipment, thus transmitting data to the telephone channel. When the distant station receives this signal it reconverts it into data communication signals compatible with the teletypewriter machine; this causes the data to be typed as page copy. Simultaneously, the calling station also reads the signals from the line and causes a monitor copy to be printed by its page printer. (Notice that the only function performed by the operator was the initial dialing of the telephone connection. It is interesting to speculate on the possibility of making the calling station as well as the called station unattended; the simple addition of an automatic dialing device, in conjunction with a clock, is all that would be required.)

After transmission of the message, the tape-out pin rises on the tape transmitter. This stops the transmitter and initiates the transmission of a go-ahead signal to the called station. (The circuits are so arranged that the Datacom unit initiating the go-ahead signal cannot receive it.) The Datacom unit at the called station receives this signal and starts its teletypewriter transmitter. The message being sent from the called station is received at the calling station and, as before, at the called station for a monitor record.

When transmission of the message is completed, another go-ahead signal is initiated, this time by the called station. The calling station will receive this tone, but because its tape-out pin will be in the raised position it will transmit the go-ahead signal back to the called station. Since the called station has no message its tape-out pin will be up; therefore, it will again send the go-ahead signal to the calling station. This back-and-forth sending of the go-ahead signal will continue for several seconds. At the end of this time, signal-detecting equipment in each Datacom unit will "time out," and both units will release themselves from the line.

As previously mentioned, an operator at either station can, at any time, initiate an alarm condition by operating the ALARM button on the Datacom unit. This causes a different tone to be transmitted to the line, which is received by the equipment at both stations. This alarm signal halts transmission, prevents time-out from the signal-detecting equipment, lights an alarm lamp, sounds a buzzer, and connects the transmitters of the telephones. Operators at both stations can now converse in a normal manner. This alarm condition is cleared by an operator at either station by operating the GO-AHEAD button to allow further data transmission. Notice that action by operators at both stations is not required; the operator at one station can cause an alarm in order to attempt a conversation and if the other station is unattended this same operator can release the alarm. Should the alarm persist for one minute without being answered, the particular unresponding Datacom unit releases itself from the line.

Another operating feature of the Datacom unit is called "delayed alarm." At times it is advantageous to discuss a message with the distant operator before transmitting it. This is accomplished by operating the DELAYED ALARM key. In this case the receipt of the go-ahead signal will, instead of starting the transmitter, cause an alarm signal to be sent out.

It was recognized that different users would have many different communication requirements, and therefore the Datacom unit was designed to provide maximum flexibility of operation. Several of these possible modes of operation are discussed in the following.

KEYBOARD TRANSMISSION

It is quite possible that in certain applications transmission to the line directly from a teletypewriter keyboard would be desired. This has the advantage that the tape perforators and tape transmitter are not needed; however, it is wasteful of line time, since no operator can type as fast as a tape transmitter can transmit. Also it is not possible to proofread the message before transmission. At any rate, the Datacom unit accommodates keyboard transmission without any difficulty.

OPERATION IN A MANUAL TELEPHONE SYSTEM

This equipment can be operated with a manual telephone exchange. In such a case the attendant initiating the call operates the SUBSCRIBER DIAL-OPERATOR key to the Operator position, and then pushes the START button. This causes the transmitter of the telephone to be connected to the line; the attendant can now pass instructions to the operator at the central office. When the distant station answers, the handset is replaced, the GO-AHEAD button is pressed, and transmission begins automatically.

SECURITY SYSTEM

In certain applications of the fully automatic system positive identification of the distant station would be required before starting transmission. Such a security system has been added. In this case transmission of a message is contingent upon the receipt of a predetermined code from the distant station. (In a telephone system the recognition of the called party's voice usually provides the only security measure.)

AUTOMATIC DIALING

The delivery of collection of information during night-time hours would permit the user to take advantage of low rates, but the necessity of having even the calling operator on duty at this time might make such operations undesirable. The addition of an automatic dialing device, e.g., the Dialaphone, in conjunction with a timing device, would make such night-time operation completely automatic.

Conclusions

In the not-too-distant future the telephone industry will be as intimately interested in the transmission of data over their lines as they will be with the transmission of voice. More and more there will be a requirement for devices capable of translating the language of business machines into the language of the telephone channel. Speed and reliability requirements will be increased and, as a result, telephone channels will be upgraded and new electronic equipment will be designed. The exact direction of this design work is as yet unknown and will very likely remain so for a considerable time to come. Design, test, and redesign must determine the devices which will best serve the industry. The concept followed in the development of the Datacom unit is simply one solution; a very logical one we believe, but nevertheless only one.

Just as the amount of data being used by man is increasing by leaps and bounds, the facilities for the transmission of data must follow. The point-to-point transmission of these data, accurately and rapidly, is a challenge to the entire telephone industry.

The New Nation-Wide Telephone Numbering Plan

O. MYERS
MEMBER AIEE

THE PRESENT NATION-WIDE telephone numbering plan, adopted in 1947, was expected to last beyond the year 2000, but now it appears that it will be outgrown by about 1975. The telephone industry in the United States and Canada has, therefore, adopted a new plan with several times the code capacity of the present one which should last well into the next century.

The new plan, shown in Table I, provides uniform dialing procedures for all types of central offices. Under the present plan, procedures vary with the type of office. The following are also provided:

1. A prefix for customer dialed person-to-person, collect, credit card, and other calls requiring operator assistance. The recommended prefix is "0" (zero).
2. A simplified toll office access code for DDD (direct distance dialed) calls in step-by-step central offices. With the present plan a step-by-step central office customer making a DDD call uses a 3-digit access code such as "112" to reach the toll office. The access code may be followed by as many as ten digits giving a maximum of thirteen digits. With the new plan, the recommended DDD access code is the single digit "1" and the maximum number of digits is therefore eleven.
3. A prefix to prevent error when local-intended calls reach toll points in cities using telephone systems like no. *5* and no. *1* crossbar which store and process the dialed digits (common control type). The new plan requires the use of a prefix, "0" or "1," on all toll calls. Hence a wrong office code digit on a 7-digit local call (no prefix being dialed) cannot convert a local-intended call into a toll call.

Background

The present nationwide numbering plan operates with 152 area codes of the form A1X or A0X (A represents 2 to 9; X represents 0 to 9). Of the potential 160 codes, eight are used for service codes in the series A-1-1. For example, the information code in a common control city is 411. The area code is generally followed by two letters of an office name and five numbers. See Table II for present and ultimate capacities.

With the present practice of using central office names, each area has a capacity of about 540 office codes. It would seem that there should be 640 possible office codes. (Eight dial pulls for the first digit times eight dial pulls for the second digit times ten for the third digit. Only eight holes on the dial have letters.) In practice, however, there are only about 60 usable letter combinations for the first two digits instead of 64. This is because of the difficulty in finding names to fit the dial pulls 5-5, 5-7, 9-5, and 9-7 (5 corresponds to JKL, 7 to PRS, and 9 to WXY). Also, since there is considerable confusion between the letter "O" and the numeral zero, the latter is usually avoided in the central office designation. This leaves us with 60 usable letter combinations multiplied by nine numerals for a total of 540 codes.

Each office code has capacity for 10,000 telephone numbers. The original plan of using office names was recently amended. All-number calling (ANC) is now recommended and 640 codes are available at present in areas that elect to use ANC. The combination of ANC and new dialing procedures will produce 792 office codes.

Eighty-six of the 152 area codes were assigned when operator nation-wide dialing was started in 1947. The remaining 66 area codes were expected to care for many years of growth. However, there has been a telephone explosion in the United States. In the decade 1950–1960, while the United States population grew from about 150 million to 180 million, telephones grew from about 41 million to 71 million. Growth during the next 15 years is expected to be even greater. Telephones are expected to double in number from 71 million to 142 million while population may increase to 237 million.

These data are somewhat misleading. Telephones rather than telephone numbers have been discussed while only the latter affect numbering capacity. Much telephone growth will merely result in an increased number of extensions rather than in more numbers. Some of the

Table I. The New Numbering Plan

	Ultimate Stage	Initial Stage
Home area DDD	1+AXX+4N(numbers)*	(1)+ABX+4N†‡§
Home area special toll	0+AXX+4N	0+ABX+4N
Foreign area DDD	1+*AXX*+AXX+4N‖	(1)+*A0/1X*+ABX+4N
Foreign area special toll	0+*AXX*+AXX+4N	0+*A0/1X*ABX+4N

* A represents 2 to 9; X represents 0 to 9.

† (1) Indicates that the prefix may be used in common control areas but must be used in SXS areas.

‡ In the initial phase, existing type access codes, such as 112, may be retained. Ultimately access codes other than 1 and 0 should be used only where the switching system design requires their use.

§ All-number calling is now recommended; therefore, ABX represents the two letters of the office name followed by a number or three numbers of the recommended all-number office designation. For the present the first two office digits are limited to 2 to 9.

‖ Italicized codes are area codes

Paper 60-1210, recommended by the AIEE Communication Switching Systems Committee and approved by the AIEE Technical Operations Department for presentation at the AIEE Fall General Meeting, Chicago, Ill., October 9–14, 1960. Manuscript submitted June 13, 1960; made available for printing August 5, 1960.

O. Myers is with the Bell Telephone Laboratories, Inc., New York, N. Y.

Table II. Capacity of New Numbering Plan

Initial		
Area codes:	A1/0X	152
Office codes:	ABX (Names)	540
	AXX* (All-Number Calling)	640
Ultimate		
Area codes:	AXX	800
Office codes:	AXX	792†

* X in this case represents the digits 2 to 9. When the new plan is implemented it will represent 0 to 9 and 792 office codes will be available.

† Eight codes in the A-1-1 series are reserved for service codes in common control cities.

Service codes: No change
Operator code: "0"
AHAD permitted: Requires an arrangement to determine whether the number includes an area code.

growth will cause an increase in telephone numbers and, therefore, in office and area codes.

New services will increase the demand for numbers and codes considerably. Today, we need 117 area codes. Most of the increase from the original 86 is due to unanticipated growth, but several area codes were also added for dialing to points beyond the continental United States and Canada such as Hawaii, Alaska, and Puerto Rico. Other new services are also having an effect which will increase as times goes on. Direct inward dialing to PBX (private branch exchanges) is one such service. This requires PBX extensions to have standard 7-digit numbers and results in a telephone number per extension rather than in one per PBX trunk.

Another new service that will require telephone numbers is data switching over the telephone network. Each data station will require one or two numbers, so additional numbers, office codes, and area codes will be added because of this service. Still other uses for area and office codes will be generated by paging systems, mobile systems, military systems, and extension of dialing to additional points.

Requirements of the New Plan

The new plan was devised to meet the following requirements:

CAPACITY

Additional capacity is a basic requirement. Capacity could be extended for a few years beyond the expected exhaust date with relatively modest changes in the present plan but experience with temporizing has been bad. Underestimations have led to difficulties in the past. It seems sensible to set up a large capacity plan that will last well into the next century. The eight-hundred area codes provided by the new plan are considered adequate. This number of codes is obtained by using eight digits, 2–9, in the first code position and ten digits, 1–0, in the second and third positions.

While we have been thinking primarily in terms of capacity that would be adequate for North America, we have not been unaware of the ultimate desirability of a world-wide plan. The door has been left open for arrangements such as doubled prefix digits which will allow the proposed plan to grow into a world-wide plan.

A PROGRAMMABLE PLAN

A plan that would require a simultaneous nation-wide switch from the existing to the new would be completely impractical. Apart from the large costs of such a cutover, the co-ordination of work in thousands of central offices could not conceivably be handled without major difficulties and service interruptions. The plan adopted can be implemented in easy stages.

NO MODIFICATIONS OF CUSTOMERS' EQUIPMENT

The chief objection to modifying equipment, such as telephones on customers' premises, is cost. From the standpoint of features certain modifications of telephones are attractive One which has been discussed is the use of specially designated buttons on dials and on keysets proposed to replace dials, which customers would push instead of dialing prefix digits such as "0" or "1." Other changes have also been suggested, but costs have prevented adoption of any of these ideas as a requirement of the new plan.

COSTS

Reasonable over-all costs are obviously a necessity. It is also desirable that money be expended only where needed and at the time a change in plan is needed.

ABBREVIATED HOME AREA DIALING (AHAD)

The new plan recommends the prefix "1" or "0" followed by the 7-digit number for calls within the home numbering plan area. At the time when area code shortages forces the use of the same code for both an area and an office, arrangements will be needed to determine whether the first three digits represent an area code or an office code.

CUSTOMER ACCEPTANCE

It was felt that a plan that was essentially an extension of the present plan would be more readily accepted by users than a radically new plan. Such a plan would also be most desirable from a customer education standpoint.

Description of the Plan

The numbering plan adopted will be implemented in three stages:

1. A period during which area codes of the present type will be employed.
2. A period during which ABO codes may be used to augment present-type area codes.
3. The ultimate stage when 800 area codes of the AXX-type will be available. At this time 792 AXX-type office codes will also be available with ANC (8×10×10 minus the eight A-1-1 type service codes).

DIALING PROCEDURE PRIOR TO AREA CODE SHORTAGE

Common control areas. Regular (sent-paid station-to-station) foreign area DDD calls will be dialed as at present. Home area DDD calls will be either 7 or 10 digits, depending on the preference of the operating telephone company.

Customer-dialed special toll calls such as person-to-person and collect will require the prefix "0" (zero) which will be followed by seven or ten digits as in the case of regular DDD calls.

For assistance calls, "0" alone will be dialed. Since special toll calls may use the prefix "0", an appropriate circuit will wait where the prefix "0" is used to see if further digits are forthcoming. Service codes will be of the present form, namely A-1-1.

At the option of the operating telephone company, the prefix "1" may be adopted at an early date for regular DDD calls to act as a barrier against reaching toll points in error on local-intended calls.

Step-by-step or mixed areas with rotary dials. For regular DDD calls, the toll office access code "1" followed by seven or ten digits is recommended to simplify dialing.

Customer-dialed special toll calls should use the prefix "0" followed by seven or ten digits.

"0" will still be used. For assistance operator calls when customer dialing of special toll calls is inaugurated with the "0" prefix, existing service codes of the form "11X" will be retained.

DIALING PROCEDURES IN EARLY STAGES OF AREA CODE CONGESTION

When the area code capacity of the present numbering plan is exhausted, unused office codes of the form ABO may be used for area codes. These can provide additional area codes at the expense of office code capacity which would be correspondingly reduced.

ULTIMATE SITUATION

In the mid-1970's additional area code capacity may be needed. The "1" access code for regular DDD calls will then be standard. Area codes will be of the form AXX of which there are 800. There will be a maximum of 792 AXX-type central office codes. It will be desirable and probably essential to adopt all-number calling before office codes of the A1X and AOX type are used.

For special toll calls dialed by customers but still requiring operator assistance such as person-to-person, the prefix "0" will continue to be used.

Assistance operator calls will continue to use "0" alone. No change is contemplated in service codes.

The same procedures will be recommended for common control, step-by-step, and mixed areas. However, no one will be required to adopt all the elements of the proposed plan, particularly with equipment where parts of the plan might not be feasible. Thus, 2- and 3-digit access codes may be used with systems which require them although they are not recommended. A two or three digit access code followed by the prefix "0" for special toll calls may also be used.

Abbreviated home area dialing will be used. Thus home-area toll calls will have the form 1 AXX XXXX or 0 AXX XXXX. It will be necessary to provide a feature to distinguish between eight and 11 digit calls where conflicts exist between area and office codes.

Special barrier codes are not a part of the plan. The access codes "1" and "0" are in themselves barriers against reaching toll points in error, and once they have been adopted their use will be mandatory.

Equipment Modifications Required

All existing telephone switching systems, both local and toll, with the possible exception of step-by-step intertoll equipment, will need to be modified. It is too early to describe the modifications required in detail, but some general observations can be made on the nature of the changes.

All common control local systems must be modified to enable them to do the following:

1. To register the prefix "1" or "0" and to signal the translating equipment which prefix has been received. The prefix will not be sent to the toll office.
2. To check after an initial "0" to see whether more digits are forthcoming. If only "0" is received the call will be routed to the operator.
3. To route calls selectively on the basis of the prefix and the code which follows.
4. To determine whether an 8- or 11-digit call is intended in areas using AHAD.
5. To provide translation capacity for up to 800 area codes and 792 office codes.
6. To determine whether a code is used both as an area code and an office code where AHAD is provided.
7. To block toll calls which are received without a prefix.

The step-by-step local system will need to have special trunks from the "1" and "0" levels. The "1" level trunk will cause an immediate seizure of a trunk to the toll office and a fast seizure of a sender or register at that office. If the second digit is 2 to 9, it and succeeding digits will be repeated to the toll office equipment and stored there. However, if the second digit is a "1," it will be absorbed, the toll office trunk will be immediately released, and the auxiliary selector will accept the third digit and route to a service trunk.

The "0" level trunk will be arranged to distinguish between prefix "0" toll calls such as person-to-person and collect, and "zero" operator calls.

At the toll office some of the important new features are as follows:

1. Additional translation capacity for up to 800 area codes and 792 office codes.
2. Arrangements for determining whether a seven or ten digit number is intended.
3. New trunks for the "0" prefix calls.

Some of the work mentioned has already been started. The simple access code "1" arrangement has been developed for step-by-step and no. *5* crossbar, and will soon be in use in many locations.

The prefix "0" arrangements are also in use in a few locations now arranged for customer dialing of person-to-person toll calls. Many more will use it as they install equipment for customer dialing of calls requiring operator assistance.

A Transistorized Cable Carrier Repeater

C. G. GRIFFITH
ASSOCIATE MEMBER AIEE

THIS PAPER describes a repeater which was designed for a medium-haul cable-carrier system. It is called the Lenkurt type *4587A* repeater unit. By use of transistors, power requirements are minimized. By the use of conservative design techniques, a high degree of reliability is expected.

Since this subject may be of interest primarily to those in telephone operating companies and to circuit engineers, emphasis will be directed at (1) applications of the repeater as related to the basic problem, and (2) some design features and performance of the circuitry.

A repeater for the type *45BN* cable carrier system was described in an earlier paper.[1] Because of the continuing usage of this type of repeater, it has been redesigned as a completely transistorized unit to meet demands for reduced power requirements.

A distinct cost advantage in system power-feed is derived from the use of the transistorized repeaters. Since this repeater consumes only 4 watts, a power-feed point may supply a larger number of repeaters than was possible with higher voltage units.

The Problem

The essential problem in cable transmission is that of amplifying signal levels at certain intervals along the cable route. It is necessary to minimize degradation of system performance caused by noise, crosstalk, and sidetone, as a result of adding amplifiers. Since signal amplitudes vary because of temperature effects on the cable and other conditions, it would be desirable to hold repeater output levels constant. Also, high frequencies are attenuated more than low frequencies in cable transmission, causing a large slope

to appear across the spectrum. Slope cancellation or appropriate compensation is required to provide a good frequency response for the 24-channel group.

A repeater unit, designed to fill these needs in a cable carrier system, will be discussed.

Description of Operation

The repeater is designed to be used with a 24-channel carrier system. The specific system for which it is intended is the type *45BN* cable carrier system, although the repeater is functionally interchangeable with the type *N* repeater for use in Western Electric "N" and "ON" systems.

The *45BN* is a 24-channel system using single-sideband suppressed-carrier transmission. The 24 channels are transmitted in a range of 40–140 kc (low group) or of 164–264 kc (high group). A terminal that transmits low group will receive high group, or vice versa. A single high-level pilot, 96 kc for low group or 208 kc for high group, is transmitted for regulation. Placed at intervals up to 8 miles, the repeater accepts the incoming frequencies of 40–140 kc or 164–264 kc for both directions of transmission. The main functions provided are frequency translation amplification, and regulation. The repeater dissipates 4 watts by taking a current of 100 milliamperes with a drop of 40 volts. Fig. 1 is a simplified block diagram of the operation.

Frequency translation, or "frogging," has a cancelling effect on the slope of the frequency spectrum caused by increased attenuation with frequency in the cable. Each repeater modulates the incoming group 40–140 kc or 164–264 kc with a 304-kc signal, thus changing a low group to a high group or vice versa. Each channel is thereby inverted as to its order in the group. An incoming negative slope of 8 db (decibels) is transposed to an output positive 8-db slope. The groups are interchanged at successive repeater points as shown in Fig. 2. Each repeater thereby equalizes one-half of the cable section on either side of the repeater, leaving the carrier terminals to provide 8 db of equalization for the half-cable section on each end to complete the system equalization. Small additional cable variations can be compensated for by a variable slope equalizer in the repeater. Each repeater includes a variable-gain amplifier which provides an over-all repeater gain of 46 db at the normal control setting. This gain figure was selected by considering the approximate maximum loss in an 8-mile section of 19-gage cable. To compensate for varying input levels created by temperature effects on the cable, and for other influences, regulation is provided. Output levels will remain constant within 1 db over an input range of ±8 db.

Other Features

Each repeater includes necessary equipment for two directions of transmission. Both circuits may be used to go from low group (40–140 kc) transmission to high group (164–264 kc) or from high to low. Two coaxial connectors are used in each direction of transmission to connect the repeater for the right mode of operation.

Time delay is normally used in the regulator to allow system alarms to function in the event of complete failure of transmission. A strap option makes it possible to have operation without time delay if it is desired.

A gain control is provided to enable adjustment of the output-level operating point over a range of 12 db.

A slope switch with 0, 2, or 4 db of additional slope equalization is provided.

Repeater Circuitry

Filter-Modulator-Equalizer

The incoming signals enter a subassembly called the filter-modulator-equalizer. It is composed of slope-correction networks, a low-pass filter for the 40–140-kc group, a modulator, and a 164–264-kc band pass filter, in that order.

Since the low group will have approximately 4 db more slope than the high group, a slope equalizer is needed to make the frequency-frogging operation successful. To accomplish this, 2 db of slope is removed from the received low groups and 2 db of slope is added to the received high groups.

To allow for minor deviations in slope resulting from unequal lengths of repeater sections, two additional networks are included in the slope-equalizer section of the filter-modulator-equalizer. A 3-position switch on the front of the panel will set the desired condition of either 0, 2, or 4 db of additional slope. Equal loss is

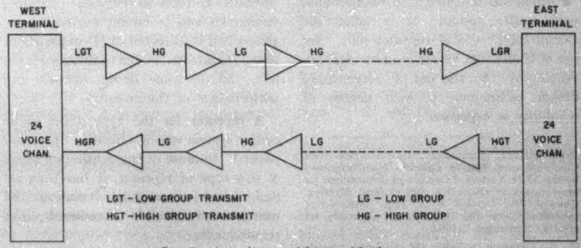

Fig. 2. Interchange of low and high groups

Vol.
Pt. 1

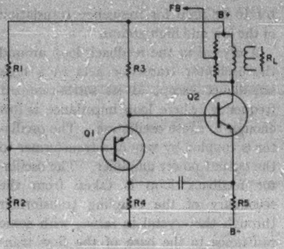

Fig. 3. Schematic of compound transistor

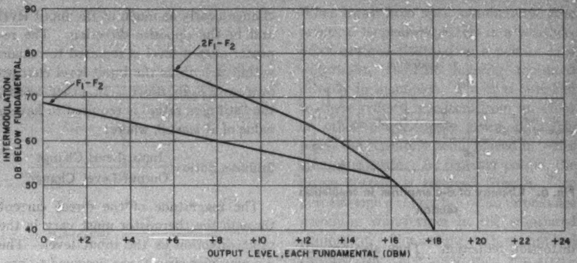

Fig. 4. Intermodulation distortion

given at the pilot frequency for the three positions so that the output level of the repeater is not disturbed by making an adjustment.

The low-pass and bandpass filter design requirements are based on rejection of unwanted out-of-band tones, repeater sing suppression, crosstalk suppression, amplifier unloading, and frequency response. In each filter, a rejection notch is placed at the carrier frequency of 304 kc in order to reduce carrier leak.

The Appert Modulator[2] is used because of its low-distortion characteristics.

A low-group spectrum first passes through the slope equalizer and then through a low-pass filter for the 40–140-kc band. It then modulates a 304-kc signal which is generated within the repeater. A 164–264-kc bandpass filter selects the lower sideband of the products, and from there the high group enters the preamplifier.

An important feature of the filter-modulator-equalizer is that it is bilateral. By interchanging the input-output terminal connections it can be used to receive low group and pass the resulting high group on to the amplifiers, or to receive the high and send on low group.

The insertion loss of the filter-modulator equalizer is 13 db.

TRANSMISSION AMPLIFIER

The transmission amplifier consists of four stages: a preamplifier, a regulation stage, a driver stage, and a power-output stage.

The preamplifier is a common emitter configuration using a drift transistor. After the preamplifier, the remainder of the circuit could be called a closed-loop servomechanism, where a portion of the repeater output is rectified and amplified in the regulator circuitry and used to control the gain of the regulation stage in the transmission amplifier.

The second or regulation stage employs a drift transistor in a common emitter circuit with its gain controlled by a shunt-feedback resistance around the stage. For fixed-gain operation a resistor is used in the feedback circuit, but for the normal regulation mode, a directly heated thermistor is used. The thermally sensitive resistor is controlled by the d-c output of the regulator section.

The third stage, also a common emitter, is a driver for the output power amplifier.

The power-amplifier stage is a compound transistor circuit using a drift transistor and a 4-watt n-p-n silicon power transistor. By the use of a compound circuit, it is possible to obtain low nonlinear distortion and reduce the sensitivity of the amplifier performance to variations in the power transistor.

The "compound transistor"[3] shown in Fig. 3 is a special case of base current feedback.[4] Its configuration is similar to the Darlington compound except that the collector of *Q*1 is returned to the emitter of *Q*2 rather than to the collector of *Q*2. A grounded emitter version of the compound transistor was chosen as it has greater power gain and requires less current from the driver stage because of its high input impedance. Intermodulation distortion of the repeater is shown in Fig. 4.

In order to describe the manner in which distortion reduction has been accomplished, the different forms of distortion will be discussed. These forms of distortion in a transistor, or in any active device, are derived from nonlinearities in: (1) voltage gain, (2) current gain, and (3) input impedance.

First, the notation will be introduced and the pertinent equations given. Consider an active device that is inserted between a resistive load and a source with an internal resistance as shown in Fig. 5. Starting with the relationships $E_1 = I_1 Z$ and $E_2 = I_2 R_L$, the second expression can be divided by the first, giving

$$\frac{E_2}{E_1} = \frac{I_2 R_L}{I_1 Z}$$

Let voltage gain $= V = E_2/E_1$ and current gain $= I = I_2/I_1$; then

$$V = I\frac{R_L}{Z}$$

or

$$R_L = \frac{VZ}{I}$$

Since R_L is a fixed independent linear quantity, the total nonlinearities in VZ/I must cancel. It is possible for one of the quantities on the right-hand side to be linear with the other two nonlinear, but it is not possible for only one to be nonlinear. Therefore, if the current gain I is linearized, the output distortion will decrease as the input impedance Z is made linear. Also, if the voltage gain V is linear, the output voltage will be undistorted when the amplifier is driven from a zero-impedance voltage source. This suggests that the output distortion will decrease as the source impedance Z_0 is decreased.

In the repeater power amplifier, compounding has the effect of making current gain, I, more linear since the input impedance is increased by the addition of resistance between the emitter of *Q*2 and ground. The bias resistors will tend to make the input impedance more linear. The addition of a fixed linear high admittance to a nonlinear low admittance makes this possible. Distortion is further decreased by using a source impedance, Z_0, which is low compared with the input impedance of the compound stage.

*R*1 and *R*2 make up a parallel admittance combination which contributes to

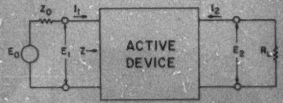

Fig. 5. Terminology associated with 2-port device

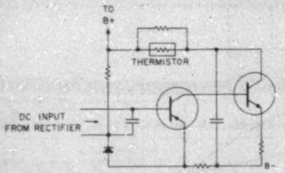

Fig. 6. Circuitry of d-c amplifier in regulation section

distortion reduction. They also provide a stiff base voltage for *Q*1. *R*3 is used to stabilize the direct current of the first transistor's emitter since the emitter current depends on both the constant current through *R*3 and also the base current of the second transistor which varies among units.

The collector of the first transistor is connected to the emitter of the second by a large capacitor which offers a low impedance to signal currents. A type of bridge feedback is used to set the output impedance, further reduce distortion, and stabilize gain.

The over-all gain of the transmission amplifier is 59 db.

REGULATION SECTION

To accomplish regulation, a portion of the output voltage is taken from a tap on the primary winding of the output transformer. This voltage is rectified and amplified and the direct current used to control resistance in the feedback thermistor of the transmission amplifier's second stage.

An isolation amplifier is used to decouple the rectifier distortion from the repeater output. The rectifier output voltage is compared with a reference diode voltage. The difference voltage is the input to a 2-stage d-c amplifier shown in Fig. 6.

In determining the regulator characteristics, the first requirement is that the gain of the regulating amplifier must change nearly as much as the input level and in the opposite direction. The repeater output level is required to remain within ±1 db as the input level changes over a ±8-db range. In other words, the "stiffness ratio" is required to have a value of at least 8, where:

$$\text{Stiffness Ratio} = \frac{\text{Input-Level Change}}{\text{Output-Level Change}}$$

The magnitude of the direct current through the thermistor must vary in the same direction as the input level. The d-c amplifier circuit was designed to produce the specific range of current needed. Since the output range is required to be less than 2 db, this 2-db change in bias at the d-c amplifier is required to produce a range of output current that will cause a gain variation of 16 db in the regulating amplifier.

Regulation time-delay is accomplished by connecting a tantalum capacitor between the emitter of the d-c amplifier's second stage and the base of the first. This acts as a feedback path. An instantaneous change in the output level of the repeater causes an instantaneous change in input voltage to the d-c amplifier. The capacitor prevents any instantaneous change in the output of the d-c amplifier. Thus a sharp drop in input level is not immediately compensated for and the repeater output level also drops for the same amount. Recovery of the output level by regulation action is slow enough to permit operation of system alarms. This provision is necessary because regulation action tends to maintain a high-output level even with a complete loss of input signal. System alarms are set to actuate for a certain decrease in signal power received at the terminal.

304-KC OSCILLATOR

The 304-kc oscillator in Fig. 7 is a crystal-controlled transistor-feedback oscillator. The purpose of the oscillator is to provide a high-level tone for the modulator to be used for frequency translation of the low and high groups.

A crystal in the feedback loop around the oscillator transistor acts as a high impedance except at its series-resonant frequency, where loop impedance is low enough to cause oscillation. The oscillator is coupled by way of a transformer to the output power amplifier. The oscillator feedback loop is taken from the secondary of the coupling transformer through the crystal in series, with some resistance to the base of the first transistor. The resistance includes a negative-temperature coefficient-resistor to compensate for variations in crystal resistance with temperature.

A tank circuit at the transformer primary prevents crystal operation in a spurious mode, decreases distortion, and provides fine tuning. A level control is included in the power amplifier.

Performance Characteristics

The *4587A* repeater unit has a maximum insertion-gain deviation of 0.3 db across the 40–140-kc band and from 164–264 kc. The repeater fixed-gain is 46 db. In the normal-regulation mode of operation, output level may be varied ±6 db by a screwdriver control on the faceplate.

For input variations of ±8 db, the output level remains constant within less than ±1 db. The input impedance is 600 ohms and the output, 130 ohms. (In the associated shelf equipment, the 130-ohm cable impedance is transformed to 600 ohms for the repeater input.) Upon loss of signal, time delay prevents immediate transition of the repeater amplifier to maximum gain. After a sharp decrease in input signal, there is a lapse of at least 7 seconds for a 1-db increase in insertion gain.

Very low sidetone has been obtained. With the two directions of transmission, called West-East (W-E) and East-West (E-W), a tone injected in the West-East

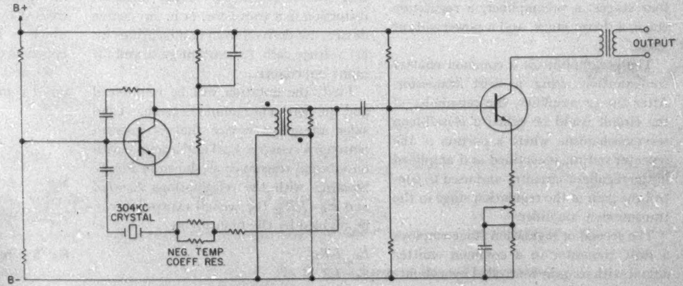

Fig. 7. Schematic of 304-kc oscillator

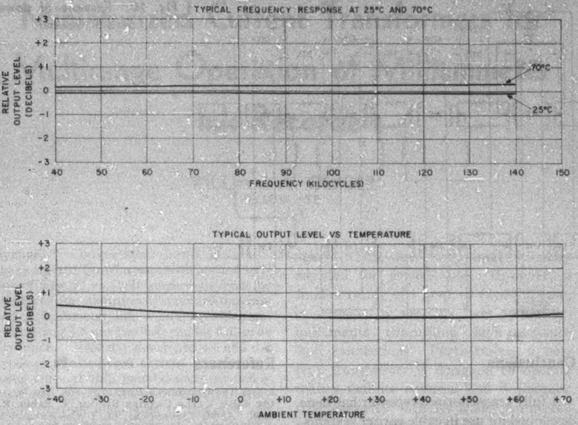

Fig. 8. Temperature effects on output levels and frequency response

direction of transmission is more than 60 db down at the East-West output, and likewise for East-West to West-East.

The repeater has shown insensitivity to extreme temperatures in numerous tests, which included temperature cycling from −40 to +70 C (degrees centigrade) and also prolonged operations at abnormally high temperatures. Performance is not degraded under these conditions, as indicated in Fig. 8.

Physical Characteristics

The repeater unit is the heart of a complete repeater installation. It is designed for plug-in mounting in the Lenkurt line equipment unit. The line equipment unit, in turn, may be mounted either in a repeater shelf or in a gastight container to be placed in an underground location. Also, the repeater only may be mounted in a repeater mounting-adapter for a Western Electric mounting bracket.

The repeater unit occupies a space 8 inches high, 10 inches long, and $3^{5}/_{8}$ inches wide. Its weight is $6^{3}/_{4}$ pounds. The circuitry for both directions of transmission is included. The two filter-modulator-equalizers are wired in units mounted on top of the unit and the two amplifier-regulator circuits are mounted on phenolic cards, one on each side of the unit. One card is a mirror image of the other. The oscillator circuitry is mounted on a card across the back of the unit, while on the front are coaxial connectors for selecting low-high or high-low operation. Below the connectors are two selector switches for additional slope correction, screwdriver controls for setting the output-level operating point, and a metering jack which provides appearance of W-E output level, E-W output level, repeater-unit supply voltage, and the local oscillator level. A view of the repeater unit mounted on a line equipment unit is shown in Fig. 9.

Power-Feed Considerations

Sometimes repeater locations conveniently coincide with a telephone office or a repeater hut needed for other systems. When away from such installations, it is practical to place repeaters in a weatherproof cabinet mounted on a pole or in a watertight, gastight housing mounted directly in manholes. Power is supplied to these remote repeaters from an office or other power-supply point by cable pairs, the repeaters being placed in series along the route. At repeater points, the direct current is received from a cable pair through a center tap on an impedance matching transformer in the associated equipment. The return path is supplied through the cable pair used for transmission in the opposite direction.

A 43-volt zener diode is connected in parallel with each repeater across the 40-volt supply; thus, when a repeater is removed from the line, the voltage across the other repeaters will remain constant.

When repeaters are spaced at 8-mile intervals using 19-gage cable, a total of seven repeaters may be powered from a single supply point using two 130-volt d-c supplies connected together in series. This method is illustrated in Fig. 10. In determining voltage drop in the cable sections, no. *19* American wire gage cable simplex resistance at 43 C is used with a repeater spacing of 8 miles.

System Length

Repeater design considerations, which include noise, intermodulation, and sidetone, are based on a system length of 30 repeaters.

Although the repeater was designed to amplify signal levels that have been at-

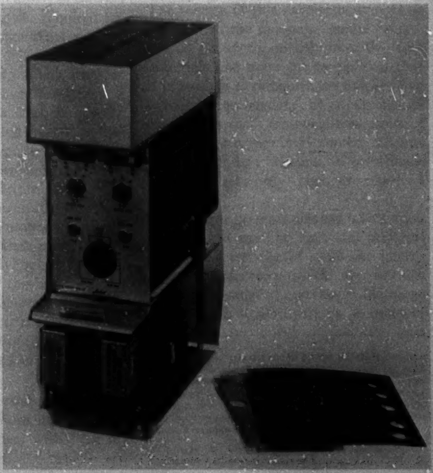

Fig. 9. View of repeater unit and associated line equipment

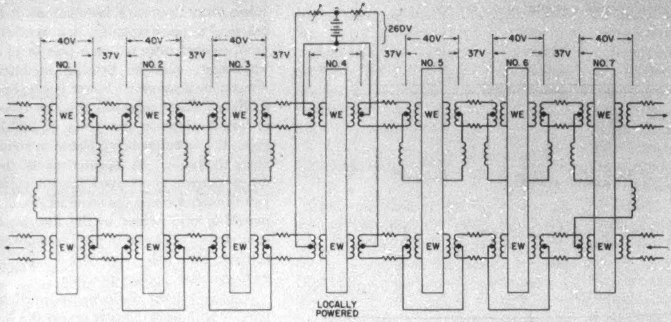

Fig. 10. Example of power feed to repeater

tenuated by 8-mile sections of 19-gage cable, shorter cable lengths may be necessary for various geographical reasons. Also 13-gage or 16-gage cable may be used. Under these circumstances, span pads and artificial lines are available. Receive pads of 0 to 30 db in 2-db steps and transmit pads of 4, 8, 12, 16, or 20 db may be used. Artificial lines of 1, 2, and 4 miles are available for the receive or transmit side.

Conclusions

A fully transistorized repeater has been developed for use in cable carrier systems. Some of the most important advantages include low sidetone, low distortion, reliable operation obtained by use of conservatively rated solid-state devices and low-power consumption. The last is of prime importance in view of high costs for maintaining power-supply facilities.

Miniaturized Current Transformers for Multirange Operation of Milliammeter Ink Recorders

WILLIAM A. GEYGER
FELLOW AIEE

Synopsis: Conventional forms of multirange current transformers with a rated output of 5 or 10 va (volt-amperes) cannot be employed for operation of standard moving-coil milliammeter ink recorders which require about 1.5 mw (milliwatts) for full-scale deflection. Recently developed a-c and d-c types of miniaturized current transformers using cores of thin molybdenum-permalloy tape and special construction (extremely small cross-sectional area of the core and very large number of turns of the secondary winding) make multirange operation of such recorders possible.

This paper presents detailed design information and performance characteristics of small-size instrument transformers, which are suitable for measurement of currents in the range of 0.1 ma (milliampere) to 10 amp (amperes) with an accuracy of ±0.3 to 0.5%. High a-c and d-c voltages up to about 10,000 volts may be measured by employing the current range 0–1 ma and adding a series resistor (1,000 ohms per volt) corresponding to the multiplier resistor of an ordinary voltmeter.

The paper also describes simple differential-type test circuits for high-precision measurement of actual current ratio and percentage current-ratio error. It presents oscillograms which characterize the dynamic performance of small-size d-c transformers under half-cycle-response operating conditions. With these conditions, the load current is not only linearly proportional to the direct control current, but to some extent will even have similar oscillographic variation when this control current varies, owing to a superimposed a-c component.

THE application of nickel-iron-alloy core materials to instrument transformers makes it possible to reduce the imperfections of such transformers to the minimum and to approach very closely the ideal operating conditions. By providing means for varying the turns ratio of ring-core current transformers, e.g., a tapped primary or a cable primary threaded through the window opening, measurements in the laboratory and test room can be made over a wide range of currents with a high degree of accuracy and with the use of a minimum amount of expensive equipment. As a result of standardization on instrument transformers, the normal rated secondary current for current transformers is 5 amp, a figure which has been internationally adopted for general use. However, a smaller rating of 1 amp, or even 0.5 amp, is occasionally used to meet special requirements concerning high-resistance lead connections. Furthermore, a current transformer is designed to operate with a definite external-load impedance (the ammeter with its leads) connected to the secondary terminals. The rated external load impedance is the impedance value with which the current transformer can be loaded, so that with the rated secondary current flowing, the actual error values do not exceed the limits given by the respective specifications.

In view of the properties and advantages of standard d-c milliammeter permanent-magnet moving-coil ink recorders, recent research and development work has been devoted to the application of similar current-transformer techniques for multirange operation of such recorders and panel-type milliammeters. Of course, the conventional forms of precision-type current transformers with a rated output of 5 or 10 va cannot be employed for this purpose, because the power required for full-scale deflection of a standard moving-coil ink recorder (e.g., Esterline-Angus type, 0–1 ma) is 1.5 mw. Thus, the specific problem consisted of developing a miniaturized form of a 60-cycle current transformer with a rated output in the order of milliwatts for multirange operation of such milliampere ink recorders. An additional requirement is, of course, to provide any desired current ratio, within certain limits, with full ampere-turns and identical accuracy on each range. This can be achieved simply by tapping the primary winding. In this way, by the choice of a suitable turns ratio it is possible to arrange for the readings to be taken at the upper part of the scale where the precision is highest, for all values of the primary current.

A similar situation exists with regard to multirange operation of milliammeter moving coil-ink recorders with "d-c instrument transformers"[1–4] which are based upon the inherent current-transformer properties of ordinary saturable-reactor circuits with nickel-iron-alloy core material.[5] These circuits operate in conjunction with a full-wave rectifier and a moving-coil d-c ammeter which indicates the half-cycle average value of the alternating current flowing through the a-c windings of two equally rated saturable-reactor elements. In this case, the problem consisted of developing a 60-cycle-operated prototype design of a miniaturized d-c instrument transformer, similar to its a-c counterpart.[6]

Closely associated with the development of both the a-c and d-c type of these small-size current transformers are special problems concerning high-precision measurement of actual current ratio. In order to measure with a high degree of accuracy the percentage current-ratio error of these transformers, differential-type test methods have been introduced. Further investigations are concerned with the dynamic performance of miniaturized d-c transformers with half-cycle-response operating conditions. With these conditions, the load current is not only linearly proportional to the direct control current, but to some extent will even have similar oscillographic variation when this control current varies, owing to a superimposed a-c component.

This paper reports on the solution of these problems and describes both a-c and d-c types of miniaturized current transformers having a maximum output of about 50 mw and a rated full-load secondary current of 1.0 ma corresponding to full-scale deflection of a standard 1-ma 1,500-ohm moving-coil ink recorder. The success of this development work is based upon the unique magnetic properties of modern nickel-iron-alloy core materials and upon the recognition that it is possible to minimize the magnetizing current requirements by applying an extremely small cross-sectional area of the core and a very large number of turns of the secondary winding, in accordance with the relatively high external-load resistance.

The paper presents detailed information on core and winding data and performance characteristics of small-size instrument transformers which are suitable for measurement of currents in the range of 0.1 ma to 10 amp with an accuracy of

±0.3 to 0.5%. High a-c and d-c voltages up to about 10,000 volts may be measured by employing the current range 0-1 ma and adding a series resistor (1,000 ohms per volt) corresponding to the multiplier resistor of an ordinary voltmeter. The paper also describes simple differential-type test circuits for high-precision measurement of actual current ratio and presents oscillograms which characterize the dynamic performance of miniaturized d-c instrument transformers under half-cycle-response operating conditions.

Miniaturized Current Transformer for A-C Measurements

DESIGN CONSIDERATIONS

The design of this transformer has been based upon a rated full-load secondary current of 1.0 ma and a rated external resistance of 2,000 ohms. This prototype design, therefore, operates with a resistive external load and a rated secondary output of 2×10^{-3} va. As a result of these quite unusual operating conditions, it is necessary to use a special test circuit to determine the full ampere-turn handling capacity of the current transformer and its performance characteristics showing the percentage current-ratio error as a function of the primary current with the load resistance as a parameter. It is to be noted that the primary current will be measured in terms of the average value of full-wave-rectified secondary current flowing through the moving-coil system of the ink recorder or panel-type milliammeter. Thus, in accordance with the basic principle of rectifier instruments, this arrangement is susceptible to waveform errors which, in general, will depend upon the phase as well as the magnitude of the harmonics that are present. With sinusoidal waveform of the primary current, the ratio of average to rms values is 0.909, and the recorder or panel meter can be calibrated to read rms values of alternating current or voltage.

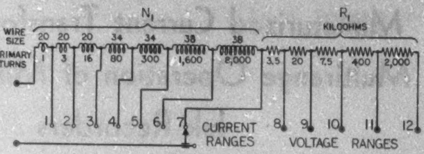

Fig. 2. Auxiliary resistance network with range-selecting switch used in conjunction with the tapped primary winding N_1 of a miniaturized instrument transformer for a-c measurements

With regard to the lowest current range, 0–1,000 μa (microamperes), the magnetizing and iron-loss components of the primary exciting current should be reduced to very small values by the application of nickel-iron-alloy high-permeability core material. In order to reduce the ampere-turn requirements and the current-ratio error to the minimum, the following aspects are considered to be of prime importance:

1. High-permeability core materials having an extremely low coercive force (H_c), e.g., supermalloy type, are definitely preferred in this special application to the grain-oriented nickel-iron alloys in order to minimize the ampere-turn requirements of the current transformer.

2. Although the frequency of the primary current, 60 cps (cycles per second), is low, 2-mil tape cores are considered to be particularly suitable in this application to minimize eddy-current effects.

3. The miniaturized current transformer must be designed to have a very small cross-sectional area of the core and a correspondingly high number of turns of the secondary winding, e.g., 10,000 turns.

4. A sufficiently large core window must be provided to avoid application of undesirable extremely thin wire for the windings, and excessively high values of winding resistance.

PROPERTIES AND DIMENSIONS OF COMPONENTS

In order to minimize the ampere-turn requirements, a Mo-permalloy 2-mil tape core (inside diameter, 1.250 inches; outside diameter, 1.500 inches; tape width, 0.125 inch) is used in the construction of the prototype design. Fig. 1 presents the 60-cps hysteresis loop of this core, which has been automatically recorded by means of a simple dynamic **B-H** loop tracer[7–9] with silicon-diode chopper circuits (Ferrotracer) and a chopper-type *x-y* plotter. The magnetic-core test circuit itself has been designed so that the core sample is tested under sinusoidal flux excitation conditions.

By tapping the primary winding (total number of turns = 10,000 corresponding to the lowest current range, 0–1 ma), the current ratio can be varied conveniently, with full ampere-turns and identical accuracy on each range. When using this lowest current range for measurement of high a-c voltages up to about 10,000 volts, the voltage ranges may be varied by means of a tapped series resistor, or "multiplier," as in the case of an ordinary voltmeter. Actual number of turns of the secondary winding can be changed (10,000, 9,950, or 9,900 turns, respectively, of no. *38*, B & S [Browne and Sharpe] wire) to obtain optimized performance of the current transformer with the rated external-load resistance of 2,000 ohms.

Table I presents the effective numbers of turns of the primary winding, the effective resistances corresponding to the 12 positions of the selecting switch (Fig. 2), and the resultant current ranges, corresponding to the rated-secondary-current value of 1.0 ma, the full-scale deflection of the ink recorder or panel meter. It is to be noted that the ratio

Table I. Effective Turns of Primary Winding N_1 and Effective Resistance Values Corresponding to the 12 Positions of the Selecting Switch

of conversion of the current ranges and also that of the voltage ranges, four or five respectively, are selected in such a way that the value to be measured and recorded may be read directly on the linear 50-division scale of the Esterline-Angus recorder. The voltage range may be extended up to about 10,000 volts by employing modern high-resistance components.

High-Precision Measurement of Actual Current Ratio

Since the primary current is measured here in terms of the average value of the full-wave-rectified secondary current, the most important test to be made on this miniaturized current transformer is to find how correctly the secondary current is an exact measure of the corresponding quantity to be measured, i.e., to measure with high precision actual current ratio, preferably with various values of secondary current and external-load resistance. The simple test circuit of Fig. 3 takes advantage of the fact that the turns ratio N_1/N_2=10,000/10,000=1 is available in this special design. Both primary and secondary alternating currents, $I_{1\sim}$ and $I_{2\sim}$, are converted into unidirectional currents, I_1 and I_2, by means of two bridge-type full-wave rectifiers with silicon-diode elements; and these unidirectional currents are superimposed in the moving-coil microammeter M (e.g., −50–0–+50 μa, 600 ohms) so that

$$I_M = I_2 - I_1 = \frac{I_{2\sim}}{k_f} - \frac{I_{1\sim}}{k_f} \qquad (1)$$

where k_f is the form factor, i.e., the ratio between rms value and average value of the alternating currents, $I_{1\sim}$ and $I_{2\sim}$, having identical waveform provided that the current transformer has normal operating conditions with rated values of secondary current and external-load resistance. Thus, the percentage current-ratio error in terms of primary current I_1, i.e., the deviation of the actual current ratio $K_I=I_2/I_1$ from its ideal value N_1/N_2 =10,000/10,000=1, is

$$\Delta K_I = 100\,\frac{I_2 - I_1}{I_1} = 100\,\frac{I_M}{I_1} \qquad (2)$$

This error ΔK_I is positive when, with a given primary current I_1, the actual secondary current I_2 is in excess of its ideal value, i.e., when the ink recorder or panel meter reads too high.

Furthermore, the deviation of actual current ratio I_2/I_1 from its ideal value may be expressed in terms of the maximum value, $I_{1\max}$, of the current range, i.e., in per cent of full-scale deflection of the instrument which measures the average value of secondary current I_2:

$$\Delta K_I\,\frac{I_1}{I_{1\max}} = 100\,\frac{I_2 - I_1}{I_{1\max}} = 100\,\frac{I_M}{I_{1\max}} \qquad (3)$$

The purpose of the test circuit of Fig. 3 is to measure with a high degree of accuracy the percentage current-ratio error, which is due to imperfections of the magnetic core. Obviously, imperfections of the microammeter M measuring the error current $I_M=I_2-I_1$ enter into the measurement as errors of second order. Therefore, it is possible to employ an ordinary panel-type microammeter for measuring ΔK_I with an accuracy of about ±1 to 2%.

Using the test circuit of Fig. 3 with N_1= 10,000 turns and with various numbers of turns N_2, within the range of 9,900 to 10,000 turns, actual magnitude of error current I_M has been measured as a function of the primary current I_1. Fig. 4 shows $I_M=f(I_1)$ with load resistance R_L= 100 ohms (A), and with R_L=2,000 ohms (B) for the lowest current range, I_1=0–

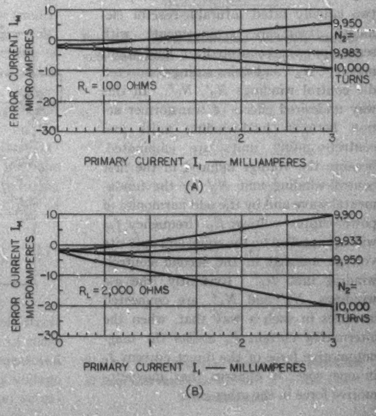

Fig. 5. Error current $I_M=I_2-I_1$ as a function of the primary current, I_1=0–3 ma, with number of turns N_2 of secondary winding as a parameter

A—Characteristics with load resistance R_L=100 ohms
B—Characteristics with R_L= 2,000 ohms

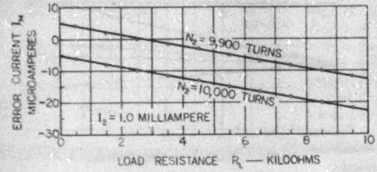

Fig. 6. Error current $I_M = I_2 - I_1$ as a function of load resistance, R_L = 0—10 kilohms, with I_2 = constant = 1.0 ma, and with number of turns N_2 of secondary winding as a parameter

1,000 μa. Fig. 5 presents corresponding characteristics for the current range I_1= 0–3 ma. Fig. 6 shows I_M as a function of load resistance, R_L=0–10,000 ohms, with I_2=constant=1,000 μa, and with number of turns, N_2, of the secondary winding as a parameter. Evidently, error current I_M and percentage current-ratio error $\Delta K_I = 100\, I_M/I_1$ depend upon the load resistance R_L and can be minimized by proper selection of the number of turns, N_2, of the secondary winding (9,900, 9,933, 9,950, 9,967, and 10,000 turns, respectively).

The results of these measurements show that actual current ratio varies within the limits of about ±0.2 to 0.3% with optimum adjustment of the number of turns of the secondary winding. Therefore, this prototype design of a miniaturized current transformer for a-c measurements is suitable for multirange operation of standard moving-coil ink recorders and ordinary panel meters without impairing the accuracy of measurements corresponding to the performance of such instruments (about ±1 to 2% of full-scale deflection).

Miniaturized D-C Instrument Transformer

Basic Saturable-Reactor Circuit

The ordinary "series-connected" saturable-reactor circuit, Fig. 7(A), employs two equally rated saturable-reactor elements (twin-core arrangement) with series-opposing-connected a-c load windings N_L', N_L'', and series-aiding-connected d-c control windings N_C', N_C''. In this way undesired effects of transformer action between load-winding units and control-winding units are eliminated, because the voltage induced in the first control-winding unit N_C' by the fundamental wave and by the odd harmonics of power-supply voltage E_P (frequency f_P) will be cancelled by the equal and opposite voltage induced in the second control-winding unit N_C''. Evidently, the a-c windings, N_L' and N_L'', are connected in series in such a way that, when the alternating current I_N assists the magnetomotive force of the direct current I_C in one core, it opposes that magnetomotive force in the other core.

Fig. 7(A) shows that the moving-coil d-c ammeter A_L (load resistance R_L) is supplied with full-wave-rectified current I_L representing the half-cycle average value of the alternating current I_N flowing through the a-c load windings, and I_LR_L is the average value of load voltage E_L. The control windings are supplied from the d-c signal source (signal voltage E_S) with control current I_C representing the direct current to be measured.

Application of the arrangement of Fig. 7(A) for measurement of direct currents is based upon the current-transformer character (law of equal ampere-turns[10]) which is the result of inherent negative-feedback properties ("intrinsic" negative feedback) of the ordinary saturable-reactor circuit using nickel-iron-alloy core material. That is, the ratio between the average value of the rectified load current I_L and the average value of the control current I_C is substantially equal to the ratio between the number of turns of d-c control windings $N_C' = N_C'' = N_C$, sometimes termed "primary windings," and a-c load windings $N_L' = N_L'' = N_L$, sometimes termed "secondary windings":

$$\frac{I_L}{I_C}=\frac{N_C}{N_L} \tag{4}$$

or

$$I_LN_L=I_CN_C \tag{5}$$

Actually, as a result of the inherent negative-feedback properties, the current ratio I_L/I_C is to a certain extent independent of variations in magnitude, frequency, and waveshape of the a-c power-supply voltage E_P; and, within certain limits, I_L/I_C will also be independent of changes in load resistance R_L.

Fig. 7(B) shows schematically the corresponding input-output characteristic $I_LN_L = f(I_CN_C)$ of the circuit of Fig. 7(A). The actual or measurable average value of unidirectional load current I_L is the resultant of the "exciting-current component" I_{LO}, which is practically independent of the control current I_C, and of the "load component" I_{LC} flowing in response to changes in control current I_C. Equal increments in control ampere-turns, ΔI_CN_C, produce approximately equal increments in load-current ampere-turns, ΔI_LN_L, in the linear region of the characteristic. Thus, since I_{LO} representing the magnetizing current of the saturable-reactor elements can normally be made very small compared with I_{LC}, equation 5 holds to a good degree of accuracy. However, this is true only when the measured load current I_L is expressed in average values over one half-cycle. Therefore, it is essential that a moving-coil instrument with a full-wave rectifier circuit be used. Instruments measuring rms values, such as iron-vane ammeters, will not give the same results.

Specific Problem and Design Considerations

The 60-cycle-operated prototype design of a miniaturized d-c instrument transformer, similar to its a-c counterpart described in the first section of this paper,

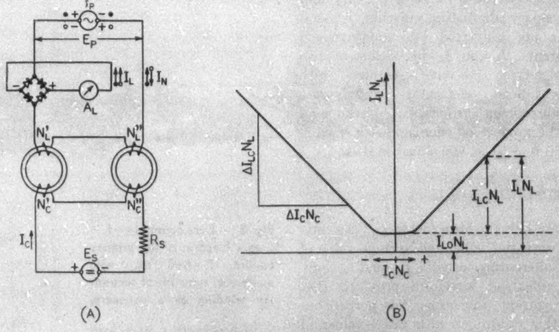

Fig. 7. The series-connected saturable reactor

A—Circuit diagram
B—Input-output characteristic $I_LN_L = f(I_CN_C)$

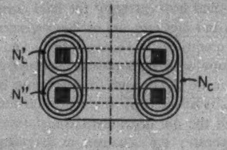

Fig. 8. Toroidal arrangement of a-c load windings $N_L'N_L''$ and d-c control winding N_C employed in the prototype design of a miniaturized d-c instrument transformer

should make it possible to measure direct and low-frequency alternating currents in the range of from 1/1,000 to 10 amp with an accuracy of about ±0.5 to 1%. When using the current range 0–1 ma, a series resistor (1,000 ohms per volt) will be provided for measurement of high d-c voltages up to about 10,000 volts; and a standard 1-ma 1,500-ohm moving-coil ink recorder may be used in conjunction with this arrangement.

Because the maximum load-current value corresponding to full-scale deflection of the recorder is 1,000 μa, the magnetizing-current component of the saturable-reactor elements, Fig. 7(A), should be of the order of 1% of this value, that is, about 10 μa, or less. In order to reduce the exciting-current component I_{LO}, Fig. 7(B), to the minimum, the following aspects, similar to those concerning the miniaturized current transformer for a-c measurements, are considered to be of prime importance:

1. Although the rectangularity of the dynamic hysteresis loop of the magnetic core materials with very low coercive force (H_c), e.g., supermalloy type, is less pronounced than that of the grain-oriented nickel-iron alloys, the low-coercive-force materials are definitely preferred in t is design in order to minimize the magnetizing current requirements of the two saturable-reactor elements.
2. Although the saturable-reactor elements are operated with the low power-supply frequency of 60 cps, 2-mil tape cores are employed to minimize eddy-current effects.
3. The saturable-reactor elements must be designed to have a very small cross-sectional area of the core and a correspondingly high number of turns of a-c windings, $N_L' = N_L''$, Fig. 7(A).
4. A sufficiently large core window must be provided to avoid application of undesirable extremely thin wire for the windings, N_L', N_L'', N_C, and excessively high values of winding resistance.
5. In order to reduce actual magnitude of the magnetizing-current component, I_{LO} in Fig. 7(B), to the minimum, it is desirable to provide an a-c bais circuit[11] fed from the power-supply voltage E_P, Fig. 7(A).

In accordance with common practice in the design of magnetic amplifiers,[12] it is advantageous to apply two individually wound a-c windings, N_L' and N_L'', and only one d-c control winding, N_C, which embraces both magnetic circuits; Fig. 8. With this arrangement of saturable-reactor windings, there is no resultant a-c flux through the common control windings, N_C, and no net voltage of fundamental frequency can appear across the control-circuit terminals.

Properties and Dimensions of Components

Mo-permalloy 2-mil tape cores with magnetic properties characterized by the 60-cps **B-H** loop of Fig. 1 were used in the construction of Fig. 8. The core and winding data may be summarized as follows:

Mo-permalloy 2-mil tape cores: tape width = 0.125 inch; inside diameter = 1.250 inches; outside diameter = 1.500 inches.

A-c load windings, N_L' and N_L'': 10,000 turns each of no. *38* (B&S) wire; resistance, 760 ohms each.

D-c control winding, N_C: 10,000 turns with six taps and sections having different wire sizes, corresponding to the arrangement shown in Fig. 2; total resistance, 1,720 ohms.

The full-wave rectifier bridge circuit consists of four silicon diodes (Texas Instrument Company, no. *606*).

The effective numbers of turns of the d-c control winding, N_C, corresponding to those of the primary winding N_1 of the a-c transformer are indicated in Table I. By tapping N_C in this way, the current ratio of the d-c instrument transformer can be varied conveniently, with full ampere-turns and identical accuracy on each range. When using the lowest current range, 0–1 ma, for measurement of high d-c voltages up to about 10,000 volts, the voltage ranges may be varied by means of a tapped series resistor (multiplier), as in the case of an ordinary voltmeter. Since the ratio of conversion of the current ranges, and also that of the voltage ranges, is four or five, respectively, the value to be measured and recorded may be read directly on the linear 50-division scale of the Esterline-angus recorder. In this case, too, the voltage ranges may be extended to higher values by employing modern types of high-resistance components.

Compensation of Magnetizing-Current Component with A-C Bias Circuit

In the orginal saturable-reactor circuit of Fig. 7(A), the average value of magnetizing current I_{LO} has been measured as a function of the power-supply voltage E_P. Fig. 9 shows $I_{LO}=f(E_P)$ and actual

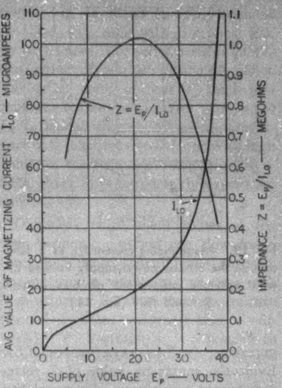

Fig. 9. Magnetizing current I_{LO} and actual impedance $Z = E_P/I_{LO}$ as a function of the 60-cps power-supply voltage E_P

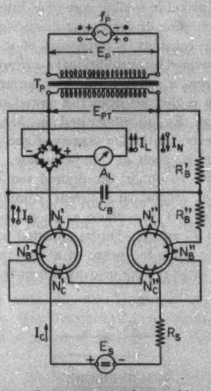

Fig. 10. Series-connected saturable reactor with additional a-c windings N_B', N_B'' acting as bias windings

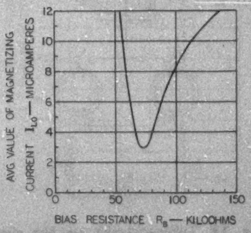

Fig. 11. Magnetizing current I_{LO} as a function of total bias resistance $R_B = R_B' + R_B''$ (C_B = 0.1 microfarad)

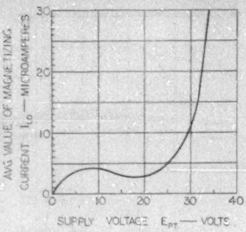

Fig. 12. Magnetizing current I_{LO} as a function of the 60-cps power-supply voltage E_{PT} with optimum adjustment of bias resistors R_B' and R_B'' (Fig. 11)

impedance $Z=E_P/I_{LO}$ as a function of E_P. Evidently, maximum value of Z corresponding to a maximum of permeability occurs with $E_P=21$ volts, and $I_{LO}=20$ μa (stand-by power$=E_P\ I_{LO}=420$ microwatts).

Since the magnetomotive force required by a nickel-iron-alloy core over intervals of increasing or decreasing fluxes is practically constant, a large part of it may be provided by an additional a-c winding[11] fed from a synchronous bias current I_B which is derived from the power-supply voltage E_P, as illustrated in Fig. 10. However, with low-coercive-force core materials, such as Mo-permalloy, it is possible to obtain the desired reduction of the magnetizing-current component I_{LO} only if the phase relationship between I_B and E_P can be adjusted to the proper value by means of a correspondingly rated reactor or capacitor in the a-c bias circuit. In this case, adjustment of the respective components of the a-c bias circuit must be made so that the fundamental waves of I_{LO} and I_B are in phase, in order to bring I_{LO} to the minimum.[11]

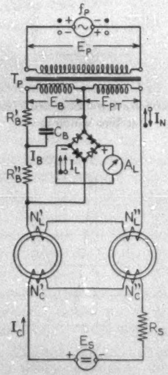

Fig. 13. Differential-type a-c bias circuit which eliminates the additional a-c windings N_B', N_B'' (Fig. 10) of the saturable-reactor elements

Fig. 10 illustrates the application of such an a-c bias circuit in the series-connected saturable-reactor circuit of Fig. 7(A). The series -opposing- connected a-c bias windings N_B', N_B'' have, when using the dimensions of components described in the preceding section, 1,000 turns each of no. *38* (B&S) wire (resistance, 90 ohms each). Bias resistors R_B', R_B'' and shunt capacitor C_B must be properly rated to obtain optimum value of phase displacement between the fundamental waves of bias current I_B and secondary voltage E_T of the power-supply transformer T_P.

Fig. 11 shows the average value of the magnetizing-current component I_{LO} as a function of total bias resistance $R_B=R_B'+R_B''$ with $C_B=0.1$ microfarad. With optimum adjustment ($R_B'=38{,}000$ ohms, and $R_B''=42{,}000$ ohms), I_{LO} has been reduced to about 3 μa, that is to about 1/7 of its original value without a-c bias; Fig. 9. Fig. 12 shows $I_{LO}=f(E_{PT})$ for the case that the a-c bias circuit, Fig. 10, is provided with optimum adjustment of R_B' and R_B''.

Similar effects can be introduced by applying the differential-type circuit of Fig. 13 with a modified power-supply transformer T_P having a center-tapped secondary winding. This advantageous arrangement eliminates the additional a-c windings, N_B' and N_B'', in Fig. 10, and simplifies the construction of the saturable-reactor elements, Fig. 8. With $R_B'=60{,}000$ ohms, $R_B''=1.1$ megohms, and $C_B=0.1$ microfarad, optimum results have been obtained with this arrangement. Here, again, the magnetizing-current component I_{LO} has been reduced to about 1/7 of its original value without a-c bias (Fig. 9).

HIGH-PRECISION MEASUREMENT OF ACTUAL CURRENT RATIO

The purpose of a d-c transformer is to measure the direct current or low-frequency alternating current (I_C) flowing through the control winding (N_C) in terms of the average value of unidirectional load current (I_L). When measuring voltages, the direct voltage or low-frequency alternating voltage is translated into a corresponding control current (I_C) by means of a series resistor, as in the case of an ordinary voltmeter. Therefore, by far the most important test to be made on a d-c instrument transformer is to find how correctly the load current I_L is an exact measure of the corresponding quantity to be measured, i.e., to measure with high precision actual current ratio I_L/I_C and to determine how I_L/I_C is affected by the condition under which the d-c instrument transformer is to operate; e.g., changes in magnitude, frequency, and waveshape of the power-supply voltage.

In accordance with common practice in the magnetic-amplifier art, it is also possible to perform summation of several direct currents by means of several properly rated control windings, which are isolated from each other. This totalizing type of d-c instrument transformer lends itself readily to the metering of direct currents in interconnected systems at different voltages.

The novel test circuit of Fig. 14, a modification of the previously described d-c potentiometer device,[13] permits high-precision measurement on d-c instrument transformers having the turns ratio $N_C/N_L=1$ with regard to actual current ratio I_L/I_C and the influence of variations in magnitude, frequency, and waveshape of the power-supply voltage E_P, etc. This circuit takes advantage of the fact that the turns ratio $N_C/N_L=10{,}000/10{,}000=1$ is available in this special design. Load current I_L and control current I_C are superimposed in the moving-coil microammeter $M(-50\ldots0\ldots+50$ μa, 600 ohms) so that $I_M=I_L-I_C$. Thus, the percentage current-ratio error in terms of I_C, i.e., the deviation of the

(A)

(B)

Fig. 15. Error current $I_M = I_L - I_C$ as a function of the control current I_C (circuit of Fig. 14)

A—Characteristics without a-c bias
B—Characteristics with a-c bias

actual current ratio $K_I = I_L/I_C$ from its ideal value, $I_L/I_C = 1$, is

$$\Delta K_I = 100\frac{I_L - I_C}{I_C} = 100\frac{I_M}{I_C} \qquad (6)$$

This error ΔK_I is positive when, with a given control current I_C, the actual load current I_L is in excess of its ideal value; i.e., when the milliammeter A_L reads too high.

Furthermore, the deviation of actual current ratio I_L/I_C from its ideal value may be expressed in terms of the maximum value, $I_{C\max}$, of the control-current range; i.e., in per cent of full-scale deflection of the instrument A_L (moving-coil ink recorder) which measures the average value of load current I_L in the output circuit:

$$\Delta K_I \frac{I_C}{I_{C\max}} = 100\frac{I_L - I_C}{I_{C\max}} = \frac{I_M}{I_{C\max}} \qquad (7)$$

The test circuit of Fig. 14 makes it possible to measure with a high degree of accuracy the percentage current-ratio error, which is due to imperfections of the saturable-reactor elements. Because imperfections of the microammeter M measuring the error current $I_M = I_L - I_C$ enter into the measurement as error of second order, an ordinary panel-type microammeter can be used for measuring ΔK_I with an accuracy of about ±1 to 2%.

Employing the test circuit of Fig. 14 with $N_C = 10,000$ turns and the current range 0–6 ma, actual magnitude of error current I_M has been measured as a function of I_C under various operating conditions. Fig. 15 shows $I_M = f(I_C)$ without a-c bias (A), and with a-c bias (B). In both cases, the series resistor of N_C was either $R_S = 0$ or $R_S = 5,000$ ohms. Evidently, error current I_M and percentage current-ratio error $\Delta K_I = 100\ I_M/I_C$ depend upon the actual total resistance of the control-circuit loop: With high values of the series resistance, e.g., $R_S = 5,000$ ohms, I_M is considerably larger than with $R_S = 0$.

Obviously, with small values of R_S, even-harmonic currents can flow freely through the control-circuit loop ("natural"-magnetization conditions), whereas with high values of R_S, these currents are suppressed ("forced"-magnetization conditions).[14–16] Fortunately, it is possible to eliminate this undesirable effect of changes in control-circuit-loop resistance upon I_M by providing an artificial path for the even-harmonic currents, without applying additional d-c windings on the saturable-reactor elements. In the simple arrangement of Fig. 16, a shunt resistor R_N with series capacitor C_N is connected across the control winding N_C. The blocking capacitor C_N prevents direct current from flowing through the shunt resistor R_N. The optimum value of R_N, which is not critical, has been determined empirically by means of the test circuit of Fig. 14.

Fig. 17 shows $I_M = f(I_C)$ without a-c bias (A), and with a-c bias (B). Here, again, the series resistor of control winding N_C was either $R_S = 0$ or $R_S = 5,000$ ohms. The results of these measurements show that the characteristics with $R_S = 5,000$ ohms are quite different from those with $R_S = 0$. However, in both cases, error current I_M is within the limits of about ±10 to 20 μa. Further-

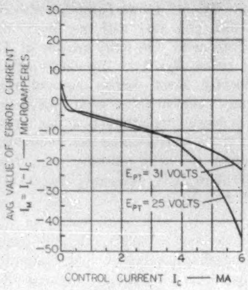

Fig. 18. Error current $I_M = I_L - I_C$ as a function of the control current I_C with 60-cps power-supply voltage E_{PT} as a parameter

more, it is clearly evident from Figs. 15 and 17 that application of an a-c bias circuit, Figs. 10 and 13, is definitely very advantageous.

Similar measurements with the test circuit of Fig. 14 concerning the influence of the usual variations in magnitude and frequency of the power-supply voltage have shown that the error current I_M may change within the limits of about ±30 μa. Fig. 18 shows as an example $I_M = f(I_C)$ with $E_P = 25$ volts and $E_P = 31$ volts, respectively.

DYNAMIC PERFORMANCE

The transient response of the series-connected saturable-reactor circuit, Fig. 7(A), using nickel-iron-alloy core material can be described by simple linear equations.[17,18] When operating in the linear region of the input-output characteristic, Fig. 7(B), the response of the load current I_L to changes of d-c control voltage E_S, power-supply voltage E_P, and load resistance R_L, is an exponential function, governed by a time constant, which varies with the load resistance and inversely with control-circuit resistance and power-supply frequency.

The response of the load current I_L to sudden changes of signal voltage E_S can be described by the control time constant T_C, which depends upon the turns ratio N_C/N_L, the resistance ratio R_O/R_C, and power-supply frequency f_P:

$$T_C = \frac{1}{4f_P}\,\frac{R_O}{R_C}\left(\frac{N_C}{N_L}\right)^2 \text{ seconds} \qquad (8)$$

or

$$T_C = \frac{1}{4}\,\frac{R_O}{R_C}\left(\frac{N_C}{N_L}\right)^2 \text{ cycles} \qquad (9)$$

where R_O is the total resistance of the load circuit and R_C is the total resistance of the control-circuit loop including the internal resistance of the signal source.

It is to be noted that the control time constant T_C of the circuit of Fig. 7(A) is the same for increasing and decreasing signal voltage E_S. The geometrical dimensions of the magnetic cores do not enter into the expressions of equations 8 and 9. However, in practice, the influence of the nonideal magnetization curve will cause certain differences between measured and calculated values of the control time constant T_C. In considering the accuracy of this theoretical method for determining the control time constant for slow-response operating conditions (T_C is about 6 to 30 cycles of the power-supply frequency, or more) it must be remembered that in most practical design problems an approximate value is all that is required.

With regard to fast-response operating conditions, where actual response time is of the order of 1 to 4 half-cycles of the power-supply frequency, experimental methods have assumed increased importance. A simple and convenient method for studying the dynamic performance of d-c instrument transformers and magnetic amplifiers with fast-response operating conditions consists of applying to the control circuit a synchronous unidirectional square-wave signal voltage, which may be derived from a synchronously operated mechanical-switch device[19] or from a magnetic switch[20,21] which consists essentially of a special saturable-reactor circuit producing a synchronous auxiliary current with rectangular waveshape.

The dynamic performance of the miniaturized d-c instrument transformer described in this paper has been studied by means of a modified form of transient analyzer which permits direct visual observation of a stationary pattern on a cathode-ray oscilloscope. In this arrangement,[22] the unidirectional square-wave signal voltage (E_S) is derived from a switching-transistor magnetic-coupled multivibrator which is synchronized with the power-supply frequency (f_P) of the d-c instrument transformer under test to obtain a stationary pattern on the screen of the oscilloscope.

The oscillograms of Fig. 19 illustrate the dynamic performance of the d-c instrument transformer with a-c bias circuit, Fig. 13, in the special case that the total resistance of the control-circuit loop has such a value that half-cycle response is obtained. The sweep frequency of the oscilloscope has been synchronized so that (A) four cycles or (B) only two cycles of the unidirectional output current I_L will appear on the screen.

It is to be noted that under half-cycle-response conditions, Fig. 19, the load current I_L is not only linearly proportional to the direct control current I_C but to some extent will even have a similar oscillographic variation when I_C varies, owing to a superimposed a-c component.[23–25]

Conclusions

Recently developed a-c and d-c types of miniaturized instrument transformers for multirange operation of standard permanent-magnet moving-coil ink recorders and d-c panel meters utilize the unique magnetic properties of nickel-iron-alloy high-permeability core materials and the possibility of minimizing the magnetizing-current requirements with special core construction (very small cross-sectional area of the Mo-permalloy 2-mil tape core, and large number of turns of the secondary winding). The design of such transformers having a maximum output power of about 50 mw is based upon a rated full-load secondary current of 1.0 ma. By tapping the primary winding any desired current ratio can be obtained, with full ampere-turns and identical accuracy on each current range. For higher ranges, the primary conductor can be threaded through the window opening for 1, 2, or 5 turns to give the 1-ma rated secondary-current value for 10-, 5-, or 2-amp primary current, respectively. When using the current range 0–1 ma, a series resistor (1,000 ohms per volt) will be provided for measurement of high a-c and d-c voltages up to about 10,000 volts.

The miniaturized d-c instrument trans-

196

former having two equally rated saturable-reactor elements with low-coercive-force 2-mil tape cores makes it possible to measure direct currents and low-frequency alternating currents without the use of shunt resistors. In this case, a properly rated a-c bias circuit is used to reduce the magnetizing currrent of the saturable-reactor units to an extremely small value, about 3 μa. A similar arrangement permits measurement of high d-c voltages, up to about 10,000 volts, in such a way that the meter circuit is insulated from the high-voltage circuit, in accordance with conventional a-c instrument-transformer techniques.

High-precision measurement of actual current-ratio error of such small-size instrument transformers using differential-type test circuits make it evident that currents in the range of from 1/1,000 to 10 amp can be measured with an accuracy of ±0.3 to 0.5%. In any case, the primary current flowing through the tapped primary winding or through the single-turn primary will be measured in terms of the average value of full-wave-rectified secondary current flowing through the moving-coil system (range: 0–1.0 ma, 1,500 ohms) of the ink recorder.

Synopsis: Waterproof cases for instruments, especially cameras, electronic flash lamps, and sonar drivers, are considered for external pressures up to 20,000 psi (pounds per square inch) which is adequate for the greatest known depths in the sea. Equations, charts, and experimentally determined values of failure are given for cylinders, end caps, and windows of various materials. Several types of pressure-resisting electric connections are shown and a pressure-testing facility is described.

THE COMPREHENSIVE article on photography in the ocean by Ewing, Vine, and Worzel[1] has a very complete bibliography covering the work on deep-sea photography from the early work of Boutan in France up to 1946. A series of designs that have proved to be helpful to equipment designers are given in the reference. This paper should be considered an extension of this important contribution.

Those who work in oceanographic instrumentation are required to put their devices in watertight containers for immersion at great depths. The pressure increases 1 atm (atmosphere) for each 32 feet. Therefore, at 2 miles depth (the average of the oceans) the pressure is about 330 atm (5,000 psi). At the greatest known depth, some 36,000 feet, the pressure is 1,130 atm or about 17,000 psi. Case designs must be adequate to withstand these continuous pressures.

The shape of the case is important in the design. A good first impression is made by the sphere shape because of its ability to equalize the forces on the walls, resulting in the lightest wall sections. However, it is difficult to utilize the interior of a sphere effectively: it is more difficult to machine and windows and electric leads disturb symmetry. The next simplest structure is the cylinder. This paper considers the design of cylindrical structures with flat end caps, with commercially available tubes and pipes of several materials in mind.

Cylindrical Tubes

Fig. 1 is a graph for cylindrical pressure vessels of various metals, commercially available, showing the maximum or collapsing pressures plotted against the t/D ratio (wall thickness to outside diameter). The figure points out the great differences between the thin-wall formulas, represented by the exponential sections, and thick-wall formulas, shown by the straight-line sections. An example is shown assuming a tube of *7075-T6* aluminum having a t/D of 0.035. If only the thick-wall formula were used, failure would be expected at 5,000 psi when, in reality, the failure would occur at 1,000 psi as shown by the thin-wall curved section of the graph. These curves are for cylinders whose effective length is greater than six times the outside diameter, since this size range is the most commonly used, and were obtained by combining formulas of Timoshenko, Carmen, and Love[2] and

further modified by experimental data from both laboratory and at sea. Slight variations from these curves may be expected since values used are averages. No allowances have been made for end-closure stresses since these are relatively small on a long tube.

Fig. 2 is a graph showing the t/D ratio (thickness/unsupported diameter) versus maximum pressure for various metallic end caps. These curves, of course, assume sufficient material to prevent shear and crushing failures. Fig. 3 gives t/D versus pressure for glass and Lucite[*] windows, showing some of the test points. From this it can be seen that a 1-inch-thick window with a 4-inch diameter ($t/D=0.25$) will break at about 2,500 psi, or approximately 1 mile. In order to use a 1-inch-thick window for greater depths, a heat-treated stainless-steel insert or ring with a $1^1/_4$-inch effective diameter is used ($t/D=0.80$, maximum $P=25{,}000$ theoretical); see Fig. 4. This design shows the effect of undercutting of the outside of the steel backup plate. This is necessary to prevent the deflection of the steel plate from affecting the glass window. Without undercutting or extremely heavy backup plate ($t/D=1$ to 1.5), failures below 50% of expected are experienced consistently.

Although regular plate glass, which is almost optically flat, has a slight greenish tint and is not the strongest window material available, it has proved to be most satsifactory. Herculite,[†] a hardened plate glass, has strengths as much as four and five times greater than that of regular plate glass. However, the slight waviness that may be introduced in the hardening process makes the seating difficult and gives highly unpredictable pressure results. These results vary from the calculated values for Herculite to values lower than for ordinary plate glass.

Fused ground quartz has been used to gain optical qualities in special cases, but for general work the slight transmission gain does not outweigh the cost ratio and there is no gain in strength.

The surfaces of the glass windows, especially the inside, must be without scratches since fracture will start at any blemish when the glass is under tension. An optical polish to a wavelength of light is necessary for the camera window. Flat Lucite or Plexiglas[‡] has proved very useful in the lower pressure ranges. Fig. 3 shows that the curve is conservative for Lucite design. Optical designers have indicated that their preference is glass, because Lucite is easily scratched and shows a loss in photographic quality because of internal stresses.

Seals for Electric Conductors

Several solutions for the electric wire connections have been found. One method is to use a pressure fitting on a solid wire which is insulated with plastic material. It is impossible to seal stranded wire since the water will find a path through the area between the strands. The Conax Company, Chicago, Ill., makes a standard line of stainless-steel pressure fittings that have been satisfactorily used (see Fig. 5). It has been found that the wire and insulation must be a tight fit in the insert if the gland is to be used at very high pressures. Great care must be used to tap clean perfect threads. The use of an undersized tap drill and a taper pipe-tap reamer is almost essential. Pipe-fitting cement such as Permatex[§] no. *1* (form *A* gasket; hardening) must be used and the fitting must be installed with considerably greater torques than required for ordinary use. The use of heavy-duty hexagonal socket wrenches is recommended to prevent rounding off of the hexagonal sides of the fittings. Other various modifications, such as multiple rubber inserts, etc., are occasionally employed.

Another convenient and successful solution to the lead problem (to about 10,000 psi) is the plug (Fig. 6) made by the Joy Company, Pittsburgh, Pa. One watertight separable plug, which gives three circuits, is the Joy-type *8107*. This plug can be attached from the outside with the three wires going through three holes in the metal. O rings and clamps complete the seal on the outside with the heavy rubber body serving to withstand the pressure that tries to extrude the three wires into the cavity. This seal is adequate to 10,000 psi at 20 C (degrees centigrade). The wires break due to rubber flow when used at about 20,000 psi for an extended time at 20 C. Perhaps the operation at lower tempera-

tures will be more favorable since the rubber hardens.

A single-pin plug, Joy-type *8372*, has been tested successfully at 14,000-psi pressure for an hour at room temperature. Failure due to shear in the rubber occurred at 20,000 psi after a sustained pressure at room temperature. At about 5 C this plug withstood 17,000 psi for 1 hour.

A newer type single-pin Joy plug no. *8372-23*, a combination of a stainless-steel pin, ceramic, and rubber insulation sealed with and to an aluminum hexagonal head screw with an O ring, has been tested to 20,000 psi for 1 hour. The mating plug with cord *x-8372-72* is available with any desired conductor arrangement; see Fig. 7.

Pressure Testing

A very important facility for developing underwater equipment is a pressure-testing chamber. Pressure tests should be applied in a routine manner to all equipment that is scheduled to be used on an expedition. In this way, faulty equipment will be found before it causes disappointments at sea. This is especially important since ship time at sea is very precious.

The pressure-testing system at Woods Hole Oceanographic Institution (WHOI) (see Fig. 8), which has been used with great success for years, consists of a 16-inch naval shell, type *HE MK 13* mods *5* (mods *0-6* can be substituted). The cavity has cylindrical dimensions of $9^5/_8$-inch diameter by 30 inches with a pointed end extending to 42 inches. The base plug is about 6 inches deep with a left-hand square thread. A standard 1/4-inch O ring is used with a brass ring insert to set the correct squeeze on the O ring. This plug weighs about 50 pounds. Another smaller hole (about $1^1/_2$ inches in diameter) at the center is closed with another left-hand thread on a screw plug with an O ring seal. This is the last plug to be placed so that the water can be observed as the shell is filled prior to the application of pressure. It is essential that no air be entrapped in the pressure system, in order to lessen the danger in case of a mechanical failure. Hard O rings of durometer 90 should be used.

Stainless-steel tubing of 1/4-inch outside diameter 0.065-inch wall and Parker* triple fittings are used to connect the hydraulic pressure pump to the shell. Oil pumps have been used, both hand and motor driven, with an oil–water interchange for pressures to 10,000 psi.

Pressures to 20,000 psi are obtained from a Sprague-Symons† pump, type *S440-200*, that operates from air pressure at 100 psi and uses water as a pressure medium.

It might be advisable to note at this point that the suitable factor of safety of four is not incorporated in this equipment, but since it is used only occasionally and the operators do not remain in the area while testing, personal safety is assured.

---

* Trade name, Union Insulating Company, Inc., Parkersburg, W. Va.

† Trade name, Symons Associates, Inc., Tiverton, R. I.

Pressures as recorded on the gage are read through an inexpensive telescope from a safe vantage point. Also, the total volume of water pumped due to the compressibility of the water and the "stretch" of the steel shell amounts to approximately 2 liters, so that even the slightest leak is noticed by the corresponding pressure drop.

In all tests it is advisable to maintain pressure for at least twice, if not four times, the expected use time to allow for plastic creep or flow that might give false confidence gained by a "pop" test.

Camera

Since conventional cameras are not easily adaptable to cylindrical shape, an in-line camera design was evolved from the standard (no. *10*) 100-foot 35-millimeter motion-picture reel. Fig. 9 shows the way in which the camera parts are lined up on a chassis that slips into the cylindrical housing. An inside diameter of 4.04 inches is required for the film spools.

A sample photograph is shown in Fig. 10. Notice that a data section has been added to each frame to record time, pressure (2,000 meters), and other information concerning the test. In this way, the essential information concerning a film always goes with the film, precluding any possibility of mismarking or mixups which often occur in processing and printing.

Electronic Flash

The elements of an electronic flash lamp are shown in Fig. 11 in a cylindrical form for insertion into a 4.04-inch-inside-diameter cylinder. The flash lamp is protected by a $1^1/_2$-inch iron pipe size Pyrex glass end cap made by the Corning Glass Works. The open end is ground flat and sealed to the metal end plate with a 1/16-inch-thick rubber gasket. It is important to use spring-lock washers on the bolts to take up the compression of the rubber, otherwise a leak may occur when the case is brought to the surface.

Experiments with Air Ions on the Trachea

JOHN C. BECKETT
MEMBER AIEE

ALBERT P. KRUEGER
NONMEMBER AIEE

MAN REGULARLY encounters changing environmental conditions. Some of these changes are severe involving extreme discomfort, while others are so subtle as to pass unnoticed. Air ionization is one factor of environment that is properly classified as a subtle change for most people. Few are consciously aware of any change in air ionization, yet the physiological importance of air ions to the function of the respiratory system has been recently quantitatively demonstrated.[1]

Radiation and ionization are closely allied factors of environment. Air ions or electrical charges in the air are a direct result of radiation energy affecting molecules in the air. At the earth's surface radioactivity of the soil is the principal radiation energy causing ionization. Cosmic rays are another important source, particularly as altitude increases. These ions from all sources vary in number and size depending on atmospheric conditions and the strength of radiation energy, but there are always ions present in air.

Delwiche and Stout have observed that changes in radioactivity of the atmosphere may take place rapidly, and a high value may fall to a low value within an hour or less.[2] This observation correlates closely with measurements of air ion density. Indeed, there is measurable correlation of radon gas with air ions near the earth's surface. Most of the ions in air close to the ground are the result of gamma rays from radioactive material in the soil and rock and alpha particles from radon gas emanating from porous earth. Cosmic rays are the second most important source of air ions over land. Maximal values are typically found in still air over land, and it is common to observe an ion density peak between 4:00 and 6:00 a.m. when the air is usually quiet. A noticeable drop in ion density after sunrise can be attributed to convection currents acting to dilute the accumulation of radon gas with greater masses of air. During hot weather the ion density often reaches a minimum about midafternoon.

It has been generally known for more than 150 years that air contains electricity. This was a popular subject of investigation as recently as the 1930's, but it has only been since 1950 that means for control of air ion density as an environmental factor has been given serious consideration.[3]

Air Ion Measurement

There are many designs of ion collectors for measuring air ion density, including those of Gerdian, Ebert, Zeleny, Erickson, Van de Graff, and Israel.[4–6] All of these devices are similar in principle, including both the concentric and parallel-plate-type units. Ion collectors have been constructed with two or more stages in series to measure more accurately the distribution of ions of different size. It is assumed that each ion has one unit charge, and this has been shown by Loeb[7] to be highly probable on particles of the size under consideration. In a uniform electric field a large ion with one unit charge (1.6×10^{-19} coulombs) will move slower than a small ion; thus, the ion mobility is inversely proportional to size. Simultaneous recording of the number of ions present in several mobility ranges provides a clearer picture of the size distribution of ions in air. Small ions are described as gaseous ions consisting of 3–8 molecules, depending on age and environmental conditions. The average mobility of these ions is between 1 and 2 centimeter/second/volt/cm.

Accurate measurement of ion mobility has been made in the physics laboratory with dry air.[8] Ion collectors for general use under various conditions of atmospheric pressure, temperature, and humidity provide a reasonable picture of the small ion "mobility spectrum"[9] estimated to be accurate within about 15%. Principal sources of error are air turbulence and the random position of ions as they enter the collector.

One type of ion collector that is particularly convenient for environmental studies has a first-stage ion trap for selectively removing high-mobility ions in predetermined steps calculated to provide a recording of the ion mobility distribution from the smallest ion through the intermediate range (4 to 0.002 cm/sec/volt/cm). The ion trap voltage is varied in logarithmic steps from 1/3 volt to 600 volts at intervals of 15 sec/step. See Figs. 1 and 2.

Another device for measuring ions is the target collector. In its simplest form this is a gold-leaf electroscope equipped with a target electrode. The time of discharge is inversely proportional to the rate of arrival of unipolar ions. A more convenient ionization flow meter of this type has been developed for the laboratory. See Fig. 3. An electrostatically shielded metal disk about 5 cm² in area is connected to an electrometer for direct reading of either polarity. This same principle is used to measure the air-to-earth current in studies of atmospheric electricity. Detection and accurate measurement of ion flow from an ion source in an electric field is reduced to the simplest form with this device. Rate of ion flow is reported in units of ions per cm² of surface area per second.

Ion Generation

The principle of ion generation and control is simple. Unipolar ion generation employs a means to produce both positive and negative ions and an electric field to effect ion separation. Desired ions can then be disseminated by means of the same electric field or with forced air passing over the ion source. Control implies careful monitoring of ion density, use of ion filtering and ion generation to compensate for natural variations.

It is possible with ion measuring equipment to demonstrate the many sources of air ions and the ease with which ions can be generated. High-voltage electric fields, incandescent materials, ultraviolet light, X ray, and radiation from radioactive isotopes have all been used. Where precise ion control is desired, that is, a uniform output of one or both polarities of ions adjustable to meet specified conditions, radioactive sources have been the most acceptable. Polonium 210, an alpha emitter, and tritium, a soft beta emitter, are commercially available for this purpose.

An ion generator for the control of room air is shown in Fig. 4. This compact portable device contains an ion source consisting of 50 millicuries of tritium gas sealed in zirconium deposited

The physiological experiments quoted herein were supported by contracts with the Atomic Energy Commission, United States Air Force (A.F. *49(638)-669*) monitored by the Air Force Office of Scientific Research of Air Research and Development Command and by grants from the National Institutes of Health (*E-2837*) and the Committee on Research of the University of California.

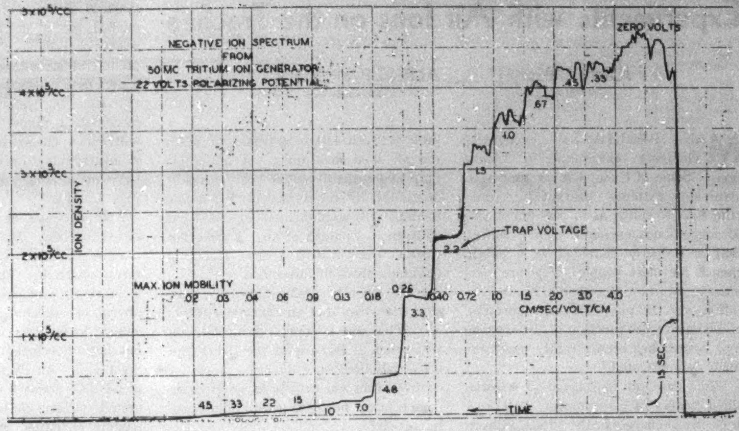

Fig. 1. Recording of negative ion mobility distribution using a parallel-plate-type ion collector equipped with an ion trap selectively to remove ions

on stainless steel foil. An electric potential difference of approximately 2,000 volts direct current is provided to separate the positive and negative ions before they are lost through recombination in the dense ion plasma surrounding the foil.[10] Tritium is a low-energy 0.0185-mev (meg-electron-volt) beta source and produces ions as a result of beta particles ionizing air through a range of about 1 cm at atmospheric pressure. The desired ions are directed by the electric field into a moving airstream created by a small fan located behind the ionizing element. The quantity of tritium used in these experiments produces not less than 10^9 ions/second in air for distribution to the work area. Siksna has shown that the maximum utilization of available ions for room air is achieved using forced air.[11] In tissue studies forced air complicates the experiment and an electric field alone is preferred for laboratory research. In the physiological studies reported here the tritium ionizing element was positioned within the animal or tissue enclosures and circulating air at low velocity was used only in long term animal studies extending for a period of several days or weeks. Typical ion distribution from a tritium ionizing element operating in ordinary air is shown in Fig. 2. Ordinary air is defined as normal air as found in rural areas free of industrial or automobile exhausts, or tobacco smoke. The small ion density is reduced if there are airborne contaminants, particularly those of submicroscopic size.[12]

Electrostatic ion generators using 5,000 volts direct-current on fine tungsten wires have been successfully developed but are

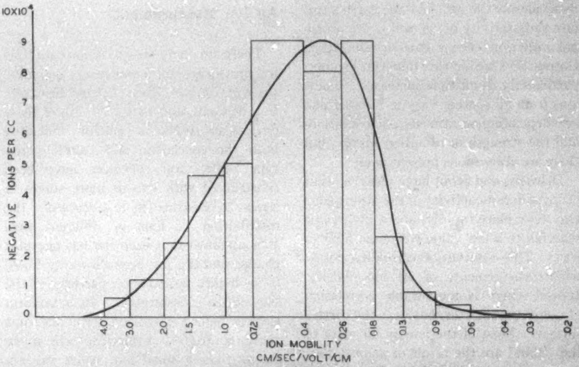

Fig. 2. Plot of data recorded in Fig. 1 showing "mobility spectrum"

Note: In the record in Figs. 1 and 2 of ions from a tritium source ion generator, small ions are trapped in a field less than 15 volts/cm within a travel distance of 7 cm at an air velocity of 75 cm/sec. Record is from a 50-millicurie tritium negative ion generator of the type illustrated in Fig. 4. The shape of this curve is approximately the same as found in nature under similar conditions

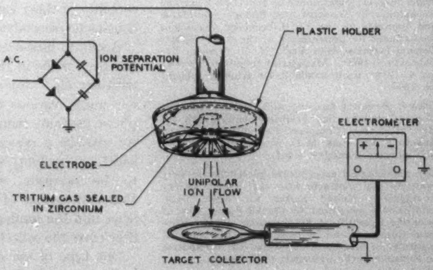

Fig. 3. The target collector may be used to measure total unipolar ion current from an ion source, or to measure ion flow per unit area when positioned close to the tissue surface

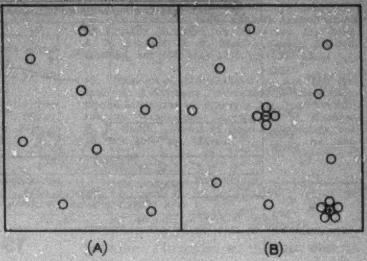

Fig. 5 (right). A small ion in air consists of a single charge attached to one molecule but associated with several to form a molecule complex. Take away the charge and this complex loses all identity

A—Molecules in air move independently and at random in absence of an electric charge

B—The essence of a small ion is the electric charge. Several molecules (3–8) become associated with a single charge, positive or negative

more susceptible to variations in ion output. Ultraviolet and thermionic sources have not been satisfactory for scientific studies because of the rapid deterioration of ion output. Ozone is often a by-product of high-voltage and ultraviolet-type ion generators and the undesirable nature of ozone makes it mandatory to use such generators with caution.

The Influence of Air Ions on the Windpipe (Trachea)

It is not at all obvious that small air ions should exert any kind of effect on living systems. The potential energy involved is extremely small, though the total energy contributed over a long period of time may be significant. Ions move relatively slowly, e.g., 1 to 2 cm/sec in a field of 1 volt/cm, and consequently cannot be expected to inflict physical damage on impact. Further, they affect only about one molecule in 5 trillion.[13] Nevertheless, these ions are easily detected by means of simple equipment and there can be no doubt about their ability to influence the surface-clearing efficiency of the mammalian windpipe (trachea) as measured by the rate of mucus flow and the beat rate of microscopic hair-like protrusions called cilia. It is the small ions that dominate in clean air and are of particular interest. The essence of the small ion is its charge; take away the charge and the gaseous molecule complex associated with the charge loses all identity. See Fig. 5. This is not the case with charged particulate matter.[14]

First experiments were performed with tracheal strips of the rat, rabbit, and guinea pig, kept in a moist chamber and arranged in such fashion that their surfaces could be viewed through a microscope equipped with an eye-piece micrometer. This made it possible to measure the rate of mucus flow by timing the progress of air bubbles in the mucus layer. Similarly, a strobotachometer providing an intense light source flickering at variable rates permitted determination of the rate of ciliary beat with an accuracy of ±50 beats/minute. See Fig. 6.

Air ions were generated within the chamber by soft beta radiation derived from tritium contained in a sealed foil; a reversible rectifying circuit allowed selection of positive or negative ions at will. The number of ions impinging on each cm^2 of surface/sec was measured with a target collector located in the same relative position as the tracheal strips and connected to a Beckman micromicroammeter.

Moderate densities ($1x10^7/cm^2/sec$) of positive ions acting for 20–30 minutes produced striking effects on the functioning of the trachea. Measurement of ions received on the tissue was accomplished immediately after observing ciliary beat rate using the device shown in Fig. 3 in place of the tracheal strips. Ciliary activity dropped by several hundred beats per minute or frequently stopped altogether, while the rate of mucus flow diminished. Positive ions contracted the posterior wall of the windpipe (trachea), dried the mucosal surface, and induced in the cilia a singular susceptibility to tissue damage (trauma). Minor mechanical stimuli that ordinarily had no effect now resulted in complete cessation of ciliary action.[15]

Negative ions accelerated ciliary activity and mucus flow above normal values and in general reversed the inhibitory effects of positive ions.

It was found that similar results could be obtained in the living animal by administering the ions to the undisturbed lining of the windpipe (trachea) through a tracheotomy aperture.[1] In addition to the functional changes noted in the isolated tracheal strip, the living animal exposed to positive ions displayed a pronounced increase in the susceptibility of the mucosal vessels to damage (trauma). The slightest pressure with a probe, which normally results in no notable vascular reaction, induced the prompt formation of a bruise (ecchymotic disc).

The next set of experiments was the exposure of unoperated, ambulatory animals to unipolar ionized atmospheres. Providing somewhat longer periods of exposure were used, they developed the identical alterations in the functional

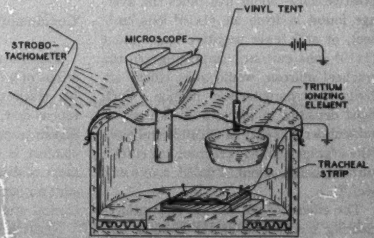

Fig. 6. Experimental arrangement for exposure of extirpated tracheal strip to air ions from a tritium source

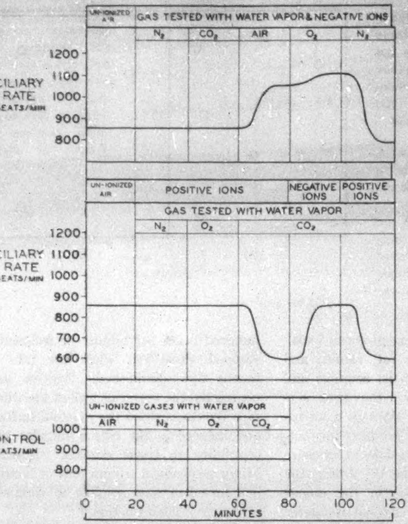

Fig. 7. Ciliary activity of anesthetized rabbits in un-ionized air and in three atmospheres, consisting of N_2, CO_2, and O_2

activity of the trachea which has already been described.

Curiosity leads one to wonder: 1. What constituents of ionized air are responsible for the observed alterations in function? 2. Are these responses to air ions essentially a laboratory phenomenon or do they occur in nature?

Experimental evidence established that negatively charged oxygen is the physiological mediator of negatively ionized air.[16] Experiments on tissue showed that only during exposure to oxygen would the ciliary beat rate increase. Nitrogen, carbon dioxide, and water vapor negative ions had no effect. Similarly, positively charged carbon dioxide is the active component of positively ionized air. Only in the presence of measurable amounts of carbon dioxide would positive charges decrease the ciliary beat rate of trachea strips. See Fig. 7. Further work with the tracheal strip and the tracheotomized animal clearly showed that a very few positive ions—about five times the average found in fresh air (1×10^4 ions/cm²/sec), or still fewer negative ions—about (1×10^3 ions/cm²/sec) impinging on the tracheal mucosa, would alter ciliary activity in characteristic fashion. Such light densities of air ions are known to exist under a variety of natural conditions (the average quantity reaching the earth's surface being about 2.5×10^3 ions/cm²/sec).[17]

The effects of air ions on the surface-clearing mechanism of the trachea and larger bronchi, as seen in the laboratory, are not limited to one particular species but apply to monkeys and man as well as to the usual experimental animals.[18] The inhibition of the clearing function by positive ions and its acceleration by negative ions appear to be entirely independent of the central nervous and circulatory systems and are triggered by relatively few ions impinging on the mucosal surface.

Recent studies have proved that negative air ions stimulate the activity of cytochrome oxidase thereby accelerating the process of reoxidation of reduced cytochrome *c*.[19] Such action on a respiratory enzyme normally found in tissues may account for the effects of negative ions on ciliary activity and perhaps on other functions as well. Positive ions exerted no influence on this particular enzyme system and appear at this time to have quite a different effect, unrelated to the negative ion enzyme action.[20]

Conclusion

Though an individual may not be conscious of a change in ciliary rate in his or her trachea, or aware of an increase in mucus flow, the importance of these findings in terms of environmental health and comfort is obvious. The specific treatment of disease, on the other hand, must wait for completion of carefully controlled clinical studies.

Negative air ions have been shown to be beneficial to respiration, but this does not mean that negative ions alone will cure a respiratory ailment or relieve a diseased condition. There is no evidence to suggest that positive ions cause asthma or hay fever; the most that can be concluded is that positive ions enhance susceptibility to trauma, may account for some mucosal irritation and may set the stage for infection if other conditions are also present.

Electrical engineers will appreciate their responsibility in the application of electrical equipment in confined spaces to avoid positive ion space charges in view of these findings. Extremes of the engineer's problem can be found on modern nuclear submarines and space ships. Closed atmospheric systems need careful study of air ions as a part of providing the most favorable environment. At the scientific level, the biophysicists and physiologists have a new challenge in the study of electrical effects on cells and tissue. Previously it was not suspected that such small quantities of electricity could cause any measurable response. Improved measuring devices and techniques have helped to make this possible.

Power Semiconductor Ratings Under Transient and Intermittent Loads

F. W. GUTZWILLER
MEMBER AIEE

T. P. SYLVAN
NONMEMBER AIEE

METHODS for rating semiconductor power rectifiers and controlled rectifiers under steady-state conditions are well established and accepted. These techniques assume uniform temperature across the entire semiconductor junction area and limit this temperature under different load and ambient conditions to a predetermined level consistent with good performance and high reliability.[1,2] Supplementary methods for determining junction temperature under transient and intermittent loads are necessary for such applications as motor-starting and lamp-dimming controls,[3] and for calculations involving other types of overload duty on semiconductor equipment. This paper discusses methods of handling these intermittent duty types of applications. Examples illustrate suggested techniques for determining the peak junction temperature under various kinds of intermittent loading.

Semiconductor Thermal Circuit

Compared with other electric components such as transformers and motors, semiconductors have very low thermal capacity, particularly in the immediate vicinity of the junction, which is the source of a major part of the heat losses. As a result, semiconductors heat up quickly upon application of load. Yet, for very short overloads this relatively low thermal capacity may be significant in arresting the rapid rise of junction temperature. In addition, the heat sink to which the semiconductor is attached may have a thermal time constant of many minutes. Both of these effects can be used to good advantage in securing attractive intermittent ratings, sometimes well in excess of the published continuous ratings for a device.

Fig. 1(A) illustrates the cross section of a typical silicon semiconductor device, in this case a diode rectifier. The main elements of the device are the *P* type and *N* type of silicon which form the active junction at their interface, suitable back-

Paper 60-69, recommended by the AIEE Semiconductor Rectifiers Committee and approved by the AIEE Technical Operations Department for presentation at the AIEE Winter General Meeting, New York, N. Y., January 31–February 5, 1960, and re-presented for discussion only, at the AIEE Fall General Meeting, Chicago, Ill., October 9–14, 1960. Manuscript submitted October 30, 1959; made available for printing July 15, 1960.

F. W. Gutzwiller and T. P. Sylvan are with the General Electric Company, Auburn, N. Y., and Syracuse, N. Y., respectively.

The authors are indebted to William Warburton of the General Electric Company Low Voltage Switchgear Department for first suggesting, in a 1957 report, the concept of transient thermal resistance.

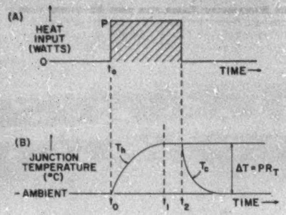

Fig. 2. Response of junction temperature to pulse of heat input

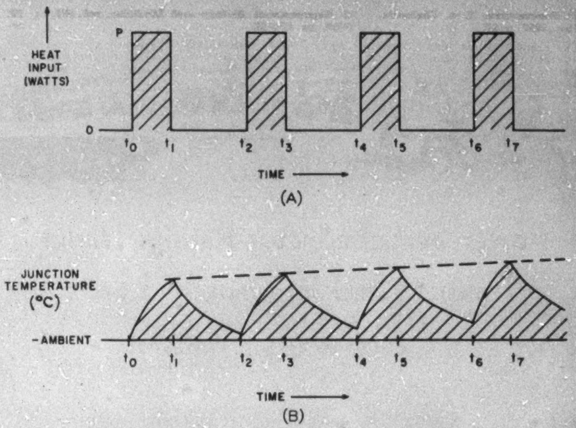

Fig. 4. Transient heating of a semiconductor under intermittent load

up plates for matching the coefficient of expansion of the silicon, and top and bottom electrodes to act both as electric connections and a path for cooling the cell. At normal load current levels, the greatest part of the total heat generation occurs at the junction with relatively insignificant I^2R (current resistance) losses occurring elsewhere in the semiconductor material, backup plates, electrodes, and the joints between these elements. At higher currents, the resistive losses become a more significant part of the total.

The thermal circuit of the semiconductor can be represented as shown in Fig. 1(B). The electrical symbol for a capacitor represents thermal capacitance, and that for a resistor, thermal resistance. For planar junctions two main networks of thermal resistance and capacity emanate from the junction to the ambient temperature: one through the materials above the junction and thence out the top lead to the ambient, the other through the materials below the junction and thence to the stud, case, fin, and ambient. In the thermal circuit of Fig. 1(B), heat is shown being introduced at the junction, as indicated by the long arrows. Heat is also generated by I^2R losses in other parts of the thermal network, as indicated by the shorter arrow.

The thermal circuit can be simplified to that shown in Fig. 1(C). This is an equivalent network emanating in only one direction from the junction and with the total heat losses of the semiconductor being introduced at the junction(s) only, instead of at various other points throughout the semiconductor device. This latter simplification is valid for current amplitudes at which I^2R losses are small in comparison with the junction losses.

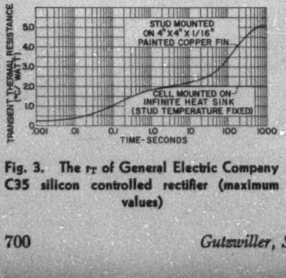

Fig. 3. The r_T of General Electric Company C35 silicon controlled rectifier (maximum values)

Junction Temperature Response to Sudden Application of Load

When a step pulse of heating power P is introduced at the junction of the semiconductor (and of the thermal circuit) as shown in Fig. 2(A), the junction temperature will rise at a rate dependent upon the response of the thermal network. This is represented by the curve T_h in Fig. 2(B). After some sufficiently long time t_1, the junction temperature will stabilize at a point $\Delta T = PR_T$ above the ambient temperature. (ΔT = temperature rise in C (degrees centigrade), P is power loss in watts, and R_T is the thermal resistance between junction and ambient). R_T is the sum of R_1 through R_n in the equivalent thermal circuit of Fig. 1(C).

If the power input pulse is terminated at time t_2 after the junction temperature has stabilized, the junction temperature will return to ambient along the locus indicated by T_c in Fig. 2(B). It is shown in the Appendix that curves T_h and T_c are conjugates of one another, i.e.,

$$T_c = \Delta T - T_h = PR_T - T_h \qquad (1)$$

Transient Thermal Resistance

By dividing the instantaneous temperature rise of curve T_h in Fig. 2(B) by the power P causing the rise, the dimensions of the ordinate can be converted from C to C/watt (per watt). This latter set of dimensions is that of thermal impedance, or, as henceforth arbitrarily termed, the transient thermal resistance r_T. Fig. 3 shows a plot of r_T for a typical medium-power semiconductor device.

The r_T for a given device can be secured by monitoring junction temperature at the end of a well-defined power pulse or after a known steady-state load has been removed. Junction temperature is measured by use of one of the temperature-sensitive junction characteristics such as reverse saturation current or forward voltage drop at low currents. Conversion of heating data to cooling data, or vice versa, can be accomplished through the use of equation 1.

To use the r_T curve with confidence in equipment designs, the curve must represent the highest values of thermal resistance for each time interval on the curve that can be expected from the manufacturing distribution of the product. An additional slight safety factor is required to provide conservative application under repetitive pulse types of load.

The r_T curve approaches asymptotic values at both the long-time and short-time extremes. For very long-time intervals the r_T approaches the steady-state thermal resistance R_T. At very short time intervals the curve approaches a limiting value which is different from zero. This asymptotic value of thermal resistance implies a peak power rating for the device so that use of the curve in the region of very short time intervals results in conservative designs. For

Vol.
Pt. 1
196

maximum utilization of semiconductor devices in the microsecond region, additional factors must be considered and other methods of rating and life testing used.

Response to Single-Load Pulse

The r_T curve forms the basis for several different types of intermittent duty calculations. The simplest is junction temperature response to a single step function of power input, as expressed in Fig. 2. Provided the junction is initially at the ambient temperature, the junction temperature rise during heating T_h can be expressed as

$$T_h = Pr_T \qquad (2)$$

where r_T is at time t (C/watt). The cooling curve T_c can be expressed as

$$T_c = P(R_T - r_T) \qquad (3)$$

where R_T = steady-state value of thermal resistance. Equation 3 is valid only if the junction has reached its steady-state temperature rise before the heat input is removed.

For example, if 100 watts are suddenly applied to the device whose r_T is defined by the infinite heat sink curve in Fig. 3, the junction temperature will rise $Pr_T = 100 \times 0.36 = 36$ C in 0.01 sec (second) and $100 \times 1.0 = 100$ C in 0.1 sec. If allowed to stabilize, the junction temperature will eventually rise $100 \times 2.0 = 200$ C above an infinite heat sink. If the power input is removed after steady-state conditions have been reached, the junction rise above the heat sink will return to $100\,(2.0 - 0.36) = 164$ C in 0.01 sec, and to $100\,(2.0 - 1.0) = 100$ C in 0.1 sec. It will return to the heat sink temperature in approximately 10 sec.

This technique is useful in calculating the maximum load-carrying capabilities of a device when subjected to single load pulses with sufficient time between pulses to allow cooling back to the initial conditions. For example, if the maximum junction temperature rating of the aforementioned device is 200 C and it is desired to determine the maximum power dissipation for 0.5 sec when the device is mounted to an infinite heat sink at 25 C, one can proceed as follows: r_T at 0.5 sec from Fig. 3 = 1.62 C/watt. Allowable temperature rise = 200 − 25 = 175 C. Maximum heating pulse = 175 C/watt/1.62 C/watt = 108 watts.

Response to Repeated Pulses

When heating pulses follow one another so closely that the junction cannot cool down to its initial temperature each cycle, the method of determining peak junction temperature becomes somewhat more complex. Fig. 4 illustrates the case where the heating pulse is not long enough for the junction to reach its steady-state rise and the OFF interval is too short for complete cooling. As a result, the junction temperature peak rises on successive cycles until, after a sufficient length of time when the temperature rise each cycle becomes the same as the temperature drop, successive peak temperatures are identical. This is the steady-state condition for that input.

Superposition: While several approximation approaches to this type of problem can be proposed, superposition[4] offers a rigorous numerical method of using the r_T curve to secure a solution, even though the steady-state conditions for equations 2 and 3 are not met. Superposition tests the response of a network to any input function by replacing the input with an equivalent series of superimposed positive and negative step functions. Each step function must start from zero and continue to infinity, to meet the steady-state requirements of equations 2 and 3.

For example, Fig. 5(A) illustrates a typical train of heating pulses. The amplitude of each successive pulse changes. Fig. 5(B) shows the equivalent heat input attained by superimposing positive and negative step functions of power. At time t_0 an infinitely long step function of heat with amplitude $+P_0$ is applied to the junction. To conclude the actual heating pulse at time t_1, an infinitely long negative step function of heat with amplitude $-P_0$ is applied to the junction. This neutralizes the initial

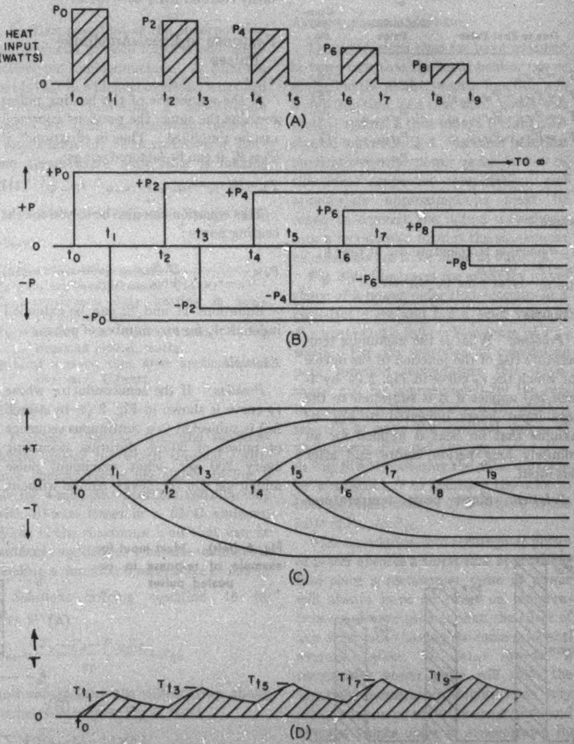

Fig. 5. Use of superposition to determine peak junction temperature. A—Heat input. B—Equivalent heat input by superposition. C—Junction temperature response to individual heat inputs in B. D—Actual junction temperature

step function from this point out to infinity. At time t_3, a positive step function P_2 is applied to initiate the second pulse. This is terminated at t_4 by a negative step function $-P_2$. The succeeding square-top pulses with varying amplitudes may be represented in similar manner.

By using the r_T curve as shown in the previous section, the temperature response of the junction may be plotted for each of the various step functions of power as shown in Fig. 5(C). Fig. 5(D) indicates the actual junction temperature variation which is simply the algebraic sum of the individual temperature response curves of Fig. 5(C).

The maximum and minimum temperatures for each cycle can be expressed in equation form, as follows:

TEMPERATURE RISE

Due te First Pulse	Due to Second Pulse	Equation No.
$T_{t_1}=P_0 r_{t_1}$		(4)
$T_{t_2}=P_0 r_{t_2}-P_0 r_{(t_2-t_1)}$		(5)
$T_{t_3}=P_0 r_{t_3}-P_0 r_{(t_3-t_1)}$	$+P_2 r_{(t_3-t_2)}$	(6)
$T_{t_4}=P_0 r_{t_4}-P_0 r_{(t_4-t_1)}$	$+P_2 r_{(t_4-t_2)}$	(7)
	$-P_2 r_{(t_4-t_3)}$	
$\vdots$		

where

T_{t_1} = junction temperature rise at time t_1
$r_{t_1}=r_T$ at time t_1
$r_{(t_2-t_1)}=r_T$ at time (t_2-t_1), etc.

Example

Problem: What is the maximum temperature rise of the junction of the device for which the r_T curve in Fig. 3 (4- by 4-inch fin) applies if it is subjected to the heat input losses indicated in Fig. 6? Assume that no heat is applied for an infinitely long period before and after this input.

Solution: Since peak temperatures will occur at the end of individual heat input pulses, we need only check the temperature at points t_1, t_3, and t_5.

$$T_{t_1}=P_0 r_{t_1}=60 \text{ watts}\times 2.19 \text{ C/watt}=131 \text{ C} \tag{8}$$

$$\begin{aligned} T_{t_3}&=P_0 r_{t_3}-P_0 r_{(t_3-t_1)}+P_2 r_{(t_3-t_2)}\\ &=60\times 2.65-60\times 2.49+50\times 2.19\\ &=159-149+110=120 \text{ C} \end{aligned} \tag{9}$$

$$\begin{aligned} T_{t_5}&=P_0 r_{t_5}-P_0 r_{(t_5-t_1)}+P_2 r_{(t_5-t_2)}-\\ &\qquad P_2 r_{(t_5-t_3)}+P_4 r_{(t_5-t_4)}\\ &=60\times 3.05-60\times 2.9+50\times 2.65-\\ &\qquad 50\times 2.49+40\times 2.19\\ &=183-174+133-124+88=106 \text{ C} \end{aligned} \tag{10}$$

It is evident that the highest temperature rise occurs at the end of the first pulse in this example. The actual junction temperature can be calculated by adding this rise to the ambient temperature. For instance, in a 50 C ambient, the junction would have momentarily reached 131+50=181 C.

Response to Equal-Amplitude Pulses

If the amplitude of the heating pulses remains the same, the previous approach can be simplified. Thus in equation 7, if $P_0=P_2$, it can be factored out as:

$$T_{t_4}=P_0(r_{t_4}-r_{(t_4-t_1)}+r_{(t_4-t_2)}-r_{(t_4-t_3)}) \tag{11}$$

This equation can also be solved for the heating power:

$$P_0=\frac{T_{t_4}}{r_{t_4}-r_{(t_4-t_1)}+r_{(t_4-t_2)}-r_{(t_4-t_3)}} \tag{12}$$

Equations 11 and 12 can be extended indefinitely for any number of pulses.

Example

Problem: If the semiconductor whose r_T curve is shown in Fig. 3 (4- by 4-inch fin) is subjected to a continuous sequence of pulses of 50-sec duration occurring every 200 sec, what maximum pulse amplitude can the device handle without exceeding a 200 C junction temperature if the ambient is 40 C?

Solution: The peak temperature rise allowable is 200 C−40 C=160 C. This is the numerator in equation 12. One can find P_0 if the denominator of this equation is available. Minimum P_0 will occur when the denominator is at a maximum. By numerical means, the series composing the denominator can be carried out to the point where it no longer increases in its total value. This will occur at approximately 1,000 sec where steady-state thermal resistance R_T is reached. At this point, the cooling terms will be equal to, and will cancel out, additional heating terms.

The following numerical solution for the denominator of equation 12 starts from the last terms and works up to the initial terms, for convenience in tabulating and solving:

Transient Thermal Resistance	C/Watt
Heating Terms	
r_{50}	+ 2.77
r_{250}	+ 4.36
r_{450}	+ 4.85
r_{650}	+ 5.04
r_{850}	+ 5.09
$r_{1,050}$	+ 5.10
Total	+27.21
Cooling Terms	
r_{200}	− 4.15
r_{400}	− 4.75
r_{600}	− 5.01
r_{800}	− 5.08
$r_{1,000}$	− 5.095
Total	−24.085

Continuing from the tabulation:

Total effective thermal resistance= +27.21 −24.085=3.125 C/watt.

From equation 12, maximum P_0=160 C/(3.125 C/watt)=51.2 watts.

Steady-State Solution: For trains of power pulses in which the period of a pulse is much shorter than the time for r_T to stabilize at R_T, the foregoing method

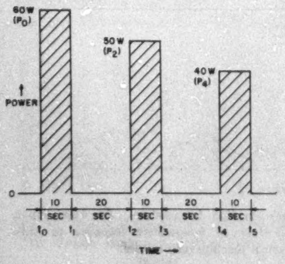

Fig. 6 (left). Heat input for example of response to repeated pulses

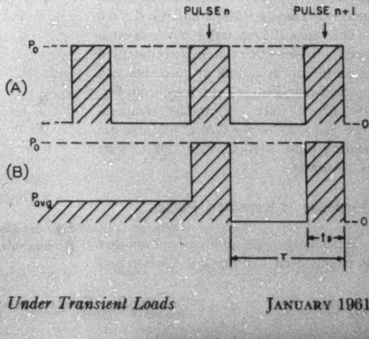

Fig. 7 (right). Heat input for steady-state pulse conditions. A—Actual. B—Assumed

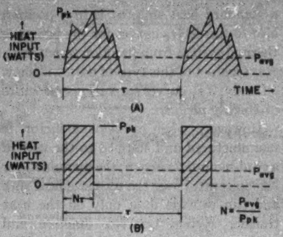

Fig. 8. Approximating an irregularly shaped power pulse by a rectangular wavesoape. A—Actual heat input. B—Equivalent heat input

of calculation may become too laborious, requiring hundreds or even thousands of calculations. In such cases an alternative approach can be used to obtain a solution with a minimum of calculation.

Assume that it is desired to determine the maximum junction temperature of a rectifier under steady-state conditions with repetitive power pulses as shown in Fig. 7(A). The pulses have constant amplitude P_0, constant width t_P, and constant period τ. Consider a pulse n which occurs after steady-state conditions have been reached. Replace the pulses prior to n by a continuous level of power equal to the average pulse power P_{avg}.

$$P_{avg}=\frac{t_P P_0}{\tau} \tag{13}$$

This condition is shown in Fig. 7(B). The maximum junction temperature rise, T_{max}, at the end of the $n+1$ pulse can then be calculated by the methods given previously:

$$T_{max}=\left[\frac{t_P R_T}{\tau}+\left(1-\frac{t_P}{\tau}\right)\times r_{(\tau+t_P)}-r_{(\tau)}+r_{(t_P)}\right]P_0 \tag{14}$$

which may also be solved for P_0:

$$P_0=\frac{T_{max}}{\frac{t_P R_T}{\tau}+\left(1-\frac{t_P}{\tau}\right)r_{(\tau+t_P)}-r_{(\tau)}+r_{(t_P)}} \tag{15}$$

The junction temperature at the beginning of the nth pulse is higher for the conditions of Fig. 7(B) than for those of Fig. 7(A). Thus the preceding calculation gives a worst-case calculation for the junction temperature. The calculation can be carried out for successive pulses beyond the $n+1$ pulse giving lower and more accurate values for T_{max}. However, the equation given for the $n+1$ pulse is usually accurate within 3%, which is sufficient for most practical applications.

Example

Problem: Calculate the maximum pulse amplitude for conditions the same as given in the previous problem.

Solution: For this problem $\tau=200$ sec, $t_P=50$ sec, ambient temperature $=40$ C, $T_{max}=200-40=160$ C. From equation 15 and Fig. 3

$$P_0=\frac{160}{\frac{(50)(5.1)}{200}+\left(1-\frac{50}{200}\right)4.36-4.15+2.78}=50.5 \text{ watts}$$

This compares with 51.2 watts obtained by the iterative solution and indicates that the solution is conservative and reasonably accurate.

Overload Following Continuous Duty

Another variation of the superposition approach can be used for overload calculations on semiconductors. A common case is that in which an overload is applied immediately following a steady-state load at less than the maximum rating of a semiconductor. The variation of junction temperature with time is defined by

$$T_J-T_A=P_{CD}R_T+(P_{OL}-P_{CD})r_T \tag{16}$$

where

T_J = junction temperature, C
T_A = ambient temperature, C
P_{CD} = continuous duty heating in semiconductor, watts
P_{OL} = heating on semiconductor during overload period, watts
r_T is at a given time after application of overload, C/watt

Example

Problem: Assume that the semiconductor device for which thermal resistance characteristics are shown in Fig. 3 (4- by 4-inch fin) operates continuously with 10-watt losses in a 55 C ambient. What is the maximum load that can be suddenly applied for 1 minute without exceeding a junction temperature of 200 C?

Solution: Solving equation 16 for P_{OL} gives

$$P_{OL}=\frac{T_J-T_A-P_{CD}R_T}{r_T}+P_{CD}$$

and substituting the values given above, and extracted from Fig. 3, gives

$$P_{OL}=\frac{200-55-10\times5.1}{29}+10=42.4 \text{ watts}$$

With the use of the published specifications for this particular device, this value of power dissipation can be translated into terms of current.

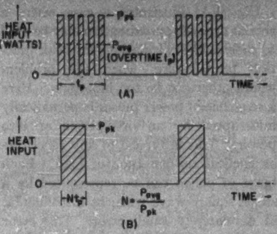

Fig. 9. Approximating a short train of power pulses with a single rectangular waveshape. A—Actual heat input. B—Equivalent heat input

Treatment of Irregularly Shaped Power Pulses

Approximation Method

The discussions thus far have assumed in every case that the input heat or power applied to the semiconductor junction was a step function, and that when power was plotted against a time base, a rectangular-shaped wave resulted. In most practical applications, the power pulse is not of this ideal shape for computation, and appropriate approximations must be made to convert the actual waveshape into a rectangular form if the subsequent calculations are to be made as outlined.

Fig. 8(A) illustrates the arbitrary waveshape of a power pulse that reoccurs at a period of τ sec and has a peak value of P_{pk} watts and a full-cycle average of P_{avg} watts. For the purpose of calculating peak junction temperature this waveshape can be approximated by the rectangular waveshape of Fig. 8(B), which is selected to have the identical values of peak power P_{pk} and average power P_{avg} as Fig. 8(A) by altering the pulse duration by a constant N to maintain the peak to average relationship. N is defined as the ratio of P_{avg} to P_{pk}.

This translation into rectangular pulses of power ensures a worst-case approximation since a rectangular pulse of power will always have an effect on temperature equal to or greater than the effect of any other pulse having the same peak and average power. In other words, a rectangular power pulse will raise the junction temperature higher than any other waveshape with the same peak and average values since it concentrates its heating effects into a shorter period of time, thus minimizing thermal losses during the pulse.

Fig. 9(A) illustrates a case where a similar type of approximation may be used to shorten the calculations for peak junction temperature, when the problem would otherwise be too laborious. Here a sequence of power pulses is periodically interrupted by an OFF period of zero power. This is typical of any repetitive or cyclical ON-OFF type of load. Each burst of pulses can be represented by a single square wave with the introduction of a relatively small error. This error will always yield a junction temperature higher than actual, and will thus provide a conservative application. In the equivalent waveshape shown in Fig. 9(B), the peak value of power P_{pk} is maintained as in Fig. 9(A). The duration of the equivalent rectangular waveshape is reduced to Nt_p where N is defined as P_{avg}/P_{pk}.

Example

The following is an example of conversion to rectangular wave power pulse.

Problem: Half-wave sinusoidal current flows through a high-current rectifier at 60 cycles per second. The full-cycle average value of this current is 50 amp (amperes). Approximate the heating effect of a sequence of four pulses of current by a single rectangular wave of power.

Solution:

$I_{pk}=\pi I_{avg}=50\pi=157$ amp
$V_{pk}=1.2$ volts at 157 amp from published specifications on the device
$P_{pk}=I_{pk}\times V_{pk}=157\times 1.2=190$ watts

Full-cycle average $P=50$ watts at 50 amp average current from published specifications on the device.

P_{avg} over 3.5 cycles (actual duration of heating) $=50$ watts$\times 4/3.5=57$ watts
$N=P_{avg}/P_{pk}=57/190=0.30$
$t=3.5$ cycles$\times 1/60$ cps$=0.0585$ sec
$Nt=0.3\times 0.0585=0.0175$ sec

Thus, the heating effect of the current can be approximated by a single rectangular pulse of power with an amplitude of 190 watts and a duration of 0.0175 sec.

Again, this is a conservative approximation. For the r_T characteristic in Fig. 3, the temperature rise due to the single pulse approximation is 85 C. With the more exact solution discussed in the section "Response to Equal-Amplitude Pulses," the temperature rise is calculated to be 82 C, indicating an error of less than 5%.

EXACT METHOD

Use of the superposition integral permits the exact calculation of the junction temperature as a function of time $T_J(t)$, provided that an analytical expression is available for both the r_T as a function of time, $r_T(t)$, and the applied power as a function of time, $P(t)$. The superposition integral may be used in either of two forms:

$$T_J(t)=P(0)r_T(t)+\int_0^t r_T(t-\tau)\frac{dP(\tau)}{d\tau}\,d\tau \tag{17}$$

$$T_J(t)=r_T(0)P(t)+\int_0^t P(t-\tau)\frac{dr_T(\tau)}{d\tau}\,d\tau \tag{18}$$

where $P(0)$ is the applied power at $t=0$, $r_T(0)$ is the r_T at $t=0$, and τ is the variable of integration.

It is found that an accurate analytical expression for the *C35* silicon controlled rectifier, shown in Fig. 3, is given by

$$r_T(t)=\frac{1+80t}{5+40t}$$

The chief disadvantage of the superposition integral is that only a limited number of waveforms can be expressed in terms of functions which can be integrated in equations 17 or 18.

Example

Problem: Assume that the power dissipation in a *C35* silicon controlled rectifier is given by

$P(t)=1{,}000t;\ 0\leq t\leq 0.1$ sec

$P(t)=0;\ t\leq 0,\ t>0.1$ sec

Determine the variation of junction temperature as a function of time and the value of the junction temperature at $t=0.1$ sec

Solution: Using equation 17 yields

$$T_J(t)=1{,}000\int_0^t\left(\frac{1+80t-80\tau}{5+40t-40\tau}\right)d\tau$$

Integrating yields

$$T_J(t)=1{,}000\left[2t-\frac{9}{40}\ln\,(1+8t)\right]$$

$T_J(0.1)=67$ C

This compares with 71.5 C obtained by approximating the actual power pulse with a rectangular power pulse.

Heat-Sink Design and Transient Thermal Resistance Curve

Since the heat sink is a major component in the heat transfer path between junction and ambient, its design substantially affects the r_T curve of Fig. 3. When the semiconductor manufacturer provides a device already mounted on a standard heat sink, he is in a position also to furnish r_T curves for the complete thermal system from junction to ambient. A typical set of this type of data will show a family of r_T curves for various velocities of cooling air.

However, when a semiconductor is manufactured and shipped to the user in a stud-mounted version, the manufacturer has no control over the ultimate heat sink and can provide data only on the heat transfer system between junction and stud, the part he manufactured. Fig. 3 shows these data as the curve identified as "cell mounted on infinite heat sink."

The equipment designer can use this curve in developing an r_T curve for the cell when mounted to a particular heat sink of his own design by means of a few simple calculations. The calculations assume the temperature throughout the heat sink as uniform even under transient loading, thus permitting the heat sink to be represented by a single time constant. This is a good assumption for fins of relatively thick cross section and fin effectiveness close to unity. This approach also assumes that the thermal capacitance of the heat sink is large compared to the thermal capacitance of the cell. By adding the calculated (or measured) r_T of the fin of the infinite heat sink curve for the cell, the applicable curve can be plotted for the complete thermal system. The method is best explained by an example illustrating how a specific heat sink design shown as the second curve in Fig. 3 (4- by 4-inch fin) can be calculated.

Example

Problem: A cell is mounted on a painted copper fin 1/16 inch thick and having 4 inches on a side. The fin is subjected to free convection air conditions. Find the r_T curve for a device mounted on this fin if the infinite heat sink curve in Fig. 3 represents the thermal characteristics of the stud-mounted semiconductor. Assume that the stud-to-fin contact resistance is negligible.

Solution: From fin design curves[8]

$h_r=0.005$ watt/inch^2 C

$h_c=0.005$ watt/inch^2 C

$h_{total}=h_r+h_c=0.010$ watt/inch^2 C

Fin thermal conductance $k=h\times A=0.01\times 4\times 4$ inches$^2\times 2$ sides$=0.32$ watt/C

Fin thermal resistance $R_F=1/k=1/0.32=3.1$ C/watt

Fin thermal capacity C
$=c\rho V=175$ watt-sec/lb C$\times 0.32$ lb/inch$^3\times 4$ inches$\times 4$ inches$\times 1/16$ inch
$=56$ watt-sec/C

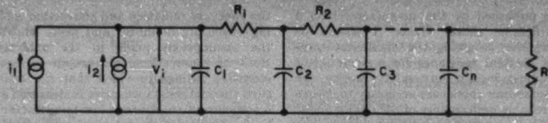

Fig. 10. Electrical analog for rectifier equivalent thermal circuit

Thermal R-C time constant $=3.1$ C/watt × (56 watt-sec)/C $=174$ sec

Equation of transient fin thermal resistance r_F

$$r_F=R_F(1-e^{-t/RC})=3.1(1-e^{-t/174})$$

The values of r_F are added to the infinite heat sink curve to secure the overall r_T of the system, as indicated in Fig. 3. Note that this fin has negligible resistance at periods of time one second or less after the application of power. In this area, it behaves as would an infinite heat sink which has no resistive element. The fin and the entire thermal system reach equilibrium at around 1,000 sec. Thereafter, the thermal capacity is no longer effective in holding down the junction temperature.

Appendix

The relationship between the heating curve and cooling curve can be derived for the electrical analog of the rectifier thermal equivalent circuit shown in Fig. 10. If the current generator i_1 produces a positive current step I, the input voltage v_i will be given as a function of time by $v_i=f(t)$. The limiting value of $f(t)$ for large values of t will be

$$\lim_{t\to\infty} v_i=\lim_{t\to\infty} f(t)=IR$$

(positive current step from i_1), where

$$R=\sum_{j=1}^{n} R_j$$

Similarly, if the current generator i_2 produces a negative current step $-I$, the input voltage v_i will be $v_i=-f(t)$, provided that the circuit elements are symmetrical. The limiting value of v_i for large values of t will be

$$\lim_{t\to\infty} v_i=-\lim_{t\to\infty} f(t)=-IR$$

(negative current step from i_2)

If the positive current step from i_1 is applied and the circuit is allowed to reach steady-state conditions, the superposition theorem indicates that a negative current step from i_2 will produce a variation in the input voltage given by

$$v_i=IR-f(t)$$

where the net input current (i_1+i_2) is zero and the limiting value of v_i for large values of t is zero. Use of the superposition theorem requires the circuit elements to be linear.

The preceding treatment applies to the thermal circuit as well as the electric circuit since they are analogs of each other. Current in the electric circuit is the analog of power in the thermal circuit; voltage in the electric circuit is the analog of temperature rise in the thermal circuit; and resistance and capacitance in electric circuit are analogs of thermal resistance and thermal capacitance in the thermal circuit.

Therefore the heating curve T_h and the cooling curve T_c of a rectifier are related by

$$T_c=PR_T-T_h$$

provided that the thermal equivalent circuit for the rectifier is linear.

The principal deviation from the ideal linear thermal characteristics would be caused by radiation effects which are proportional to the fourth power of the absolute temperature. However, tests on actual rectifiers have indicated a high degree of correspondence between the heating and cooling curves indicating that for most practical purposes radiation effects may be neglected.

Discussion

E. J. Diebold and Werner Luft (International Rectifier Corporation, El Segundo, Calif.): Anyone who has struggled with this subject, to reconcile theory and experiment, must realize that there is no simple solution. The introduction of two novel and valuable principles by the authors of this paper is greatly appreciated. The concept of transient thermal resistance or impedance is not new: however, the expansion into a concept of a more general nature, to be manipulated similarly as a particular solution of a differential equation is very original, as is also the application of the superposition principle of mathematical solution to this more practical problem.

The method outlined seems to be of general validity. Mathematical proof should be given that the transient thermal resistance curve obtained from pulse load tests can be manipulated like a partial solution of a differential equation, and that the superposition principle applies for this solution.

To be acceptable as a true transient thermal resistance curve, the measured curve should exclude side effects which substantially change the shape of the curve. This separation may be difficult because the properties of materials change substantially as the heat pulses decrease in length and increase in magnitude. The ever present problem of measuring an instantaneous temperature rise becomes almost insurmountable for very short pulses. As long as the transient thermal resistance concept is used for simple 1-pulse investigations only, these inaccuracies are of no consequence. If, however, the curve is manipulated as a mathematical solution, the results obtained by this method may be entirely in the realm of numerical differences which are substantially less than the errors of tolerance of the measured magnitudes.

For each device and for each application of the method, the limits of validity of the curves and the probable error for each part of the curve must be stated. If the curves are drawn as bands (a method which is commonly used for electronic tubes), the temptation of reaching unwarranted conclusions is greatly reduced.

Interpretation of measured curves similar to the method described by this discusser[1] can give an indication of the trend of the curves. It may be necessary to implement the measured curves with such theoretical considerations to obtain a representative theoretical curve which can be manipulated as a mathematical solution and which yields results corresponding to subsequent experimental values.

REFERENCE

1. TEMPERATURE RISE OF SOLID JUNCTIONS UNDER PULSE LOAD, E. J. Diebold. *AIEE Transactions*, pt. I (*Communication and Electronics*), vol. 76, Nov. 1957, pp. 593–98.

F. W. Gutzwiller and T. P. Sylvan: In view of the discussion it should be re-emphasized that the entire approach discussed in this paper is based on actual measurements of junction temperature response to pulse loads. The thermal networks in Fig. 1 were included for the purpose of illustration and for explaining the basic assumptions on which the subsequent development is based. The validity of the presentation does not depend on a thermal analysis of the physical construction and materials in the semiconductor, or on the equivalent thermal network, beyond establishment that the thermal circuit is linear and bilateral, and that the heat source exists at only one plane inside the semiconductor. Under these assumptions, the use of superposition is valid.

As the discussers mention, difficulties do arise in actually measuring junction temperature response to very short load pulses due to instrumentation limitations. Colleagues of the authors have developed techniques that have acceptable accuracy for measuring the junction temperature within 200 microseconds after the end of the applied power pulse. With this measurement technique it is feasible to publish transient thermal resistance curves for pulse durations down to one millisecond, as shown in Fig. 3.

It should be emphasized that the major purpose of the analytical approach presented in this paper is to permit a convenient derivation of the practical ratings of power semiconductors applied under transient conditions. Hence, errors resulting from simplifying assumptions are not a serious limitation as long as they are on the conservative side. Some of the factors which must be considered in the evaluation of this method of analysis include:

1. In any case where a lumped, linear thermal equivalent circuit is used as the basis of analysis, the method of analysis given in the paper can also be applied if the conditions of validity are the same in both cases.

2. The transient thermal resistance curve should be considered as a rating curve when it is published by the manufacturer on a specification sheet. Hence it should be interpreted as giving the maximum transient thermal resistance for a given device and must include any safety factors the manufacturer thinks are necessary to ensure the reliable performance of the device under maximum heating conditions. It is not feasible to show a band for the thermal resistance curve, as this would require the manufacturer to test and reject for the minimum thermal resistance, which would serve no practical purpose.

3. Many of the deviations of the physical device from the ideal mathematical model result in a conservative rating. For example, as the peak current through a silicon-controlled rectifier or a diode rectifier cell is increased, a larger fraction of the power will be dissipated in the bulk material, contacts, and leads, since this power is proportional to the square of the current, whereas the power dissipated at the junction is approximately proportional to the first power of the current. This, however, results in a conservative rating provided that the transient thermal resistance curve is measured at a lower current level. Another example is the effects of radiation and convection cooling which are nonlinear and hence violate the assumptions made in the analysis. Both of these effects also result in conservative ratings provided that the transient thermal resistance curve is measured at a low-current (and hence low-temperature) level. The variation of thermal conducitvity of the various materials in the device at higher temperatures is negligible for rating purposes in the temperature range at which semiconductors are used.

4. One of the most serious limitations of any method of rating semiconductor devices under transient conditions is a consequence of the inherent electrical characteristics of the device. For example, localized imperfections and irregularities in the junction can cause localized heating which becomes more severe under high-current conditions and can result in a failure even though the transient rating of the gross device is not exceeded. A practical solution to this type of problem is for the manufacturer to run a portion of his quality control life tests under conditions corresponding to the minimum time given on the transient thermal resistance curve.

A Comparison of Digital Differential Analyzer and General Purpose Equipment in Guidance Systems

M. M. DICKINSON
NONMEMBER AIEE

QUALITATIVE comparisons are often made between a digital differential analyzer (DDA) and a general purpose (GP) computer for real-time control applications. Such comparisons consider static and dynamic accuracy, flexibility, equipment complexity, solution stability, influence of random errors, and ability to cope with discontinuities. They do not clearly point to a machine for solution of a problem since the DDA is found preferable in some characteristics while the GP excels in others. This ground is not to be covered.

This paper serves to record the physical characteristics of contemporary DDA and GP equipments actually designed for solution of a particular missile control problem. Qualitative comparison is made of the equipment programing difficulty and flexibility. For the problem considered the two equipments are seen to be competitive in most respects.

The Problem

One can think of the DDA as an outgrowth of an analog computer with two significant advances: first, the dependent variable is not limited to being time; second, the data are represented and processed discretely to permit greater precision. In the same sense the GP can be considered as an outgrowth of a desk calculator with advances resultant from its stored program and logical capability.

One might logically consider the application of a DDA in the missile guidance problem by formulating the differential equations describing the missile motion in an inverse square gravitational field and programing an analog of these equations on the machine. It should be expected that the DDA would yield an efficient solution to this problem although a moderately large machine (say, one of 100 integrators) would be required to permit consideration of all meaningful physical perturbations.

One might anticipate that the missile guidance problem had been dealt with by numerical analysts. Their work leads to a solution of the guidance problem through the use of polynomial equations in which variables are multiplied by constant coefficients and summed to derive guidance commands. Indeed the coefficients are derived from consideration of the physics of the situation, but the air-borne computing problem now manifests itself in multiplication and additive arithmetic processes. Machine solution can again be instrumented with the DDA, and although the process is less direct, a simpler instrumentation should be expected. Alternatively, it is now reasonable to consider instrumentation in machinery directly capable of multiplication and addition. The GP instrumentation which is suggested turns out to be competitive, as will be shown.

These comments suggest two generalizations: First, the control problem, although it may be analyzed through a mathematical analog of the physical situation, will commonly be manifested by polynomial equations with piecewise constant coefficients in the real-time control situation. Second, the effectiveness with which DDA and GP instru-

Table I. Comparison of Physical Characteristics

	DDA	GP
Weight, lb	35	30
Volume, cubic ft	0.6	0.8
No. of components	3,840	3,989
Power, watts	60	78

mentation can be applied to a problem is critically dependent upon the mathematical details in which the problem is represented. Two computer users, each applying a control computer to a problem of a common class, could easily prefer a DDA on the one hand and a GP on the other, as a result of a slightly different approach in stating the problem. Where the user formulates the problem in terms of differential equations, the DDA is attractive; where he formulates in terms of polynomial expansions, the GP becomes more attractive.

The problem considered is the air-borne real-time control computation for a digital inertial missile guidance system. The calculations are piecewise continuous, and they involve the solution of polynomial equations. The computer input is vehicle acceleration expressed in an inertial orthogonal co-ordinate system. Vehicle acceleration is integrated and compared with required velocity to establish a velocity error. The velocity error is then used to generate missile steering signals and engine cutoff command as the computer output.

Computer Characteristics

The DDA selected is a high-frequency delay line machine and contains 30 processors which operate in a serial binary fashion at a rate of 1,500 iterations/sec (per second). The machine is constructed of 1-megacycle transistor circuits and memory is realized through the application of magnetostrictive delay lines.

The general-purpose computer is a serial machine using modular arithmetic element organization and floated-head magnetic drum storage. Separate multiply and add-subtract elements permit simultaneous instrumentation of 543 multiplication and 6,400 addition operations/sec. The machine is realized through the use of 200-kc transistor circuits and a magnetic drum memory. It has a 2,000-word serial binary storage.

Both machines have been found comparable in problem solution; both satisfy users' performance specifications. Preliminary machine organization, circuit design, and computer application studies have been effected in the consideration of the two machine types. More recently, similar machines have been realized in hardware.

The DDA iteration rate of 1,500 iterations/sec is not equalled by the GP solution rate of approximately 20 solutions/sec. The DDA rate is established by the maximum ratio of the time rate of change of problem variables to the corresponding variable resolution. For example, a 30,000-ft/sec (foot/sec) velocity range and 20-ft resolution requirement demand (30,000 ft/sec)/(20 ft/increment), or 1,500 increments/sec.

The GP rate is normally established by the bandwidth characteristics of the guidance system-missile dynamic control loop; that is, a control loop with a 5-cps (cycle/sec) bandwidth is found to behave satisfactorily when controlled by command signals generated at a rate of 20 times/sec.

For a control system with a 10-cps bandwidth, the GP would require twice the capacity, while the DDA would not necessarily be changed. Hence, those situations in which dynamics are critical have been popularly connected with DDA instrumentation.

Cost

The physical characteristics of the DDA and GP equipment are summarized in Table I, which includes cost factors most meaningful in equipment selection for air-borne application. Dollar cost should be proportional to component count. The relative value of the numbers tabulated points to no significant difference between the systems.

It should be recognized that the serial GP instrumentation which has been characterized in Table I is not conventional in its functional organization. It need not be for the class of control problems of which the missile guidance problem is characteristic. To realize an equipment competitive in cost with the DDA, and consistent with the problem requirements, the machine has no direct division capability. Programing is on a relative address basis requiring that the location of all data be carefully considered in the development of the program. As in the DDA, inputs are received on an incremental basis, accumulated external to the fixed program section of the machine, and the overflows of these accumulators are treated in the arithmetic element. It is under the constraints suggested by these characteristics that the following comments on relative programing difficulty and flexibility apply.

Programing of the DDA equipment involves scaling and designation of *dy* and *dx* inputs to each of the 30 processors contained in the machine. No significant restrictions are imposed on the interconnection of the processors in the machine organization selected. In the case of the GP equipment, programing involves the preparation of a 1,500-word 2-address program and the location of constants and intermediate data on the magnetic drum in such fashion as to permit utilization of the machine arithmetic element. The machine employs fixed-point arithmetic, and accordingly the programer must scale all data involved in the calculation. The ratio of programing difficulty based on limited observation of programing work would indicate that the effort involved in GP programing is four times greater than that involved in DDA programing. Similarly, programing modifications are more readily effected on the DDA equipment than on the GP, since changes in the GP program may require reoptimization of the location of significant portions of the program and intermediate storage.

Both digital differential analyzers and general-purpose machines offer the advantage of considerable flexibility over analog computers, since their programs and interconnections may be changed to satisfy the requirements of various problems. The machines may also be called upon to execute operations other than arithmetic, such as terminal equipment control and logical decisions based upon input parameters. Even in digital differential analyzers, decision and servo elements have been developed which extend their usefulness in this regard. DDA's are limited, however, in their capabilities to perform such functions as table look-up operations and certain logical choices and, indeed, some of these operations may be impossible.

It should be understood that the GP computer, with its broader logical and arithmetic capabilities, is more flexible than the DDA in executing secondary systems assignments. Where secondary assignments can be considered significant, then the GP solution is attractive. For example, in addition to the calculations involved in missile inertial guidance, the computer can be used for system ground checkout, platform calibration, and platform erection with nominal increase in machine memory. It is found that the same equipment can be time-shared between principal and secondary applications.

Selection

As stated, for the problem considered the two equipments are seen to be broadly competitive. Minor modifications in either the problem definition by the user or the computer technologies could easily reverse any decision made by consideration of any single cost factor or combination of cost factors suggested. In control applications where competitive physical designs can be identified, the GP has been considered preferable because of its greater flexibility. Programing difficulties are of minor importance unless a great number of modifications are anticipated.

Experience in the use of analog, DDA, and GP technologies in guidance systems has shown that there is no single optimum technology to be selected from the three basic alternatives. Some significant work has been done in the past 5 years in integrating these technologies in such fashion as to employ the best characteristics of each approach. Indeed, some of the results of this work are illustrated in the GP equipment discussed here. Further work must be effected in the integration of these technologies in order to advance the guidance system and control computer organization.

Hybrid computing equipments employing analog, DDA, and GP elements should be anticipated with increasing efficiency over the next 5 years. This trend will come to eliminate much of the question of choice between GP and DDA control system instrumentation, and result in a set of control computers for efficient application to the diverse control systems problems.

Error-Correcting Codes for Correcting Bursts of Errors

J. E. MEGGITT
NONMEMBER AIEE

IN DATA transmission systems that are subject to noise, it is found that errors do not occur randomly but in bursts. Consequently, much interest has centered lately on the problem of constructing suitable error-correcting codes.

In most of the codes described so far, difficulties have occurred with their implementation because different courses of action, depending on the nature of error burst that is detected, have to be followed by their decoders. This has made them expensive in equipment. The main purpose of the present paper is to show how some of these codes may be transformed to make their implementations simple.

Feedback Linear Sequential Systems

Feedback linear sequential systems whose feedback logic contains only modulo 2 adders may be conveniently described by modulo 2 matrix arithmetic. If such a system contains k elements, its state at any time may be described by a k-by-1 vector $\mathbf{x}$ whose elements are zero or one. The state at the next time is described by the vector:

$$\mathbf{Tx} \qquad (1)$$

where $\mathbf{T}$ is a k-by-k matrix all of whose elements are zero or one and the matrix multiplication is performed using modulo 2 arithmetic.

The behavior of such systems is determined, except in special circumstances, by the characteristic equation of degree k, that $\mathbf{T}$ satisfies.

$$F(\mathbf{T})=0 \qquad (2)$$

By a suitable choice of $F(\mathbf{T})$ it is possible to make the system go sequentially through 2^k-1 different states. This just means that the vectors $\mathbf{T}^r\mathbf{x}$ take all possible values for different r, except 0.

Such a characteristic equation will be described here by:

$$M(k\mathbf{T})=0 \qquad (3)$$

An excellent discussion of these ideas is provided in reference 1.

The same ideas, it transpires, are very useful in coding theory and the object of this paper is to explain their relevance.

Application to Codes

In the class of codes to be considered, data are transmitted in message blocks of n binary digits. In each block there are k check digits and n-k information digits. As each message is received, error correction is carried out.

If the digits in the message are a_1, a_1, $\ldots$ a_n, then the class of codes to be considered is defined by the equation:

$$a_1\mathbf{x}+a_2\mathbf{Tx}+a_3\mathbf{T}^2\mathbf{x}+\ldots+a_n\mathbf{T}^{n-1}\mathbf{x}=0 \qquad (4)$$

where $\mathbf{T}$ is a k-by-k matrix such as has been described, $\mathbf{x}$ is a k-by-1 vector and n is the lowest value of r for which

$$\mathbf{T}^r\mathbf{x}=\mathbf{x} \qquad (5)$$

These k equations 4 define k of the a's in terms of the other n-k. Thus only n-k digits are independent and these are taken to be the information digits in the message. The other k dependent digits are taken to be the check ones.

If the received message is a_1', a_2' $\ldots$ a_n', where the a's are the received and possibly incorrect digits, then it is possible to calculate:

$$a_1'\mathbf{x}+a_2'\mathbf{Tx}+\ldots+a_n'\mathbf{T}^{n-1}\mathbf{x}=\mathbf{z} \qquad (6)$$

This code is clearly capable of correcting any set of errors that produce different vectors $\mathbf{z}^2$, and the object of code design is to choose a $\mathbf{T}$ that ensures that the class of errors to be corrected does, in fact, produce different vectors $\mathbf{z}$.

When a matrix $\mathbf{T}$ has been chosen, equation 4 does not give the only set of coding equations that corrects the desired errors. It is possible to replace $\mathbf{T}$ in equation 4 by

$$\mathbf{U}=\mathbf{STS}^{-1} \qquad (7)$$

and $\mathbf{x}$ by $y=\mathbf{S}\mathbf{x}$, where $\mathbf{S}$ is a nonsingular matrix.

When this is done, the coding equations are transformed, but clearly the errors that such a code corrects are invariant under the transformation. The characteristic equation that $\mathbf{T}$ satisfies is also preserved under this transformation, and exactly as a linear sequential system is, in general, described by a characteristic equation,[1] so the code is determined in general by the characteristic equation that $\mathbf{T}$ satisfies.

Thus, when once a code is designed by the choice of a $\mathbf{T}$, it is possible to transform it into another form and convenient to transform it into such a form that is

196

easily implemented. It is the object of this paper to describe how this is done.

Examples of Codes Determined by Characteristic Equations

EXAMPLE 1

If **T** is chosen to satisfy

$$M(k\mathbf{T})=0 \tag{8}$$

then the codes defined by equation 4 are such that single-error correction is possible, and by definition $n=2^k-1$. This is seen at once because a mistake in a_r leads from equation 6 to

$$\mathbf{z}=\mathbf{T}^{r-1}\mathbf{x} \tag{9}$$

By definition all the vectors $\mathbf{T}^{r-1}\mathbf{x}$ are different for different r. This set of codes was first noted by Abramson.[3]

As an example, it is possible to take

$$M(3\mathbf{T})\equiv\mathbf{T}^3+\mathbf{T}+1 \tag{10}$$

This gives a single-error correcting code of message length 7 with three check digits. It is then equivalent to one of the simple Hamming codes.

EXAMPLE 2

The above single-error correcting codes may be extended by adding a total parity-check equation. They are then capable of performing single and double adjacent error correction. For single errors, the code works as above. If, however, there is a double adjacent error in the rth and $(r+1)$th digits, this fact is indicated by the parity equation while the other equations lead to:

$$\begin{aligned}\mathbf{z}&=\mathbf{T}^{r-1}(1+\mathbf{T})\mathbf{x}\\&=\mathbf{T}^{r-1}\mathbf{x}^*\end{aligned} \tag{11}$$

Again, since by definition all the vectors $\mathbf{T}^{r-1}\mathbf{x}^*$ are different for different r, the value of r may be determined.

The extended code is still of the form of equation 4, but the new **T**, $\mathbf{T}^*$ say, is the $k+1$-by-$k+1$ matrix.

$$\mathbf{T}^*=\left[\begin{array}{c|c}\mathbf{T}&0\\\hline 0&1\end{array}\right] \tag{12}$$

where **T** is the k-by-k matrix used in the single-error correcting case.

Since **T** satisfies $M(k\mathbf{T})=0$, $\mathbf{T}^*$ satisfies

$$(\mathbf{T}^*+1)M(k\mathbf{T}^*)=0 \tag{13}$$

This class of codes was also noted by Abramson.

EXAMPLE 3

Melas[4] conceived the idea of extending the described simple additional parity check to a more elaborate set of equations. In this case, the factor $(\mathbf{T}^*+1)$ in equation 13 is replaced by $M_1(k_1\mathbf{T}^*)$ where $2^{k_1}-1$ is a factor of 2^k-1, and so the characteristic equation becomes

$$M_1(k_1\mathbf{T}^*)M(k\mathbf{T}^*)=0 \tag{14}$$

Such a code is capable of correcting various types of burst error. As in the examples, equation 2, the first factor in equation 14 indicates the nature of the burst, while the other factor positions it.

A simple example of such a code is the code described by

$$(\mathbf{T}^{*2}+\mathbf{T}^*+1)(\mathbf{T}^{*4}+\mathbf{T}^{*3}+1)=0 \tag{15}$$

This code has message length 15, six digits being check ones and it is able to correct single, double, and triple adjacent errors, together with two errors separated by one correct digit.

EXAMPLE 4

Another group of codes, and one that has been described in an unpublished paper by Fire, arises by replacing the factor $\mathbf{T}^*+1$ in example 2 by $\mathbf{T}^{*k_1}+1$ where k_1 is prime to 2^k-1.

One form of such a code is:

$$a_1\begin{bmatrix}1\\0\\0\\.\\.\\.\\0\\-\\\mathbf{x}\end{bmatrix}+a_2\begin{bmatrix}0\\1\\0\\.\\.\\.\\0\\-\\\mathbf{T}\mathbf{x}\end{bmatrix}+\ldots+a_n\begin{bmatrix}0\\.\\.\\0\\0\\.\\1\\\hline\mathbf{T}^{n-1}\mathbf{x}\end{bmatrix}=0 \tag{16}$$

Once more the first k_1 equations define the nature of the burst while the second k position it. Such codes are quite powerful. For example, the characteristic equation

$$(\mathbf{T}^{*5}+1)(\mathbf{T}^{*5}+\mathbf{T}^{*2}+1)=0 \tag{17}$$

gives a code of message length 155, with ten check digits. It is able to correct all burst patterns, 1, 11, 101, 111, 1011, 1111.

EXAMPLE 5

Bose and Chaudhuri[5] have given possible forms for general multiple-error correcting codes. From their theory it is possible to prove that a code with the characteristic equation

$$M(k\mathbf{T})M(k\mathbf{T}^3)=0 \tag{18}$$

corrects all double errors. Thus, for example, the code described by

$$(\mathbf{T}^4+\mathbf{T}+1)(\mathbf{T}^4+\mathbf{T}^3+\mathbf{T}^2+\mathbf{T}+1)=0 \tag{19}$$

has fifteen digits, eight of which are check ones, and is capable of correcting all double errors. Such a code may still be considered as a burst correcting code, although there are a large number of different burst patterns to be corrected.

Transformations

It is, therefore, seen that many useful codes are specified in terms of their matrix characteristic equations and, as has been stated, these equations completely determine their properties. Hence, sets of many apparently different codes, all with the same properties, can be constructed by using different matrices **T**, as long as all of them satisfy the same characteristic equation. Thus many transformations of the codes given by Abramson, Melas, and others exist, some of which are easier to implement than those which have previously been described.

There exists, in fact, a general procedure for implementing any code whose characteristic equation is given, and this will now be described.

The general characteristic equation has the form

$$\mathbf{T}^k+C_{k-1}\mathbf{T}^{k-1}+C_{k-2}\mathbf{T}^{k-2}+\ldots+C_1\mathbf{T}+C_0=0 \tag{20}$$

where the C's are zero or one. A convenient matrix that satisfies this equation is the associated matrix

$$\mathbf{T}=\begin{bmatrix}C_{k-1}&C_{k-2}&C_{k-3}\ldots C_1&C_0\\1&0&0\ \ldots 0&0\\0&1&0\ \ldots 0&0\\0&0&1\ \ldots\ .&.\\.&.&.\ \ldots\ .&.\\.&.&.\ \ldots\ .&.\\.&.&.\ \ \ldots 1&0\end{bmatrix} \tag{21}$$

The vector **x** of equation 4 can be chosen arbitrarily provided it is such that

$$F(\mathbf{T})\mathbf{x}\neq 0 \tag{22}$$

for any polynomial F of degree less than k. This may be ensured by taking

$$\mathbf{x}=\begin{bmatrix}1\\0\\0\\.\\.\\.\\0\end{bmatrix} \tag{23}$$

as may easily be seen.

This form of **T** is chosen because if the vector

$$\mathbf{T}^r\mathbf{x}=\begin{bmatrix}p_0\\p_1\\p_2\\.\\.\\.\\p_{k-1}\end{bmatrix} \tag{24}$$

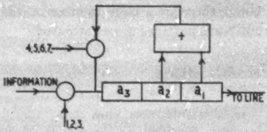

Fig. 1. Encoder

$$\mathbf{T}^{r+1}\mathbf{x}=\begin{bmatrix} C_{k-1}p_0+C_{n-2}p_1+\ldots+C_0p_{k-1} \\ p_0 \\ p_1 \\ \cdot \\ \cdot \\ \cdot \\ p_{k-2} \end{bmatrix} \tag{25}$$

Clearly, the operation of multiplying by **T** corresponds to a shift in a certain linear feedback shifting register.

Example 1

By using a matrix of the form 21, the Abramson code, equation 13 described by the equation

$$(\mathbf{T}+1)(\mathbf{T}^3+\mathbf{T}+1)=0 \tag{26}$$

which has seven message digits and which corrects single and double adjacent errors, has the form:

$$a_1\begin{bmatrix}1\\0\\0\\0\end{bmatrix}+a_2\begin{bmatrix}1\\1\\0\\0\end{bmatrix}+a_3\begin{bmatrix}0\\1\\1\\0\end{bmatrix}+a_4\begin{bmatrix}1\\0\\1\\1\end{bmatrix}+a_5\begin{bmatrix}0\\1\\0\\1\end{bmatrix}+a_6\begin{bmatrix}0\\0\\1\\0\end{bmatrix}+a_7\begin{bmatrix}0\\0\\0\\1\end{bmatrix}=0 \tag{27}$$

Explicitly, the coding equations are:

$$\begin{aligned} a_1+a_2+a_4&=0\\ a_2+a_3+a_5&=0\\ a_3+a_4+a_6&=0\\ a_4+a_5+a_7&=0 \end{aligned} \tag{28}$$

It is seen that each equation has the form of the previous one and this is important for the implementation to be described. This happens, of course, because the **T** used corresponds to a shift register. The same code as originally described by Abramson has the form

$$a_1\begin{bmatrix}1\\0\\0\\1\end{bmatrix}+a_2\begin{bmatrix}0\\1\\0\\1\end{bmatrix}+a_3\begin{bmatrix}1\\0\\1\\1\end{bmatrix}+a_4\begin{bmatrix}1\\1\\0\\1\end{bmatrix}+a_5\begin{bmatrix}1\\1\\1\\1\end{bmatrix}+a_6\begin{bmatrix}0\\1\\1\\1\end{bmatrix}+a_7\begin{bmatrix}0\\0\\1\\1\end{bmatrix}=0 \tag{29}$$

the last equation being the total parity check. The explicit coding equations here are obviously more complicated.

Example 2

The Melas code based on equation 15 produces the six coding equations:

$$\begin{aligned} &a_1+a_4+a_5+a_6+a_9+a_{10}=0\\ &a_2+a_5+a_6+a_7+a_{10}+a_{11}=0\\ &\cdot\\ &\cdot\\ &\cdot\\ &a_6+a_9+a_{10}+a_{11}+a_{14}+a_{15}=0 \end{aligned} \tag{30}$$

as may be verified.

Example 3

The Bose-Chaudhuri code based on equation 19 produces explicitly the eight coding equations:

$$\begin{aligned} &a_1+a_2+a_4+a_8=0\\ &a_2+a_3+a_5+a_9=0\\ &\cdot\\ &\cdot\\ &\cdot\\ &a_8+a_9+a_{11}+a_{15}=0 \end{aligned} \tag{31}$$

Implementation of Transformed Codes

For brevity, the encoding and decoding apparatus that is, in general, required will be described in detail only for the code 27. However, the method is absolutely general and the extensions will be shown.

When the message is transmitted, digits will be sent serially in order, starting with a_1. The last four digits (in general the last k) are chosen to be the check digits, and from equation 28 it is seen that they are defined by:

$$\begin{aligned} a_4&=a_1+a_2\\ a_5&=a_2+a_3\\ a_6&=a_3+a_4\\ a_7&=a_4+a_5 \end{aligned} \tag{32}$$

It is seen that each check digit is defined in terms of only the earlier digits, and this again is a consequence of using a **T** defined by equation 21.

Encoder

An encoder that imposed the conditions 27 is shown in Fig. 1. The squares indicate a shift register. Information flows into the register at times 1, 2, and 3 as shown by the timing pulses, while data are fed back at times 4, 5, 6, and 7 when the check digits are formed. The configuration is shown at time 4.

Extensions for codes 30, 31, and others are obvious. For 30, for example, the register is of length 9, and there are feedback connections from positions 1, 4, 5, 6, and 9.

Decoder

A decoder for the code 32 is shown in Fig. 2. The operation of the decoder is to store the received data in a shifting register of length 7, and to calculate the vector **z** of equation 6. The elements of **z** are defined by:

$$\begin{aligned} a_1+a_2+a_4&=z_1\\ a_2+a_3+a_5&=z_2\\ a_3+a_4+a_6&=z_3\\ a_4+a_5+a_7&=z_4 \end{aligned} \tag{33}$$

The z's are calculated in the same way that the check digits themselves are calculated, and they are calculated as the message is received and fed to a second shifting register. The decoder is shown at time 8, which is the same as time 1, times being measured from the arrival of the first digit in the message.

Henceforth, until time 4, the lower shifting register is fed back so that its contents are continually changing, while simultaneously, information leaves the main register. As this happens, the detection circuit seeks coincidences with one of the two patterns 0001, 0010. When a coincidence is found, the digit currently being output from the end of the

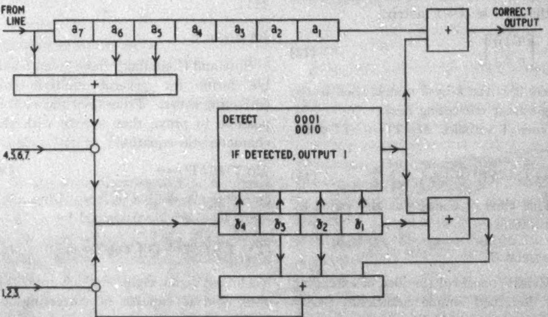

Fig. 2. Decoder

main register is inverted and corrected. Simultaneously, the lower register is altered to indicate that the burst pattern which is now left to be corrected is a simpler one, since the first digit of it has already been corrected.

This arrangement corrects, in this case, all single and double adjacent errors in the message.

Theory of Decoder

The role of the fed-back shifting register is to operate repeatedly on its contents **p** with $\mathbf{T}^{-1}$. Since the operation of **T** corresponds to the operation of a shift register, it is clear that the operation of $\mathbf{T}^{-1}$ can also be implemented by a shift register whose feedback connections are determined by the *C*'s of equation 20 and these are the connections shown.

The detection circuit is arranged to detect

$$\mathbf{p}=\mathbf{x}=(0001) \text{ and } \mathbf{p}=(1+\mathbf{T})\mathbf{x}=(0010) \qquad (34)$$

Thus, if there is a single error in the *r*th digit so that

$$\mathbf{z}=\mathbf{T}^{r-1} \qquad (35)$$

the detection circuit operates after $(r-1)$ shifts. However, at this time the *r*th digit is currently being output from the main register so that it is inverted as required.

The detection circuit also adds **x** to the lower register. This is accomplished just by adding an extra one to the feedback adder of the register, since **x** has the very simple form $\mathbf{x}=(0001)$.

Thus in the case of a single error $\mathbf{p}=\mathbf{x}+\mathbf{x}=0$ when the mistake is corrected, and the register becomes zero so that no further corrections take place.

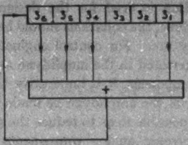

Fig. 3. Connections for Melas code, equation 15

For a double adjacent error in the *r*th and $(r+1)$th digits:

$$\mathbf{z}=\mathbf{T}^{r-1}(1+\mathbf{T})\mathbf{x} \qquad (36)$$

and again the detection circuit operates after $r-1$ shifts and corrects the *r*th digit. When this happens, the lower register contains $\mathbf{p}=(1+\mathbf{T})\mathbf{x}+\mathbf{x}=\mathbf{T}\mathbf{x}$ because of the addition of **x**.

The error now looks like a single error in the $(r+1)$th digit, so the correction of this digit takes place at the next digit time as previously described.

For a general code, the decoder is exactly similar. However, it is necessary to detect a different pattern in the detector for each burst configuration it is required to correct. Thus, if the code corrects, amongst other things, a burst pattern $q_1, q_2 \ldots q_r$, then it is necessary to detect in the lower register.

$$(q_1+q_2\mathbf{T}+q_3\mathbf{T}^2+\ldots+q_r\mathbf{T}^{r-1})\mathbf{x} \qquad (37)$$

and to correct all simpler burst patterns.

Thus, in the code of Melas, equation 15, which corrects error patterns 1, 11, 101, 111, the detection circuit must detect the four patterns

$$\mathbf{x},\ (1+\mathbf{T})\mathbf{x},\ (1+\mathbf{T}^2)\mathbf{x},\ (1+\mathbf{T}+\mathbf{T}^2)\mathbf{x} \qquad (38)$$

For a general code too, the main register has length equal to the message length. The lower register has length equal to the number of check digits, and the feedback connections to it are such that its successive contents are multipled by $\mathbf{T}^{-1}$. Fig. 3 illustrates these connections for the Melas code, equation 15.

Conclusions

A simple implementation has been given for codes described by a characteristic equation, and it has been observed that codes often arise in this form. Hence, this is a very powerful approach to the coding problem.

Many codes that have previously been described have been too complicated for them to be taken seriously. These, on the other hand, are all extremely economical in hardware. The implications of this simplicity are clearly enormous.

Amplidyne Circuit Analysis

G. W. BILLS
ASSOCIATE MEMBER AIEE

Synopsis: A method is shown for obtaining an analog of a typical amplidyne which has four control windings. Both the need for electronic analog differentiators and the possibility of circuits containing even-numbered amplifiers which give rise to unstable oscillations have been eliminated by the use of inverse inductances.[1,2] This makes it possible to have each amplidyne parameter represented by a computer component, which makes for ease of analysis and synthesis. Nonlinearities may be included in the analog and the analysis can be as rigorous as desired, limited only by the number of analog computer elements available. The method presented is applicable to circuit or machine containing mutual reactances.

ALTHOUGH the amplidyne has been thoroughly and competently analyzed for the cases where only one control winding is employed, little has been published on the analysis of multicontrol winding amplidynes.[3,4] Such amplidynes are widely used; elevator systems and and positioning controls are two applications that appear frequently in control analysis. In transient analysis of systems containing multicontrol winding amplidynes, the usual approach is simply to add directly together all the control winding signals. This neglect of mutual effects between control windings gives erroneous time constants for the amplidyne and should be avoided.

Since the transient analysis of complex amplidyne circuits is extremely difficult

G. W. BILLS is with North American Aviation, Inc., Downey, Calif.

The author wishes to express his thanks to Mr. Paul Lackey for suggesting the problem. This paper is a partial fulfillment of the requirements for the degree of Master of Science at the University of California, Los Angeles, Calif.

unless some form of digital or analog computer is used as an aid, it is the purpose of this paper to develop and present an adequate analog of a fairly complex amplidyne. Transient solutions may then be obtained by setting this analog on an electronic analog computer or digital differential analyzer.

Circuit Analysis

The first step in the amplidyne circuit analysis is to write equations expressing the transient electrical behavior of the amplidyne (Fig. 1) in a manner similar to that of Bower.[3] Voltages denoted by V are generated voltages whereas those denoted by E are impressed voltages. Self-inductances are expressed as L_n and mutual inductances as M_{mn}, where m refers to the circuit in which a voltage is induced by a current in circuit n. Voltages arising from moving conductors cutting a flux are similarly denoted by $N_{mn}I_n$.

All the equations are expressed in operational form, specifically Laplace transforms. Because amplidyne speed is assumed constant, the transient mechanical behavior of the amplidyne is not included in the equations.

$$(R_f+L_fS)I_f+M_{f1}SI_1+M_{f2}SI_2+M_{f3}SI_3+M_{fc}SI_c-M_{fd}SI_d-M_{fq}SI_q-M_{fs}SI_s=E_f \quad (1)$$

$$M_{1f}SI_f+(R_1+L_1S)I_1+M_{12}SI_2+M_{13}SI_3+M_{1c}SI_c-M_{1d}SI_d-M_{1q}SI_q-M_{1s}SI_s=E_1 \quad (2)$$

$$M_{2f}SI_f+M_{21}SI_1+(R_2+L_2S)I_2+M_{23}SI_3+M_{2c}SI_c-M_{2d}SI_d-M_{2q}SI_q-M_{2s}SI_s=E_2 \quad (3)$$

$$M_{3f}SI_f+M_{31}SI_1+M_{32}SI_2+(R_3+L_3S)I_3+M_{3c}SI_c-M_{3d}SI_d-M_{3q}SI_q-M_{3s}SI_s=E_3 \quad (4)$$

$$M_{cf}SI_f+M_{c1}SI_1+M_{c2}SI_2+M_{c3}SI_3+(R_c+L_cS)I_c-M_{cd}SI_d-M_{cq}SI_q-M_{cs}SI_s=E_c \quad (5)$$

$$-(N_{df}-M_{df}S)I_f-(N_{d1}-M_{d1}S)I_1-(N_{d2}-M_{d2}S)I_2-(N_{d3}-M_{d3}S)I_3-(N_{dc}+M_{dc}S)I_c-(R_d+N_{dd}+L_dS)I_d+(N_{dq}-M_{dq}S)I_q+(N_{ds}-M_{ds}S)I_s=V_d \quad (6)$$

$$(N_{qf}+M_{qf}S)I_f+(N_{q1}+M_{q1}S)I_1+(N_{q2}+M_{q2}S)I_2+(N_{q3}+M_{q3}S)I_3+(N_{qc}+M_{qc}S)I_c-(N_{qd}+M_{qd}S)I_d-(R_q+N_{qq}+L_qS)I_q-(N_{qs}+M_{qs}S)I_s=V_q \quad (7)$$

$$-M_{sf}SI_f-M_{s1}SI_1-M_{s2}SI_2-M_{s3}SI_3-M_{sc}SI_c+M_{sd}SI_d+M_{sq}SI_q+(R_s+L_sS)I_s=E_s \quad (8)$$

These equations describe the voltage drops in the circuits of the amplidyne and can include effects due to saturation and brush shifts away from the neutral position. Considerable simplification of these equations is possible and desirable. If information is need for the design of an amplidyne, the equations should be solved as they are. For control engineers who are interested in the amplidyne as a control component, it is imperative that the analog of the amplidyne be made as simple as possible so as to reduce the number of electronic analog components necessary to represent it.

Amplidynes are normally operated so that brushes are set close to the neutral zones and pairs of brushes are usually set 180 degrees apart. For these conditions, it can be shown that the mutual effect between the direct and quadrature circuits is zero so that $M_{dq}=M_{qd}=0$, and $M_{qf}=M_{q1}=M_{q2}=M_{q3}=M_{qc}=0$ because the control windings are not collinear with the quadrature coils.

If the direct-axis compensating winding is 100 per cent effective, $M_{df}=M_{d1}=M_{dc}=M_{d3}=M_{dc}=0$. Also, $N_{fd}=N_{1d}=N_{2d}=N_{3d}=N_{cd}=0$, and it should be remembered that M's are symmetrical, i.e., $M_{nm}=M_{mn}$. The internal construction of an amplidyne is such that mutual inductances between all the windings except those between the control windings and between the control and compensating windings are very small when brushes are set near neutral, so that $M_{sc}=M_{dc}=M_{qc}=M_{sf}=M_{s1}=M_{s2}=M_{s3}=M_{cf}$ $M_{c1}=M_{c2}=M_{c3}=0$. Therefore, equations 1 through 8 may be simplified to

$$(R_f+L_fS)I_f+M_{f1}SI_1+M_{f2}SI_2+M_{f3}SI_3=E_f \quad (9)$$

$$M_{1f}SI_f+(R_1+L_1S)I_1+M_{12}SI_2+M_{13}SI_3=E_1 \quad (10)$$

$$M_{2f}SI_f+M_{21}SI_1+(R_2+L_2S)I_2+M_{23}SI_3=E_2 \quad (11)$$

$$M_{3f}SI_f+M_{31}SI_1+M_{32}SI_2+(R_3+L_3S)I_3=E_3 \quad (12)$$

$$(R_c+L_cS)I_c=E_c \quad (13)$$

$$N_{dq}I_q-(R_d+N_{dd}+L_dS)I_d+N_{ds}I_s=V_d \quad (14)$$

$$N_{qf}I_f+N_{q1}I_1+N_{q2}I_2+N_{q3}I_3-N_{qd}I_d-N_{qs}I_s-(R_q+N_{qq}+L_qS)I_q=V_q \quad (15)$$

$$(R_s+L_sS)I_q=E_s \quad (16)$$

Further simplifications are possible when it is assumed that the quadrature series and quadrature armature circuits are connected in series and the compensating and direct armature windings are also connected in series. For these connections

$$V_q-E_s=V_q'$$

$$I_s=I_q$$

$$N_{qd}-N_{qc}=N_{qd}'$$

$$R_q+N_{qq}+N_{qs}=R_q'$$

$$L_s+L_q=L_q' \quad (17)$$

$$V_d-E_c=V_d'$$

$$I_c=I_d$$

$$N_{dq}+N_{ds}=N_{dq}'$$

$$R_c+R_d+N_{dd}=R_d'$$

$$L_d+L_c=L_d' \quad (18)$$

$$N_{dq}'I_q-(R_d'+L_d'S)I_d=V_d \quad (19)$$

$$N_{qf}I_f+N_{q1}I_1+N_{q2}I_2+N_{q3}I_3-N_{qd}'I_d-(R_q'+L_q'S)I_q=0 \quad (20)$$

It can be assumed that an amplidyne is connected as shown in Fig. 2 so as to control a drive motor in a positioning system. The black dots denote the polarity of each control winding, and loop currents have been indicated to aid in the analysis. Current I_7 is in the spillover circuit which limits the current in the control field and provides damping.

The entire control system is as shown in Fig. 3. This system was actually designed, built, and operated. Transient behavior of this system was determined before it was built by employing the amplidyne analog presented in this paper. Initial attempts to represent this system resulted in failure, and it was not until the analog, based on nodal analysis, was derived that a satisfactory solution was obtained. Except for the amplidyne, the control components were represented in a straightforward fashion.

The drive motor may be represented by

$$V_m=(R_m+L_mS)I_6+V_B \quad (21)$$

$$V_B=K_BS\theta_m \quad (22)$$

$$T_1 = \frac{J_1}{F_1} \tag{25}$$

$$V_T = K_T S \theta_m \tag{26}$$

An obvious approach in obtaining an analog representation is to apply block diagram algebra[5] to solve for the seven currents in Fig. 2. Once these currents are determined, the remaining unknown quantities may be easily determined by computer analysis.

Two difficulties can arise when mutual effects exist in electric circuits: 1. straightforward representation on an electronic analog computer would require the use of differentiating circuits which are not usually stable, and 2. avoiding the need for differentiation by equation manipulation leads to computer representations which include loops of even-numbered amplifiers which have no integrators. Such arrangements usually produce unstable oscillations.[6] To avoid such possibilities, the nodal form of equations can be used in block diagram algebra when mutual reactances are encountered. The only objection to this procedure is that the inverse self- and mutual inductances must be calculated, and this requires evaluation of determinants whose orders are equal to the number of inductances which are mutually coupled together. For this problem, the determinant order number of 4 does not present a difficult task.

Fig. 4. Amplidyne analog; signals are assumed to be added positively unless a negative sign appears in quadrant

Analog Derivation

By proper application of block diagram algebra and the use of inverse inductances, the analog of the control system shown in Fig. 3 can be derived. This analog is shown in Fig. 4.

Inverse inductances are denoted by Γ_{mn} and are found by inversion of the inductance matrix as follows:

$$\Gamma_{mn} = \frac{C_{mn}}{D}$$

$$D = \begin{vmatrix} L_{11} & L_{12} & L_{13} & L_{14} \\ L_{21} & L_{22} & L_{23} & L_{24} \\ L_{31} & L_{32} & L_{33} & L_{34} \\ L_{41} & L_{42} & L_{43} & L_{44} \end{vmatrix}$$

where

C_{mn} = cofactor of determinant D

Note that the saturation curve of the amplidyne is included in the analog diagrams.

From the analog in Fig. 4, an electronic analog representation may be readily determined and scaled depending on the parameters of the amplidyne and the control system.

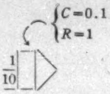
Specific Example

To illustrate the analysis procedure, the actual values for the components of a typical positioning control system, using the amplidyne shown in Fig. 2 will be given. Detailed calculations will be shown for the calculation of the inverse inductances.

By employing the amplidyne analog of Fig. 4, an actual setup for a Donner electronic analog computer is derived. In the diagram for this setup, potentiometers are represented by circles and amplifiers are denoted by the usual symbols.

For straight amplification:

For integrators:



The numbers on the inputs refer to the amplifier gain independent of the integration, whereas the numbers on top of the symbol are the microfarad and megohm values of the capacitors and resistors in the amplifier feedback circuit.

It should be mentioned that all values of amplification and potentiometer settings may have to be rescaled should the actual computer voltages represented on the computer be too high. However, this can be readily accomplished once the problem is set on the computer.

The only loop of amplifiers which does not contain integrators has an odd number of amplifiers and should not give rise to computer instability. Even this loop could have been made to include an integrator by using another block diagram approach. Also, the differentiator-type circuits were eliminated by the use of inverse inductances or block diagram algebraic manipulations.

Calculation of Inverse Inductances

The control field parameters for the amplidyne used in this specific example are given in the following table:

Winding	Designation	Turns	Inductance, Heurys	Resistance, Ohms
Main control	f	400	5.6	49.8
Speed overshoot	1	200	1.41	42.4
Stabilizing and differential	2	300	3.15	108.2
IR (voltage drop) compensation	3	200	1.41	43.8

Using these data, the inverse inductances are calculated as follows:

Assuming the coefficient of coupling K is 0.95 for all windings

$$M_{f1}=K\sqrt{L_fL_1}=0.95\sqrt{(5.6)(1.41)}=2.67$$

$$M_{f2}=K\sqrt{L_fL_2}=0.95\sqrt{(5.6)(3.15)}=3.99$$

$$M_{f3}=K\sqrt{L_fL}=0.95\sqrt{(5.6)(1.41)}=2.67$$

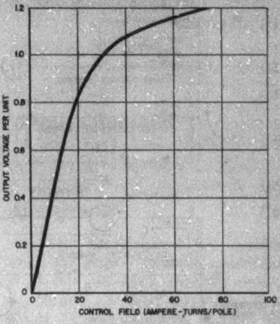


Fig. 5. Saturation curve, ampere-turns × 10/4π = gilberts

$$M_{12}=K\sqrt{L_1L_2}=0.95\sqrt{(1.41)(3.15)}=2.0$$

$$M_{13}=K\sqrt{L_1L_3}=0.95\sqrt{(1.41)(1.41)}=1.34$$

$$M_{23}=K\sqrt{L_2L_3}=0.95\sqrt{(3.15)(1.41)}=2.0$$

$$\Gamma_{23}=-\frac{\begin{vmatrix} 5.6 & 2.67 & -3.99 \\ 2.67 & 1.41 & -2.0 \\ 2.67 & 1.34 & -2.0 \end{vmatrix}}{\Delta}=2.2471$$

Positioning Control System Data

The following constants are assumed for the positioning system in addition to those which have been given for the amplidyne windings.

$R=100.0$ ohms
$R_f=49.8$ ohms
$R_1=3000$ ohms
$R_2=108.2$ ohms
$R_3=43.8$ ohms
$R_4=50.0$ ohms
$R_5=3{,}300.0$ ohms
$R_6=0.2$ ohm
$R_7=22.0$ ohms
$R_T=90.0$ ohms
$R_d'=3.88$ ohms
$R_m=1.126$ ohms
$R_q'=5.65$ ohms
$L_d'=0.4$ henry
$L_m=0.05$ henry
$L_q'=1.5$ henrys
$T_q'=0.266$
$N_{qf}=400$
$N_{q1}=200$
$N_{q2}=300$
$N_{q3}=200$
$N_{qd}'=8$
$N_{dq}'=5$
$C_1=500$ microfarads
$C_4=1{,}000$ microfarads
$F_1=0.20$ foot/radian/second
$J_1=0.1426$ slug-feet^2
$T_1=J_1/F_1=0.713$
$K_g=1.88$ volts/revolutions/second
$K_t=1.19$ pound-feet/ampere
$K_T=0.74$ volt/revolutions/second

K_q may be determined by setting up portion of analog from function generator to the amplifier whose output is $-Vd'/S$. The saturation curve, Fig. 5, is then placed on the function generator and, as NI is varied, the gain of the amplifiers connected internally with the function generator is adjusted to give the correct magnitude of output voltage. This operation simulates a no-load condition.

The block diagram for an analog computer representation, for a Donner computer, is shown in Fig. 6.

Logical Organization of the Honeywell H-290

JOSEPH J. EACHUS
NONMEMBER AIEE

THE Minneapolis-Honeywell Regulator Company's *H-290* is a general-purpose digital computer which is provided with input and output paths which make it particularly easy to relate the computer to sensing and control devices.

The computer is fully parallel, operating on an 18-bit word. Typical execution rates are additions, 700 per second, and multiplications, 1,200 per second. The machine is provided with a core memory of 4,096 words, plus 8,192 words of drum storage.

Within one meaning of the term, the *H-290* is "micro-programed." That is, there is a clearly defined control section, and a clearly defined controlled section, so related that the wiring of and the hardware content of the controlled section is unaffected by changes in the computer's command vocabulary. This relationship may be said to function with the controlled section being capable of performing, on receipt of control signals, any of a collection of microsteps, and it being the function of the controlling section to cause these microsteps to be taken in sequence so that the eventual result is the execution of a command in the conventional sense.

It was the design objective, in the *290*, to produce a controlled section which would permit the execution of any general-purpose computer command, permit ready communications outward to

Paper 60-971, recommended by the AIEE Computing Devices Committee and approved by the AIEE Technical Operations Department for presentation at the AIEE-AIChE-IRE-ISA-ASME Joint Automatic Control Conference, Cambridge, Mass., September 6–9, 1960. Manuscript submitted April 25, 1960; made available for printing July 29, 1960.

JOSEPH J. EACHUS is with the Minneapolis-Honeywell Regulator Company, Newton Highlands, Mass.

other electric devices, permit ready communications inward from electric devices, provide communications to and from paper tape, to provide direct visual communications to the operator, and to permit the operator to communicate directly to the machine. It was required that no feature of this section place significant restraints on the nature of equipment with which it might communicate, and that no lack of ability prevent the performance, under appropriate control, of any standard arithmetic or logical operation. This paper reports the logical nature of the controlled section designed to meet these objectives.

Notation and Terminology

Capital letters are used in the following several senses:

1. When one of the letters *A* through *V* is followed by three digits, one inverting amplifier is designated. The same symbol is used as the logical (Boolean) variable that is realized by the amplifier. Amplifiers are associated in pairs, the first of the three digits, always 0 or 1, distinguishing between the two of a pair, and the last two digits designating the pair. If the letter is among the 1's *A* through *K*, each pair of amplifiers is cross-coupled to form a bistable circuit, one or the other amplifier being saturated and its mate cut off. In this case, as logical variables one or the other of a pair is a 1 and its mate a 0. The statement: "Amplifier *A*013 is cut off" is to be taken as interchangeable with the statement: "The logical variable *A*013 is a 1." Similarly, "*A*013 is saturated" and "*A*013=0" are equivalent.

2. When one of the letters *A* through *V* is followed by two digits, the pair of amplifiers is designated. The expression: "Transfer from *D*13 to *A*13" means, in full, if *D*013 is a 1, cause *A*114 to become a 0, but if *D*113 is a 1, cause *A*014 to become a 0. Not all pairs of amplifiers are cross-coupled, and in particular, those designated by the letter *M* are not. The expression: "Transfer from *M*07 to *B*07" means, in full, if *M*007 is a 1, cause *B*107 to become a 0, or if *M*107 is a 1, cause *B*007 to become a 0, but if both *M*007 and *M*107 are 0, do nothing which will alter the state of the *B*07 pair. Restraints will be observed later which prevent both *M*'s of a pair from being simultaneously 1.

When referring to a cross-coupled pair, a statement such as "*C*12 contains a 0" is to be taken to mean that *C*012=1 and *C*112=0, and *C*12 contains a 1 and that *C*012=0 and *C*112=1. The term "Set *E*01 to 1" means, analogously, to cause *E*001 to become 0.

3. A letter without numerical suffix is used to designate the set of amplifiers which are individually designated by that letter with suffixes. If these amplifiers are cross-coupled pairs, the term "register" will be applied to the collection.

4. The letters *Y* and *Z* are used to designate signals emanating from the control section which cause action in the controlled section. *Y* followed by two digits designates such a signal which is normally off and comes on to cause action. *Z* followed by one digit designates such a signal which is normally on, and goes off to cause action. As logical variable, a *Y* is normally 0, but sometimes becomes 1, and *Z* is normally 1, but sometimes becomes 0. It is the function of the control section to emit these signals in orderly sequence.

While the nature of the control section is not a subject of the present discussion, reference must be made to a set of 12 cross-coupled amplifier-pairs therein, *W*00 to *W*11, inasmuch as some transfers take place, both ways, between them and elements of the controlled section. It is, in fact, the state of the *W*-register that determines which *Y*'s and *Z*'s will be emitted by the control section.

5. At times when an accurate and lucid description of an element and its function can be conveyed in words, letter symbols for the element will be omitted. For instance, the "drum busy flip-flop" is so treated.

Autonomous Parts

There are three integral portions of the computer, each of which is capable of a certain amount of independent action, such action being carried out on receipt of a signal asking for it. They are:

1. The core memory, which will act on receipt of a "read" or "write" request signal. On the advent of a read signal the memory address corresponding to the contents of *E*00–*E*11 will be read, the result appearing in the *F* register. On the advent of a write signal, the contents of *F*00–*F*17 will be written at the address specified by the contents of *E*00–*E*11.

2. The drum memory, which acts in a manner similar to that of the core memory, but with *Q*00–*Q*12 supplying addresses and *V*00–*V*17 serving as data register. Due to the indeterminate length of time required for the drum to reach the angular position corresponding to a given address, a means of indicating whether or not the last-called-for action has been completed is supplied, in the form of the drum busy flip-flop. This flip-flop is set to 1 by either the read request signal or the write request signal. It is set to 0 by the actual execution of a read or write, and hence contains a zero when, and only when, the drum memory is capable of receiving a new request for action.

3. The paper-tape punch section. This section contains eight data flip-flops *U*00 to *U*07, the punch busy flip-flop *U*08, and the punch motor flip-flop. This section will take cognizance of any of three request signals, namely, turn on punch motor, turn off punch motor, and punch. The third of these will turn on the punch motor if not already on, and cause to be punched one character on paper tape, that character having holes and lack of holes in accordance with 1's and 0's contained in *U*00 to *U*07. If the tape has fewer than eight levels, the higher order *U*'s are ignored. This section is capable of handling either the Friden eight-level punch, which is clutched, or the Teletype high-speed punch, which is continuously rotating.

Registers

At this point it is appropriate to enumerate the registers, give them short names, and indicate the number of flip-flops in each. The reader is cautioned to avoid interpreting the names in a restrictive way since, while in most cases a register does perform the function implied by its name, in many cases it performs additional functions.

The registers are:

Letter Designation	Number of Flip-Flops	Name
A	20	accumulator
B	18	quotient
C	19	sequence
D	20	utility
E	18	memory address
F	18	memory local
G	18	display
H	18	output selection
I	18	input selection
J	18	output magnitude
K	18	input magnitude
Q	13	drum address
U	8	punch
V	18	drum local

Subsequently, there will appear a set of logical variables composed of the letter *T* followed by four digits. The first digit has value 1, 2, or 3, the second has value 0 or 1, and the last two range from 00 to 17. Two of these *T*'s, differing only on the second digit of suffix, are paired in the same way as are the logical variables representing a flip-flop. It will therefore cause no confusion to refer to registers

Vol.
Pt. 1
196

$T1$, $T2$, and $T3$, even though the electrical states representing these logical variables do not arise from flip-flops. In the case of $T1$ and $T2$ they arise from manually set switches or, alternatively from the points of relays, and in the case of $T3$, they are the outputs of a real time clock.

Logical Entities Other Than Registers

There are two logical networks which provide interrelations among the register, which are now described.

1. The transfer amplifiers comprise a set L of 36 inverting amplifiers, not cross-coupled, having many controlled paths into them, and a second set of 36 inverting amplifiers M, not cross-coupled, with many controlled paths out, there being a smaller set of controlled paths from the L's to the M's.

A typical subset of the L's realize the equations:

$$\bar{L}013=A013\,Y15+B013\,Y16+C013\,Y17+D013\,Y18+E013\,Y19+F013\,Y20+K013\,Y21+T1013\,Y44+T2013\,Y45+T3013\,Y46+V013\,Y60$$

$$\bar{L}113=A113\,Y15+B113\,Y16+C113\,Y17+D113\,Y18+E113\,Y19+F113\,Y20+K113\,Y21+T1113\,Y44+T2113\,Y45+T3113\,Y46+V113\,Y60$$

$$\bar{L}014=A014\,Y15+B014\,Y16+C014\,Y17+D014\,Y18, \text{ etc.}$$

For these L's having last two digits from 00 to 05, there is an extra term: $W---Y04$, where the dashes represent the same digits as the suffix of the L. It is a constraint placed on the control section that at most, one of the numerous Y's in these equations may be 1 at any time.

It is seen, then, that if none of the H's involved is 1, then every L is 1, and if some Y other than $Y60$ is 1, then one of each pair of L's is 0, and that if $Y60=1$, then one of each pair $L00$ to $L05$ is 0, and all L's from $L06$ to $L17$ are 1.

A typical pair of M's realize the equations:

$$\bar{M}013=(L013+Z2)(L113+Z4)(L012+Z5)(L014+Z6)$$

$$\bar{M}113=(L113+Z1)(L013+Z3)(L112+Z5)(L114+Z6)$$

$\bar{M}00$ and $M17$ have an "end around" input:

$$\bar{M}000=(L000+Z2)(L100+Z4)(L017+Z5)(L001+Z6)$$

$$\bar{M}100=(L100+Z1)(L000+Z3)(L117+Z5)(L101+Z6)$$

$$\bar{M}017=(L017+Z2)(L117+Z4)(L016+Z5)(L000+Z6)$$

$$\bar{M}117=(L117+Z1)(L017+Z3)(L116+Z5)(L100+Z6)$$

Table I. Functions Performed by Y's

Control Signal	Function Performed
$Y01$	transfer $M01$–$M16$ to $A01$–$A16$
$Y02$	transfer $D00$–$D18$ to $A01$–$A19$
$Y03$	transfer $M01$–$M17$ to $B01$–$B17$
$Y04$	transfer $W00$–$W05$ to $L00$–$L05$
$Y05$	set $C18$ to 0 and disable counting by C
$Y06$	transfer $M00$–$M17$ to $D00$–$D17$
$Y07$	transfer binary output of adder to $D00$–$D19$
$Y08$	transfer decimal output of adder to $D00$–$D19$
$Y09$	transfer $M00$–$M17$ to $E00$–$E17$
$Y10$	transfer $M12$–$M16$ to $F12$–$F16$
$Y11$	transfer $E01$–$E17$ to $F00$–$F16$ (right shift)
$Y12$	transfer $M00$–$M17$ to $G00$–$G17$
$Y13$	transfer $M00$–$M17$ to $H00$–$H17$
$Y14$	transfer $M00$–$M17$ to $J00$–$J17$
$Y15$	transfer $A00$–$A17$ to $L00$–$L17$
$Y16$	transfer $B00$–$B17$ to $L00$–$L17$
$Y17$	transfer $C00$–$C17$ to $L00$–$L17$
$Y18$	transfer $D00$–$D17$ to $L00$–$L17$
$Y19$	transfer $E00$–$E17$ to $L00$–$L17$
$Y20$	transfer $F00$–$F17$ to $L00$–$L17$
$Y21$	transfer $K00$–$K17$ to $L00$–$L17$
$Y22$	transfer $M00$ to $A00$
$Y23$	transfer $M00$ to $B00$
$Y24$	transfer $M00$–$M17$ to $C00$–$C17$
$Y25$	cause C to count one
$Y26$	transfer $M00$ to $F00$
$Y27$	turn on punch motor
$Y28$	turn off punch motor
$Y29$	transfer $D18$ to $A17$ and $D19$ to $A18$ and $A19$
$Y30$	transfer $D18$–$D19$ to $A18$–$A19$
$Y31$	transfer $A00$–$A19$ to $D00$–$D19$
$Y32$	set adder to add
$Y33$	set adder to subtract
$Y34$	set adder to decimal
$Y35$	set adder to binary
$Y36$	set $B01$ to 1
$Y37$	transfer $M17$ to $A18$–$A19$
$Y38$	transfer $M17$ to $W09$
$Y39$	transfer $M00$–$M07$ to $U00$–$U07$ and start punch motor
$Y40$	transfer $U08$ to $W09$
$Y41$	set $B00$ to 0
$Y42$	set $B00$ to 1
$Y43$	transfer $M12$–$M17$ to $W00$–$W05$
$Y44$	transfer manual register 1 to $L00$–$L17$
$Y45$	transfer manual register 2 to $L00$–$L17$
$Y46$	transfer time register to $L00$–$L17$
$Y47$	cause core memory to read
$Y48$	cause core memory to write
$Y49$	start paper-tape reader
$Y50$	set $K17$ to 1
$Y51$	transfer $N19$ to $W09$
$Y52$	transfer $M17$ to $F17$
$Y53$	transfer $M00$–$M17$ to $I00$–$I17$
$Y54$	transfer $E00$ to $W09$
$Y55$	transfer $M01$–$M11$ to $F01$–$F11$
$Y56$	transfer $C18$ to $W09$
$Y57$	transfer $M17$ to $A17$
$Y58$	stop primary clock
$Y59$	transfer $M00$–$M17$ to $V00$–$V17$
$Y60$	transfer $V00$–$V17$ to $L00$–$L17$
$Y61$	transfer $M00$–$M11$ to $Q00$–$Q11$
$Y62$	read drum
$Y63$	write on drum
$Y64$	transfer drum busy flip-flop to $W09$
$Y65$	start input converter
$Y66$	transfer $M12$ to $Q12$

From these equations it is seen that if $Y15=1$, $Z1=0$, and $Z2=0$, then each M takes on the state of the A having the same suffix, but if $Y16=1$, $Z1=0$, and $Z2=0$, each M takes on the state of the B having the same suffix. Here is thus a mechanism which will produce a copy of the contents of any of dozen sources at a common location, the M amplifiers.

If, instead of activating $Z1$ and $Z2$ and some Y, $Z3$, $Z4$, and $Y15$ are activated, each M takes on the state opposite that of the A having the same suffix, and thus can also be produced, at the M's, the complement of the contents of any of the source registers.

Use of $Z5$ or $Z6$ permits the generation, at the M's, of the contents of any source register displaced one position left or one position right, respectively.

If $Y15=1$, $Z1=0$, and $Z3=0$, every M with first digit of suffix 1 becomes a 1, and each M with first digit of suffix 0 becomes 0. That is, at the M's, a word of 1's is produced. Similarly, any input to the L's and $Z2=0$, $Z4=0$ will generate a word of 0's.

The mechanism whereby data generated at the M's are put into registers is manifested in the logical equations for those register flip-flops. For instance, the complete logical equations for $G13$ are:

$$\bar{G}013=G113+M113\,Y12$$

$$\bar{G}113=G013+M01\,Y12$$

The first term on the right in each of these two equations is an indication of the stabilizing cross-coupling. If $Y12=0$, or if $M113=0$ and $M103=0$, both these equations are satisfied by either $G013=0$, $G113=1$, $G113=0$. If, however, $Y12$ becomes 1 simultaneously with $M113$ or $M013$, only one of the two conditions $G013=0$, $G113=1$ and $G013=1$, $G113=0$ satisfy both equations. It is seen, then, that if $Y12=1$, the operation "transfer $M13$ to $G13$" is performed.

$Y12$ appears in every G equation, and consequently its becoming a 1 causes the operation: transfer M to G.

Registers A, B, C, D, E, F, G, H, I, J, Q, U, and V have similar transfer means from M, but in not all cases does one Y cause all 18 bits to be transferred. For example, $Y01$ causes the transfer of $M01$–$M16$ to $A01$–$A16$, $Y22$ causes the transfer to $M00$ to $A00$, and $Y57$ causes the transfer of $M17$ to $A17$, and $Y37$ causes the transfer of $M17$ to both $A18$ and $B19$. All such separations may be seen in the itemization of functions performed by Y's in Table I.

Consider now the effect of $Y16=1$, $A1=0$, $Y01=1$, $Y22=1$, $Y57=0$, all other Y's and Z's inactive. No M with first suffix 0 may become 1, and hence no A flip-flop may be changed from containing a 1 to containing a 0. On the other hand, an M with first suffix 1 may become a 1 if the B with the same suffix is 1, that is, if the corresponding B flip-flop contains a 1. The net result is that A will finally contain a 1 at any position in which it originally had a 1, and in addition at any position at which it originally had a 0 if the corresponding position of B contains a 1. That is, there has been produced in A the logical sum of the original contents of A and the contents of B.

The effect of $Y16=1$, $Z2=0$, $Y01=1$, $Y22=1$, $Y57=0$, all other Y's and Z's inactive, is similar, except the result in A is 0 at any position where either A or B had a 0, that is, to produce in A the logical product of original contents of A and contents of B.

2. The adder network is a complex logical network which provides elementary arithmetic ability. It has as inputs all amplifiers of A register and of B register. It has, in addition, three other steady-state logical inputs: $S0$, $S1$, and $S2$. Inasmuch as the control section emits only transient signals, the S's are realized in flip-flops which are set by control Y's. $Y33$ causes $S0=0$ and $S1=1$; $Y34$ causes $S0=1$ and $S1=0$; $Y34$ causes $S2=1$; and $Y35$ causes $S2=0$.

The adder network has two sets of 19 pairs of outputs, N and R. There will be at the N's the sum of the number contained in A and the number contained in B if $S0=1$, $S1=0$, and $S2=0$, with all numbers considered as binary. If, however, $S0=0$, $S1=1$, and $S2=0$, there will be at the N's the number in A minus the number in B, again with all numbers considered as binary. If $S0=1$, $S1=0$, and $S2=1$, the result appears at the second set of outputs R, and is the sum of the number in A and the number in B, this time numbers being expressed in the standard binary coded decimal fashion. Finally, if $S0=0$, $S1=1$, and $S2=1$, the result is at the R's, and is the number in A minus the number in B, numbers being expressed in binary coded decimal fashion. Results get back into the register array via controlled paths from N and R to D. A typical D pair has equations:

$$\begin{aligned}
\bar{D}005 &= D105+N105Y07+R105Y08+---\\
\bar{D}105 &= D005+N005Y07+R005Y08+---
\end{aligned}$$

$Y07$ and $Y08$ are in corresponding positions in all D equations, and hence $Y07$ is called "transfer binary output of adder to D," and $Y08$ "transfer decimal output of adder to D."

As previously indicated, equations for the adder network are quite complex. However, those for any two-bit positions, four apart, are alike, and it will suffice to give the equations for one group of four, say 04 to 07. Two letters, P and Q, not previously mentioned as logical variables, appear in these equations. However, they are fully defined by the equations and require no further description. It is readily seen that they play the role of borrows and carries. These equations are:

$$\begin{aligned}
\bar{P}004 &= B104Q103+S1A004B104+\\
&\quad S1A004Q103+S0A104B104+\\
&\quad S0A104Q103\\
\bar{P}104 &= P004\\
\bar{P}005 &= P105\\
\bar{P}105 &= B005P004+S1A105B005+\\
&\quad S1A105P004+S0A005B005+\\
&\quad S0A005P004\\
\bar{P}006 &= B106P105+S1A006B106+\\
&\quad S1A006P105+S0A106B106+\\
&\quad S0A106P105\\
\bar{P}106 &= P006\\
\bar{P}007 &= P107\\
\bar{P}107 &= B007P006+S1A107B007+\\
&\quad S1A107P006+S0A007B007+\\
&\quad S0A007P006\\
\bar{N}004 &= A104B104Q103+A004B004Q103+\\
&\quad A004B104Q003+A104B004Q003\\
\bar{N}104 &= N004\\
\bar{N}005 &= A105B105P104+A005B005P104+\\
&\quad A005B105P004+A105B005P004\\
\bar{N}105 &= N005\\
\bar{N}006 &= A106B106P105+A006B006P105+\\
&\quad A006B106P005+A106B006P005\\
\bar{N}106 &= N006\\
\bar{N}007 &= A107B107P106+A007B007P106+\\
&\quad A007B107P006+A107B007P006\\
\bar{N}107 &= N007\\
\bar{Q}007 &= P107+S2N106N107+\\
&\qquad\qquad S2N105N107\\
\bar{Q}107 &= Q007\\
\bar{R}004 &= N104\\
\bar{R}104 &= N004\\
\bar{R}005 &= N105Q007+N005Q107\\
\bar{R}105 &= R005\\
\bar{R}006 &= Q007N106+P107N007N005+\\
&\quad P007N107N106N105+\\
&\quad P107N107N006N105\\
\bar{R}106 &= R006\\
\bar{R}007 &= Q007N107+Q107N007N006N105+\\
&\quad P107N106N105N107\\
\bar{R}107 &= R007
\end{aligned}$$

Miscellaneous Special Properties

Although the registers and networks already described are adequate for all required logic and arithmetic, an advantage in time to perform multistop operations can be gained by providing some transfer paths which do not utilize the transfer amplifiers, and by providing a counting means which does not use the adder net. The latter is provided by making register C a binary counter, with $Y25$ the input which causes it to count. Since the between-stage coupling which makes it into a counter tends to react undesirably when a transfer from M to C takes place, a means of disabling the counting property is provided and controlled by $Y05$.

The direct-transfer paths provided are indicated in the itemized list of control functions in Table I.

It is at times necessary for the controlling section to originate a data bit, that is, to set a register flip-flop, in performing such operations as divide or square root. $Y36$, $Y41$, and $Y42$ provide means for such actions.

It is at times necessary for the controlling section to take one of two actions, the choice being determined by the state of some register flip-flop or the state of some external device. The ability to do this is provided by a number of controlled paths to $W09$, a flip-flop of the control section. $Y38$, $Y40$, $Y51$, $Y54$, and $Y64$ control such paths.

Means have been indicated ($T1$ and $T2$) whereby the operator can communicate directly with the machine. Direct communication in the other direction is provided by an adjunct to the G register. For each four binary digits of the G register there is an illuminated display capable of showing any one decimal digit number, and capable of showing any of the two decimal digit numbers 10 through 15. They correspond to the 16 possible combinations of states of four flip-flops, and thus "display" the contents of the G register. G has no other function.

Means have been indicated for communicating outward in the form of paper tape. Means of going from paper tape to the machine is provided by the relay-point alternative of $T2$, in which case the paper-tape reader operates the coils of the relays. A control signal, $Y49$, actuates the clutch of the reader.

Registers H, I, and J provide additional outward communicating paths. Outputs of the amplifiers themselves may be brought out or, alternatively, the amplifiers are capable of operating the coils of relays, the points of which are available externally. Register K provides another inward communicating path. Wires are brought out which may be set to K flip-flops from an external source.

In the event that the external source is a device requiring a start signal, a control signal $Y65$ is provided for that purpose. $Y65$ also sets $K17$ to 1, it being the expectation that on completion of its action the external device will set $K17$ back to 0. The path K to L, L to M, $M17$ to $W09$, permits the control section to take cognizance of the state of completion of the cycle of the external device.

If the external device is an analog-to-digital converter with a number of possible inputs, the I register is used to operate the switching network which will connect an individual input to the converter.

If it is desired that the computer supply input to a digital-to-analog converter which has output to one of many destinations, the J register will supply the digital input, and the H register control the switching of output to destination.

Example of Sequencing

To illustrate the manner in which the array that has been outlined is used to execute conventional computer commands, given in detail below are the actions performed by control to execute the "tally" order, which requires that a specified address be read, the number read augmented by 1 and then stored back at the address whence it came. It was assumed that, initially, the command has been read, and is therefore in the F register, but no further action has taken place. C will contain the address from which the command has just been read, and the last stop of execution is to read the command at the succeeding address.

Step 1: $Y20$, $Z1$, $Z2$, $Y09$, $Y43$, $Y47$, $Y25$.

At this time, control has not yet been given the operation code of the command, and can therefore do only a beginning step common to all commands. $Y20$, $Z1$, $Z2$, will produce a copy of the command word at the M's. $Y09$ will put it in the E register, $Y43$ will put the operation code portion in $W00$–$W05$ of control, $Y47$ will cause the memory to read, and $Y25$ will cause the C register to augment its contents by 1.

Step 2: $Y17$, $Z1$, $Z2$, $Y06$.

This is C to L to M to D, creating a copy of the contents of C in D.

Step 3: $Y20$, $Z1$, $Z2$, $Y24$, $Y05$.

The memory read action called for in step 1 has put the operand in F. This step moves it to C.

Step 4: $Y25$.

This causes C to count.

Step 5: $Y17$, $Z1$, $Z2$, $Y10$, $Y26$, $Y52$, $Y55$, $Y48$.

This moves the new contents of C to F and causes the memory to write. E has not been changed since step 1, and therefore contains the correct address.

Step 6: $Y18$, $Z1$, $Z2$, $Y18$, $Y24$.

Although the action called for was completed at step 5, the content of C was data and not command address. This step restores in C the contents previously put aside in D.

Step 7: $Y17$, $Z1$, $Z2$, $Y09$, $Y47$.

This ending is common to all orders other than stops and jumps. It is C to L to M to E and read, which will bring the new command to F.

The tally command requires seven time-separated steps. The simplest commands take only three, while multiply requires 40 and square root 130.

Conclusions

The logical organization of the controlled section of a computer as described permits, with no wiring changes in the controlled section, wide variations of command vocabulary, including the possibility of single commands ordinarily considered prohibitively complicated. For example, one *H-290* order will scan a list of numbers, put the largest in the A register and store the location at which it was found at a special location in memory. However, a large vocabulary of complicated orders puts an immense requirement on control, and unless economical means of exercising control is available, such an organization is not to be recommended.

Transient Thermal Impedance of Semiconductor Devices

E. J. DIEBOLD
MEMBER AIEE

WERNER LUFT
ASSOCIATE MEMBER AIEE

Synopsis: In this paper the thermal behavior of the semiconductor device is referred to the junction. Devices consisting of multiple parts which are nonhomogeneous and with varying outlines are subdivided into homogeneous elements with simple outlines which are successively related to the junction. Thermal impedance calculations of cylindrical and spherical sectors are given numerically. Stationary thermal impedances provide the framework to assemble a valid succession of transient thermal impedances. The analysis is expanded for long heating cycles by a simple lumped-component approach with limits of validity.

SEMICONDUCTOR devices usually consist of a thin junction zone having a high, localized electrical and thermal resistance, within a comparatively large and thick body. During the operation of the device a large amount of heat is produced in this thin, plane zone. The heat flows by conduction into the remainder of the body which produces very little heat. Heat flowing away from the junction necessitates a temperature differential.

Heat flow from the junction into the surrounding mass of the body follows the laws of diffusion. Heating cycles which are shorter than the time required for heat diffusion through the full mass of the body, are treated with the concept of transient thermal impedance. Longer heating cycles may use the same condition but use a lumped-component approach. The ultimate limit is the stationary case (stationary thermal impedance).

In a previous paper,[1] the transient temperature rise of solid junctions was analyzed for different conditions. The present paper does not repeat this derivation but does take advantage of the formerly reached conclusions.

Pulses of increasing current, decreasing current, or constant current were correlated and equation 44 of reference 1 shows that such pulses behave similarly, hence a pulse of constant magnitude creates approximately double the temperature rise from a pulse with steadily increasing or steadily decreasing magnitude. Only pulses of constant magnitude are considered.

Successive approximations are used and a better method of correlating them has been developed. Every step is related to the junction.

It is assumed that all the heat of the device is generated only in the junction. This approximation of reality is very close.

The junction is of finite thickness but thin enough to permit a simple approximation of a plane homogeneous body in which the heat diffuses evenly, but only to one side of the plane and not through the plane. This assumption is also close to reality, except for point contact devices.

Heat escaping in both directions away from the plane is treated by calculating

the transient thermal impedance for each side and obtaining the resulting impedance from two parallel connected impedances. Heat is applied to the junction at a constant rate for a finite time. This approximation is apparently crude but was proved to be valid in the previous paper.[1]

Nomenclature

A = area, meters squared (m^2)
B = boundary
c = specific heat, watt-second per kilogram, degrees centigrade (ws/kg C)
C = thermal capacity, ws/C
d = thickness, m
D = diameter, m
γ = density, kg/m^3
k = thermal conductivity, w/mC
l = equivalent thickness (spherical section), m
O = origin of heat flow and reference point of temperature rise
p = propagation constant, m/$\sqrt{s}$
q = heat flow (at any point), w
Q = heat flow at origin (junction), w
r = radius of spherical sector, m
t = running time, seconds
T = time (fixed values), seconds
ΔT = time interval, seconds
θ = temperature rise, C
Θ = time constant, seconds
τ = temperature-rise constant, m^{2}C/w$\sqrt{s}$
u = normalized time
v = normalized transient thermal impedance
Z = stationary thermal impedance, C/w
ΔZ = incremental stationary thermal impedance, C/w
ζ = transient thermal impedance, C/w
ω = solid angle of spherical sector

Subscripts:

b = beginning
e = end
i = internal
j = junction
o = external
1, 2, 3 = specific numbered sections
w, x, y = numbered sections, general case
∞ = infinitely deep body (for diffusion)

Stationary Thermal Impedance

The stationary thermal impedance of a semiconductor device is the ratio of the temperature rise of the junction above the ambience, divided by the heat flow issuing from this junction. Heat flow may also be expressed as power dissipated in the junction.

The stationary thermal impedance can be calculated by subdividing the device into cylinders, cones, or other simple geometric bodies and determining the thermal impedance for each such section separately.

Transient Thermal Impedance

The transient thermal impedance of a semiconductor device is the ratio of the temperature rise of the junction after a given time, over the power dissipated in this junction, the only cause for this temperature rise, during the same time.

The transient thermal impedance is fictitious, but practically useful because it relates power dissipation and temperature rise in the junction to the heating-up time. This thermal impedance is meaningless for any other part of the body and for any other time. It depends to a certain extent on the time function of the heat generated in the junction.

The transient thermal impedance is always less than the steady-state thermal impedance. In the transient case, heat diffuses from the hot junction into the thermal mass of the cold parts, whereas in the steady state the heat must be dissipated to the space outside the device. Transient values determine the permissible pulse load of semiconductor devices under various conditions of initial temperature, pulse magnitude, and duration. Measurements of transient thermal behavior and failure limits can be analyzed for purely thermal or thermomechanical stress failure.

SECTIONAL SUBDIVISION OF SEMICONDUCTOR DEVICE

Heat generated in the junction of a semiconductor device diffuses through the solid in a diffusion wave which is first plane and then assumes a more spherical shape. Later the wave may be deflected into a plate or similar heat exchanger. The study of the transient thermal impedance for pulse behavior of semiconductor devices concerns mainly the initial stages but may consider the later stages by rather crude approximations. For the earlier stages only two approximations need to be considered: the plane approximation and the spherical diffusion which is found to be so flexible that it covers almost all practical cases. It is assumed that heat expands linearly into a conical body which is limited laterally by a thermally insulating cone, and in which the surfaces of equal temperature at equal times are geometrically similar parts of a sphere. The plane approximation is one particular case of the spherical approximation in which the opening angle of the cone is infinitely small and the distance from the center of the sphere to the flow volume is infinitely long.

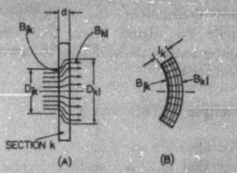

Fig. 2. Heat flow through plane disk (A) and equivalent spherical diffusion (B)

Subdivision into a plurality of sections is necessary because of the different materials which are used in semiconductor devices. Properties of the materials vary greatly and correct consideration of material constants is more important than precise coverage of dimensional variations. Thus the following analysis is based on the subdivision of a complex body into several sections which are made of different materials.

Fig. 1 shows a schematic representation of a semiconductor device without its housing. The body is assumed to have circular symmetry around the center line (CL). The different parts of the device between the junction and the cooling fin are indicated by numbers *1* through *8*. The number *0* is given to the junction. On the left-hand side, another heat-flow path is indicated by the numbers *1'* through *6'*. Practical analysis must cover both halves separately.

Subdividing the right-hand part assumes that the numbered sections are all made of different materials, except sections *5* and *6* which show abrupt change of shape. The boundary between section *5* and *6*, indicated by B_{56}, can be assumed to fit the spherical approximations for sections *5* and *6*. Section *7* is only the contact resistance between two solid bodies without mass; its transient and stationary thermal impedances are equal.

Fig. 2 shows the approximation of any of the sections *1* through *5* by a spherical body. Fig. 2(A) shows the section which is a circular, plane piece of material into which heat penetrates from the left-hand side in a fraction of its area and emanates on the right-hand side in a larger fraction of the area. In reality, comparing Fig. 1 to Fig. 2(A), the parts

1 through *5* have heat coming in from the left-hand side on a relatively small area but coming out on the right-hand side over the full area, but at unequal heat-flow density. This is studied by assuming that the diameter D_{jk} is given by the previous section *J* and the next diameter D_{kl} is not larger than D_{jk} plus two thicknesses *d* of the section, but the heat-flow density is uniformly high. In Fig. 2(B) the equivalent spherical diffusion with the boundary B_{jk}, the boundary B_{kl}, and the diffusion length l_k are shown. This approximation is easy to treat, has a stationary impedance equal to the original and a thermal mass which is approximately equal.

Fig. 3 shows another approximation of a section of a body which is similar to section *6* of Fig. 1. Fig. 3(A) shows the original with the boundary B_{56} at the left, which is assumed to be determined from section *5*. The boundary B_{67} is quite complex with heat transferred on the rim to a cooling fin and through the central stud to the hardware. A first approximation may be obtained, as in Fig. 3(B), in which the original boundary B_{56} assumes a ring shape, having the same area as in Fig. 3(A), and so does the outer boundary B_{67}. The spherical sector of Fig. 3(B) must have the same volume as in 3(A) and must present the same stationary thermal impedance as the original. Fig. 3(C) shows another approximation in which the thermal impedance is the same as in Fig. 3(B) because the volume, the areas of the boundaries, and the diffusion distances are equal.

Limits of Time and Stationary Thermal Impedance

If the device is subdivided into sections, each section must be correlated to the neighboring sections. This is done by means of fixed values of time and stationary thermal impedance. Stationary thermal impedances, similar to electrical impedances, may be added when connected in series and their reciprocals are added when connected in parallel. Transient thermal impedances, however, may not be added for sections connected in series, because the definition refers each thermal impedance to a junction, both by the heat produced and the temperature rise of the junction. By adding another section, later in the heat diffusion, the thermal impedance of the device, referred to the junction, can only be affected when the heat reaches the section, and then only in the measure that this section affects the junction. An approximation by which each section is treated as a new semiconductor device with the incoming section area a new junction, is not correct. On the other hand, if the thermal impedances and the elapsed time are simply added up, the results are also incorrect. These assumptions neglect the vital difference of the heat diffusion close to the source (steep wave) and the entirely different heat diffusion further away. Hence, an approximation is chosen in which the distance between the heat source and the section under consideration represents the real condition.

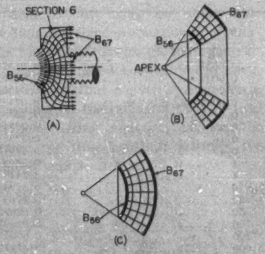

Fig. 3. Section of semiconductor device (A), first approximation of same section (B), final approximation of same section (C)

The thermal impedance of each new section is calculated by assuming that the section extends further than in reality, in both directions, towards the junction and away from the junction. The extension in the direction of the junction is made to obtain a stationary thermal impedance equal to the sum of the stationary thermal impedances of all the sections ahead of the section under investigation and between its initial boundary and a new fictitious junction. The transient thermal impedance is calculated from the new fictitious junction through the extension to the section and beyond. The heat diffusion wave reaches the end of the section when the transient thermal impedance reaches the total value of the stationary thermal impedance, referred to the end of the section. If the partial investigation is stopped at this point, the final thermal impedance is again equal to the sum of the stationary impedances from the real junction to the boundary under consideration. The diffusion time through the section is the difference of the time at which the transient thermal impedance is equal to the stationary thermal impedance at the end and the beginning of the section. The next section is treated similarly, by extending the section backwards to a new fictitious junction which creates an additional initial thermal impedance.

Briefly, each section is treated as a part of a homogeneous body which is heated by a properly located junction and into which the wave expands without obstacles. Transient impedance values are identical with partial stationary thermal impedances, their correlation establishes a time scale between impedance and heat pulse duration. When the heat wave has passed through the whole body, the final impedance is equal to the total stationary thermal impedance of the device.

The errors introduced with these assumptions are only tolerable if the investigation is applied to devices in which the incremental thermal impedance and mass show no excessive and sudden variations. The main error is that each analysis assumes that the thermal mass and conductivity per-unit volume of the preceding and following sections are identical with the section under consideration. For example, if a section with low specific heat follows a section of high specific heat, the transient thermal impedance rises much faster because the high specific heat of the preceding part is neglected.

Fig. 4 shows graphical representation of thermal impedances and times according to the foregoing assumptions. The origin O indicates the beginning of thermal diffusion when both time and transient thermal impedance are zero (the transient thermal impedance zero indicates that heat is diffusing immediately into a cold body). As heat diffuses at a steady rate into the body, the transient thermal impedance indicated by ζ_1 increases rapidly. The time is indicated by t_1. The stationary impedance of Z_1 of the first section is the limit for the transient thermal imped-

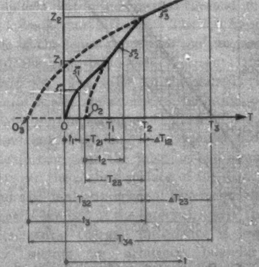

Fig. 4. Representation of nomenclature for thermal impedances and times

ance ζ_1; i.e., when the transient and the stationary thermal impedance of the first section are equal, it is necessary to assume that the heat diffusion has reached the point where the second section must be considered. The time at which the transient and stationary impedance of the first section are equal is T_1, the time limit for the first section.

Considering the second section, it is necessary to find a new origin O_2 which pertains only to the second section. This can be found if it is realized that the time T_{21} between the new origin and the time T_1, when the useful part of the approximation of the second section starts, is the time needed for the transient thermal impedance, referred to O_2, to reach the stationary thermal impedance Z_1. The running time t_2 for the second section, determines ζ_2, the transient thermal impedance. When it reaches the stationary impedance Z_2 (at the time T_{23} measured from O_2) the approximation for the second section reaches its limit of validity. The running time of the heat-diffusion wave in the second section is $T_2 = T_1 + \Delta T_{12} = T_1 + T_{23} - T_{21}$.

Fig. 4 shows also a third approximation in which the origin O_3 is put back by the time T_{32} required for the transient thermal impedance ζ_3 to reach the stationary thermal impedance Z_2 under the assumptions which were made for the equivalent body of the third section. The running time for the third section ΔT_{23} is again determined from the time required for the transient thermal impedance ζ_3 to increase from the stationary thermal impedance Z_2 to the new stationary impedance Z_3, and the time T_3, corresponding to the heat diffusion reaching the end of the third section, is computed by $T_3 = T_2 + \Delta T_{23} = T_2 + T_{34} - T_{32}$.

As plotted in Fig. 4, a solid-line plot of thermal impedance versus time is obtained. The method of successive approximations gives a correct interpretation of increasing impedance versus time, wherein each section which is further removed from the origin has a lesser increase of transient thermal impedance because of its remoteness, but an inherent rise of thermal impedance because of its physical characteristics (material and shape). Hence, ζ_2 rises steeply because of an inherently high thermal impedance but not as steeply as ζ_1, at the origin, which is due to closeness to the junction, although the inherent thermal impedance is lower.

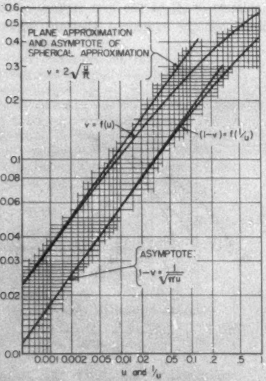

Fig. 5. Representation of equation $v = 1 - (1 - \Phi\sqrt{u})e^{u}$, shown as v versus u and $(1-v)$ versus $1/u$

Plane Approximation of a Homogeneous Section, Transient Thermal Impedance

Plane diffusion, as an approximation of this problem, is treated in reference 1. For short pulses the junction temperature is given in equation 20 of reference 1. Rewriting this equation in terms of transient thermal impedance gives:

$$\zeta = \frac{2\tau}{\sqrt{\pi} A}\sqrt{t} \tag{1}$$

This approximation is used in the immediate vicinity of the junction, as long as the heat-flow cross section remains essentially constant, as the heat wave progresses.

TIME SCALE

For each homogeneous layer, the transient thermal impedance, as calculated, is valid until the limit of equal transient and stationary thermal impedance is reached.

$$T = \left(\frac{\sqrt{\pi}}{2}\,\frac{AZ}{\tau}\right)^2 \tag{2}$$

where

$$Z = d/kA \tag{3}$$

or

$$T = \left(\frac{\sqrt{\pi}}{2}\,\frac{d}{p}\right)^2 \tag{4}$$

LIMITS OF TIME AND THERMAL IMPEDANCE

As shown for the spherical approximation, values of time and thermal impedance for successive sections can be matched by referring them back to a fictive junction.

Spherical Approximation of a Homogeneous Section

The device is subdivided into sections which are linked with each other by the limits of time and thermal impedance which are associated with the BEGIN and the END of the thermal-diffusion wave reaching and passing through each section.

Before the BEGIN the transient temperature rise of the particular section is negligible; after the END it is nearly equal to the stationary case.

Assuming that heat diffuses evenly into a homogeneous body which has the shape of a spherical sector, the lines of heat flow or heat diffusion will be straight and converge into a single point which is outside the body. All the areas of simultaneously equal temperature and heat-flow density are spherical and have this conversion point as a center. Lateral boundaries are formed by a generalized cone which is assumed to be a thermal insulator. The apex of the cone is formed by the conversion point of the flow lines. Fig. 3 shows a section of a practical body and its equivalent spherical sector, either as a ring sector or a solid sector. The numerical adaptation of any section of a real device to the spherical approximation is shown in Appendix I.

IMPEDANCE SCALE

The approximation by spherical diffusion is treated in reference 1, but there only a spherical sector with an opening angle of 180 degrees (hemisphere) is considered. The present analysis considers a general spherical sector of any solid opening angle. The basic equations presented in the former paper are written for the temperature rise of the junction (equation 51 in reference 1) and referred to heat-flow density and local tempera-

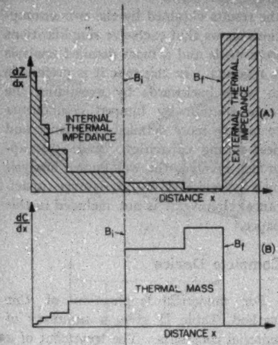

Fig. 6. Change in incremental thermal impedance (A) and capacity (B) versus distance from junction for semiconductor device

tures only and as such, are valid for any opening angle. Rewritten for the transient thermal impedance, the ratio of the temperature rises during the transient and steady-state condition for equal heat flow (of an infinitely large body) is equal to the ratio of thermal impedances for transient and steady-state heating. Equations 5 and 6 define the thermal impedances:

$$\zeta=\theta/q \tag{5}$$

$$\zeta_\infty=\theta_\infty/q=\frac{1}{\omega r_j k} \tag{6}$$

With the expressions for the solid angle and the junction radius defined by equations 21, 24, and 25, the transient thermal impedance of the infinite body is given by equation 7.

$$\zeta_\infty=\frac{1}{k\sqrt{\omega}\sqrt{A_j}}=\frac{Z_e\sqrt{A_e}-Z_b\sqrt{A_b}}{\sqrt{A_e}-\sqrt{A_b}} \tag{7}$$

TIME SCALE

Normalizing the time variable in the equation of thermal impedance can also be achieved by using the same time constant as defined in equation 52 of reference 1 and rewritten for the more generalized nomenclature defined in the foregoing. The time constant is given by equation 8, depending on the radius of the spherical junction. Using equation 25 for the radius, the time constant assumes the value of equation 9.

$$\Theta=(r_j/p)^2 \tag{8}$$

$$\Theta=\frac{\Delta Z^4}{\tau^2\left(\frac{1}{\sqrt{A_b}}-\frac{1}{\sqrt{A_e}}\right)^2\left(\frac{Z_e}{\sqrt{A_b}}-\frac{Z_b}{\sqrt{A_e}}\right)^2} \tag{9}$$

This time constant greatly simplifies the following equations. Physically it represents, for heat diffusing into an infinitely deep spherical sector, the time required by the transient thermal impedance to each 57.2% of the stationary thermal impedance of the same sector.

Numerical Values of Transient Thermal Impedance and Time

Time and transient thermal impedance are normalized, according to equations 10 and 11. Equation 51 of reference 1 is rewritten in the form of 12(A) or (B). In this equation the complement of the error function appears, which is a characteristic of diffusion.

$$t/\Theta=u \tag{10}$$

$$\zeta/\zeta_\infty=v \tag{11}$$

$$v=1-(1-\Phi\sqrt{u})\epsilon^u \tag{12A}$$

$$v=1-(\mathrm{erfc}\,\sqrt{u})\exp u \tag{12B}$$

The numerical calculation of equation 12 is easy for small values of u because both functions are well tabulated. For large arguments u, numerical values are hard to obtain, because it is necessary to handle a great number of decimals to obtain only a few significant figures. Errors are common because the expression erfc $\sqrt{u}$ decreases to zero whereas the expression exp u becomes infinite.

Another approach for large arguments u, is given by equation 13 which contains an asymptotic series. It is valid for u larger than 7.5 with an error of less than 0.1%.

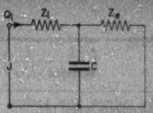
$$1-v=(\mathrm{erfc}\,\sqrt{u})\exp u=\frac{1}{\sqrt{\pi u}}\left[1-\frac{1}{2u}+\frac{3}{4u^2}-\frac{15}{8u^3}+\frac{105}{32u^4}\pm\ldots\right] \tag{13}$$

Numerical work is greatly simplified by using Fig. 5 and Table I which cover a wide range of values of the variables u and v. Beyond the given ranges the equations follow the indicated asymptotes. For low values of u this is equal to the plane approximation ($v=2\sqrt{u/\pi}$); for high values of u the series in equation 13 is unity ($1-v=1/\sqrt{u\pi}$).

Fig. 5 shows u and $1/u$ on a logarithmic scale on the abscissa, v and $1-v$ on another logarithmic scale on the ordinate, wherein v is a function of u and $1-v$ of $1/u$. Table I gives some values of v over a very wide range of u.

Long Pulses

Fig. 7. Equivalent circuit for heat dissipation for long pulses



The assumptions which led to the previous analysis were mainly that the semiconductor device contains continuously distributed heat-absorbing masses and thermal impedance arranged in a geometrical pattern. It was also assumed that no external heat-dissipation problems would arise during the short pulse duration of heat applied to the device. In reality, the diffusion wave reaches the boundaries of the device. If no other heat dissipation is provided, prolonged application of heat causes a temperature increase of the whole device. The increase of temperature of the surface over the ambient temperature causes heat dissipation to the atmosphere. At this stage these assumptions cease to be valid and another approximation must be used. The theory of continuous bodies becomes rather unwieldy and impractical if the problems of heat dissipation are also considered. One advantage of this theory which considers only mass and impedance is its flexibility, the ability to use it for almost any geometrical shape. By having to consider a third effect, this simplicity is lost because heat dissipation is not an equally distributed property of the materials. The difficulty is not as serious as it seems because it is only encountered for heat pulses which are relatively long, where the complexities of heat-wave propagation within the body of the semiconductor device lose their importance. The heat-diffusion wave, having expanded far enough to reach the outer boundaries of the device, leaves the inner sections at a temperature which is close to stationary heating and will be heated henceforth as one block.

Remaining in the realm of practical devices shows that the usual distribution of thermal masses lends itself to lumping of components. This is shown in Fig. 6(A) as a plot of incremental thermal impedance versus distance. The left-hand side of the figure represents the junction and the right-hand side represents the ambience. Fig. 6(B), on the same horizontal scale, shows the distribution of heat-absorbing masses. These figures show that a major lump of thermal impedance occurs near the junction and again between the cooling surface of the device and the ambient space. Inversely, the mass is lumped in the interval, where the incremental thermal impedance is low. By setting an arbitrary boundary B_i between the zone of predominant impedance and the zone of predominant

mass and another boundary B_c between the zones of predominant mass and of external heat dissipation, a lumped schematic diagram is obtained, Fig. 7. The internal thermal impedance Z_i represents the total sum of thermal impedances between the junction and the main mass of the device, whereas the external impedance Z_o represents the remainder of all thermal impedances counted from the main part of the mass to ambient space. The mass C is the sum of the product of the masses of the device times their specific heat.

The system is now subjected to a steady quantity of heat influx designated as Q_i flowing into the device through the internal thermal impedance Z_i.

Designate as θ the temperature rise of the junction (indicated by J) which follows equation 14:

$$CZ_o\theta'+\theta=Q_i(Z_i+Z_o) \qquad (14)$$

Solving for the temperature rise, and calculating as ζ the ratio of this temperature rise over the heat introduced at the junction, equation 15 is obtained:

$$\zeta_x=Z_i+Z_o[1-\exp(-t_x/CZ_o)] \qquad (15)$$

Correct initial conditions for this equation require matching to the prior analysis sections, such as for:

$$t_x=0,\ \zeta_x=Z_i,\ Z_i\approx Z_w \qquad (16)$$

and $t=t_x+T_w$

where the subscript x refers to the long pulse approximation, considered as another "section," and defined in the prior analysis. The subscript w refers to the last section analyzed before the lumped approximation is used. The time t is the running time measured on the same time base as for the other sections.

Graphical representation of the approximation follows the curves of the prior approximations without major deviation. If the assumptions are correct and within the properties of the device, the solution obtained by the two approximations should overlap in the interim range where the heat diffusion reaches the cooling surface. The time which appears in equation 15 is the same as the running time t of Fig. 4.

A substantial discrepancy between the results obtained by the two assumptions shows that excessive simplifications were made and a more detailed analysis is required. In this case it is preferable to work backwards by expanding the representation by lumped components to include more detailed impedance and heat-storing capacities. Since this approach involves the well-known analysis by a succession of *R-C* (resistance-capacitance) circuits, it is not included in this paper.

Complete Device

For numerical application of this method, Table II gives a summary of material constants. The treatment of a complete device is shown in detail in Appendix II.

Fig. 8 shows the cross section of a silicon diode, without enclosure or anode connector, together with the transient thermal impedance versus time curve for cathode cooling only. The numerical calculations for Fig. 8 are from Appendix II. This graphic representation shows how the successive approximations complement each other and that this method is flexible enough to cover very wide ranges of time and thermal impedances.

This method seems to be corroborated by the available test results. It is particularly helpful in guiding short-circuit or pulse load tests, in the interpretation of test curves, and in the analysis of failures. If the analysis must be undertaken with numerically inaccurate assumptions, the shape of the resulting curve helps to coordinate it with test results, which may be used to check back on the validity of the assumption.

Appendix I. Definitions of Spherical Approximation

The definitions of a spherical sector and its limits of thermal impedance and time are combined in Fig. 9. Fig. 9(A) shows the spherical section of a homogeneous

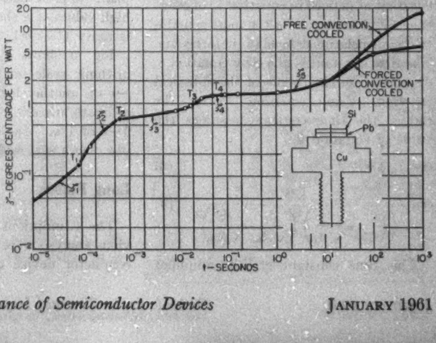

Fig. 8. Transient thermal impedance versus time for silicon diode analyzed in Appendix II

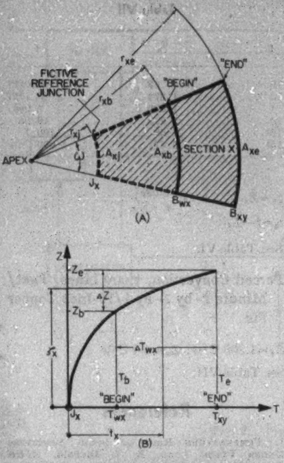

Fig. 9. Spherical section of homogeneous body (A) and its thermal impedances and times (B)

body. Section X refers to any section of the body which may be similar to Fig. 1. The spherical sector has an opening angle which is defined as a solid angle ω (and not a plane angle as shown in the figure). The solid angle is defined by the area A and the radius r of any spherical area which is cut out by the spherical sector. The solid angle is determined by equation 17. With this definition the stationary temperature rise follows equation 18.

$$\omega = A/r^2 \tag{17}$$

$$d\theta = -\left(\frac{q}{k\omega}\right)\frac{dr}{r^2} \tag{18}$$

Integrated within the boundaries of the BEGIN and the END of the section gives equation 19. The subscript x, pertaining to section X is omitted here. It is understood that these equations have different constants for each of the sections of the body.

$$\theta_b - \theta_e = \frac{q}{k\omega}\left(\frac{1}{r_b} - \frac{1}{r_e}\right) \tag{19}$$

$$\Delta Z = \Delta\theta/q = \frac{\dfrac{1}{r_b} - \dfrac{1}{r_e}}{k\omega} \tag{20}$$

Equation 19 gives also thermal impedance, as equation 20, in which ΔZ is the incremental thermal impedance of the section, between the BEGIN and the END as defined in Fig. 9(A). This incremental thermal impedance is also shown in Fig. 9(B) together with the time increment for this section.

Since the areas of the BEGIN and the END are known, equation 17 inserted in equation 20 yields the value for the solid angle, equation 21. This yields equation 22(A) and (B) for the radii shown in Fig. 9(A).

$$\omega = \left[\frac{\dfrac{1}{\sqrt{A_b}} - \dfrac{1}{\sqrt{A_e}}}{k\Delta Z}\right]^2 \tag{21}$$

$$r_b = \frac{\sqrt{A_b}\,k\Delta Z}{\dfrac{1}{\sqrt{A_b}} - \dfrac{1}{\sqrt{A_e}}} \tag{22A}$$

$$r_e = \frac{\sqrt{A_e}\,k\Delta Z}{\dfrac{1}{\sqrt{A_b}} - \dfrac{1}{\sqrt{A_e}}} \tag{22B}$$

Any particular analysis can only be fitted into the over-all analysis if the stationary thermal impedance Z_b at the BEGIN of the section is made equal to the stationary thermal impedance at the END of the previous section, indicated by Z_e in Fig. 9(B), i.e., stationary thermal impedances of successive sections must always be equal when referred to the same boundary. These boundaries are indicated in Fig. 9(B) by the letter B with the subscripts referring to the previous section w, section X under consideration, and the subsequent section y. The thermal impedance between the fictive junction J_x and the beginning B_{wx} of the section must be equal to Z_b. Equation 23 shows the value of this impedance which, when combined with equation 20, gives equation 24 for the area and equation 25 for the radius of the corresponding fictive reference junction of the section X.

$$Z_b = \frac{\dfrac{1}{\sqrt{A_j}} - \dfrac{1}{\sqrt{A_b}}}{\sqrt{\omega}\,k} \tag{23}$$

$$A_j = \left[\frac{\Delta Z}{\dfrac{Z_e}{\sqrt{A_b}} - \dfrac{Z_b}{\sqrt{A_e}}}\right]^2 \tag{24}$$

$$r_j = \frac{k\Delta Z^2}{\left(\dfrac{Z_e}{\sqrt{A_b}} - \dfrac{Z_b}{\sqrt{A_e}}\right)\left(\dfrac{1}{\sqrt{A_b}} - \dfrac{1}{\sqrt{A_e}}\right)} \tag{25}$$

These equations replace any section of a real device by a spherical section and determine a thermal impedance, characterized by a fictive junction which is remote from the section, a BEGIN area, END area, and a solid angle which numerically describes the lateral boundary (without requiring a more definite geometrical shape).

Appendix II. Example

As an example, see the device shown in Fig. 8 with the curve of transient thermal impedance versus time which is calculated in the following (see Table III).

Transient Thermal Impedance from Junction to Base

Plane Approximation.

1. Silicon (diffused junction):

$$\zeta_1 = \frac{2\tau_1\sqrt{t_1}}{A_1\sqrt{\pi}} = 14.55\sqrt{t_1}\ \text{C/w}$$

$$T_1 = \left(\frac{Z_1 A_1\sqrt{\pi}}{2\tau_1}\right)^2 = 9.12(10^{-5})\ \text{second}$$

$t_1 = t$	ζ_1

Hybrid Computers for Process Control

GEORGE BIRKEL, JR.
NONMEMBER AIEE

THERE is a need in industry for equipment of moderate complexity and cost capable of solving simple process control equations at high speed. Quite economical process control and processing of instrumentation data may be accomplished by a hybrid computer. This tool combines the best features of analog and digital systems with a simplicity and economy unavailable in either, to produce a unique combination which is capable of operating at extremely high speeds and accuracies, over large numerical ranges.

The Radiation Incorporated hybrid analog-digital (AD) computing technique is based upon AD conversion devices used as ratiometers and digital-to-analog (DA) conversion devices used as multipliers. Addition and subtraction are accomplished by digital logic and summation. Exponent bookkeeping retains the full accuracy of the data, with automatic adjustment of scale factors. Round-off of data is accomplished in the sense of "best fit."

Hybrid Computing

Process control systems often require some form of AD and DA conversion. DA conversion (decoding) provides an analog output signal directly proportional to the digital input and to the analog reference signal used; Fig. 1. That is, the output is directly proportional to the product of the digital input and the analog reference. The input multiplicand, X, is referred to the standard analog reference, R, or "unity." The multiplier, Y, is referred to the multiplicand

analog-conversion level as a reference. The result, $XRY=X\cdot 1\cdot Y=XY$, is an analog signal representing a product.

The DA converter is used as the multiplier for the hybrid computer because of its logical simplicity and speed. Multiplication requires one "bit" time, using this method.

The input to the DA converter consists only of the significant digits of a number properly normalized in standard floating-point format. Therefore,

$$2^{-1}\leqslant X<1,\ 2^{-1}\leqslant Y<1$$

The exponents x and y of multiplicand and multiplier are added together to obtain the conditional product exponent. From the foregoing,

$$2^{-1}\leqslant XY<1$$

After normalizing, the final product exponent will be $(x+y-h)$, where $h=0$ or 1.

The digital output of an AD converter is directly proportional to its analog input, W, and inversely proportional to its reference, Z. Therefore, the AD converter performs the equivalent of the division $W\div Z$; Fig. 2. The input $W\leqslant Z$ for proper operation of the equipment. If $W>Z$, W is attenuated by the fixed factor 2. When attenuation is required, the quotient exponent must be incremented. The dividend for a division may be the output of a DA converter or some data analog level. The divisor is the analog equivalent of the digital divisor required, referred to R. The exponents w and z, corresponding to the dividend and divisor, provide the quotient exponent $(w-z+g)$, where $g=0$ or 1 is determined by the attenuation condition. Division requires one "word" time.

A digital adder-subtractor is used. The AD converter operates serially, high-bit-first, to perform division. The output product-quotient has the exponent $(x+y+g-z-h)$, as noted before. Exponents x, y, and z are known at time of DA entries. Serial addition of significant bits of a term, 2^kK, may be started at time $(k-(x+y-z))$, with respect to AD

high-bit output, to adjust for exponent disparity. By delaying adder operation by one bit time, the effect of $g=1$ is provided. If $h=1$, the high bit of the product-quotient is 0, but no add-time compensation is needed. Parallel addition may be preferred.

Utilizing the AD converter for division and the DA converter for multiplication drastically reduces arithmetic costs, since the converters are usually in the process control system anyway. Moreover, the simplicity of hybrid multiplication and division ordinarily means less programing. Utilizing the programing inherent in multiplexing of raw data is straightforward for a hybrid system. (Programed multiplexing pioneered by Radiation Incorporated is a standard feature for the RADIPLEX units.) Where multiplication and division predominate, hybrid programing is especially simple. Most mathematical expressions of physical and engineering principles predominate in multiplication and division terms, with relatively few additions or subtractions. Such conversions may usually be performed with sufficient speed for time-sharing of raw data conversions and arithmetic operations.

Multiplication and division accuracies are functions of the converter quantizing errors. Round-off therefore, is taken in the sense of "best fit." Using the most stable standard references available and the best encoders available, accuracies of ±0.025% may be obtained at 384,000-bit comparisons per second. Normal care should be used to avoid errors due to "noisy" environments. The error due to the combined operations of multiplication and division may be simply measured by programing of simple numbers, for comparison with known results. This method of "confidence checking" is often included as a standard program feature, to periodically monitor system reliability, especially for remote locations designed for minimum maintenance and supervision.

Binary Floating-Point Numbers

Any number can be represented, to any desired degree of accuracy, in the floating-point form,

$$2^x(2^{-1}+A_2 2^{-2}+A_3 2^{-3}+\ldots+A_n{}^{x-n})$$

sometimes written as

$$(2 \exp x)\,(2^{-1}+A_2 2^{-2}+A2^{-3}+\ldots+A_n 2^{-n})$$

The representation is accurate to at least 1 part in 2^n or better.

The (2 exp x) part of the expression may be called the exponential scaling factor and may be arbitrarily large (or small). For example, 1,073,741,824 = 2 exp 30. Since the base 2 of the scaling factor is constant, the expression may be abbreviated by writing the exponent number only, followed by a period (.), e.g., 2 exp 30 may be written as +30., including the exponent sign. Since the base 2 is common, any two scaling factors (2 exp x) and (2 exp y) may be multiplied by addition of exponent numbers, e.g., (2 exp x) (2 exp y) = 2 exp $(x+y)$, written as $(x+y)$. Likewise, (2 exp x) ÷ (2 exp y) = 2 exp $(x-y)$, written as $(x-y)$.

The other part of the representation $X=(2^{-1}+A_2 2^{-2}+A_3 2^{-3}+\ldots+A_n 2^{-n})$, is called the significant digits part. Each of the coefficients, A_2, A_3, …, A_n, is either 1 or 0 in a binary system. Notice that X cannot be less than one half, but must be less than one.

Any number will be written in floating-point form, as:

exponent sign	exponent, base 2	·	significant digits = fraction	algebraic sign

The exponential scaling factor, including sign, is written as the binary equivalent of the exponent only and determines the relative size or scale of a number. The significant digits as a fraction $(<1, \geqslant 2^{-1})$ identify a number to the specified accuracy. The algebraic sign is the usual sign of the number.

The exponent scaling factor provides for arbitrarily large (or small) scaling factors, as required for any practical computer. The significant digits factor varies only over a 2-to-1 range, as required for a variable reference for AD encoding.

Exponent Bookkeeping

Available, fast, electronic AD converters require that the electrical reference used vary only over a restricted range. However, variation over a 2-to-1 range does not affect the linearity of the normal 12-bit binary-code output of the hybridized RADICON encoder. A practical computer requires an arbitrarily large scaling range. However, process control and most engineering and scientific computations require only a limited number of significant digits. Accuracies of 0.1% in calculations require only ten significant binary digits, which satisfies most practical requirements. (In a process control systems, the accuracy of the transducers, converters, and control elements, limits the accuracy needed from the controller.)

A hybrid system requires control of signals between all its converters. The output of $DA1$ must be suitable for use as a reference for $DA2$ operation; Fig. 3. Likewise, the output of $DA2$ must be compatible electrically with the requirements for inputs into AD. Also, the output of $DA3$ must be suitable for entry into AD as the reference. Floating-point restrictions on significant digit range variations, plus the advanced design of the RADIAN DA converter, satisfy the first and third requirement. However, the output of $DA2$ may be too high for comparison with the AD variable reference. Therefore, provisions are included for precomparing the two signals. If the $DA2$ output is too high, a provision for adjusting the signal exactly by a factor of one half is included. It is necessary that the exponent indicated for this operation then be incremented by 1. Since this (and some other operations) are in the analog domain, it may not properly be called a floating-point operation. To signify both digital and analog exponent scaling operations, the expression "exponent bookkeeping" is used.

The number of bits used for the exponent field depends upon the maximum (or minimum) exponent size anticipated. The number of bits used for significant digits is the number of bits provided by the converters. Wherever the logic for the system requires scale adjustment, the corresponding exponents are adjusted; thus, exponent bookkeeping has made hybrid computing not only possible but highly practical.

Basic Operational Cycle

Elimination of the usual digital multipliers and dividers and most instruction interpretation logic drastically simplifies process controller designs. The basic hybrid operational cycle is composed of parallel division, exponential, addition, subtraction, and multiplication computations. Maximum utilization of the cycle for a complete recycling of data would permit one division, several exponential operations, several additions or subtractions, and one multiplication per cycle.

Algebraically, the basic operational cycle is $((bx \div p)+a)$. The multiplicand b and multiplier x significant digits are gated into $DA1$ and $DA2$, respectively, Fig. 3. The divisor p significant bits are gated into $DA3$. The analog output of $DA2$ is compared to output of $DA3$, for

range compatibility. If *DA*2 output exceeds *DA*3 output, *DA*2 output is attenuated by 2, incrementing exponent for product-quotient by 1. Modified *DA*2 output is sampled as input to AD and *DA*3 output is used as AD reference, i.e., divisor. Digital output of AD becomes the addend into the adder, being added to the augend, *a*. (Other additions could have been performed during these operations, resulting in *a*.) The adder output is then ready as an input into the next cycle, in digital form.

Likewise, the operational cycle $((b \div q)+a)y)$ starts with the analog dividend *b* and divisor *q* to obtain a digital quotient from the AD converter. The quotient is then added to *a*. This sum is next multiplied by *y*, obtaining an analog product. The cycle may then be repeated.

Each of these cycles is a different form of the other and may be continuously repeated. Obviously, both analog and

digital inputs and outputs are available in any combination desired. (The time of availability will be different for a given form.) If an analog output is desired, rescaling may be required.

Programing

Cyclic programing is inherently simple. Operations occur in a definite sequence, requiring only that inputs for each operation be specified. A wide range of flexibility is thus provided. For process control and other applications where a wired-in program could be utilized for long periods of time, the sequence of data items may also be wired in. However, if random-data sequence is desirable, the data may be so entered. Usual memory media are used, although the operational cycle removes the need for storing some dynamic results which are in circulation instead. For some systems it is simpler to resample inputs than to store them.

Programing is analogous to operation of a conveyor belt. Every data item placed on the belt is available to every exit point or gate until removed. For example, a digital number input passes exits for addition (or subtraction), exits for storage in memory, exits for multiplication, and exits for division. The belt may be considered endless, repeating its operational cycle over and over. Programing consists of gating items onto the belt and removing them in proper sequence. Complicated instruction codes are unnecessary.

Successive operational cycles may be overlapped, e.g., additions and subtractions for cycle 3 may occur during multiplications for cycle 2 and division for cycle 1. Such overlapping is often convenient but by no means necessary. Programing can be automatic, of course, by addressing particular multiplexer or logic channels in the desired sequence.

Attention should be paid to the relative efficiencies of various approaches. Approximation techniques which depend on iterative improvements or convergence are ideal. Thiele's continued-fraction expansions are quite useful in hybrid programs in contrast to digital programs, where division is avoided when computing time must be minimized. Standard double or triple precision techniques, corresponding to the use of partial fractions, may be utilized. Branch points may be determined on the basis of residues as well as bit logic sequences, binary quotients, or limit functions.

When a computer is both very fast and relatively inexpensive, iterative computing programs are particularly desirable. If program exits require that two successive iterations agree, error is automatically reduced below the value of the least significant digit used. Even if a fast converging recurrence relation is not specifically known, some sort of logic and arithmetic interpolation test might be found to obtain iterative routines. For these reasons, the combined economy and extremely high operating speed of the hydrid computer may be used to virtually eliminate error effects in such programs. Since the equipment used is compatible with typical process control elements, minimum disturbance of normal operation may be anticipated for most applications.

Subroutines

To indicate the flexibility of the hybrid computer, various subroutines are described in the following sections. The similarities of the basic hybrid operational cycles to standard equations indicate the programing simplicity available. However, for complex programs, arithmetic program simplicity is relatively less important than logical simplicity. Since most programing logic functions are digital for large, complex programs, the programing system required is that of a general-purpose digital computer. A subroutine should be designed to utilize the full hybrid operational cycle wherever feasible.

SQUARE ROOT, FIG. 4

Since

$$(X^2 \div (X\pm\Delta)) = X \mp \Delta + \Delta^2/(X\pm\Delta)$$

a better approximation than $(X\pm\Delta)$ to $\sqrt{X^2}$ is

$$\frac{1}{2}\left((X\pm\Delta)+\frac{X^2}{X\pm\Delta}\right)=\frac{1}{2}\left((X\pm\Delta)+(X\mp\Delta)+\frac{\Delta^2}{X\pm\Delta}\right)=\frac{1}{2}\left(2X+\frac{\Delta^2}{X\pm\Delta}\right)=X+\frac{\Delta^2}{2(X\pm\Delta)}$$

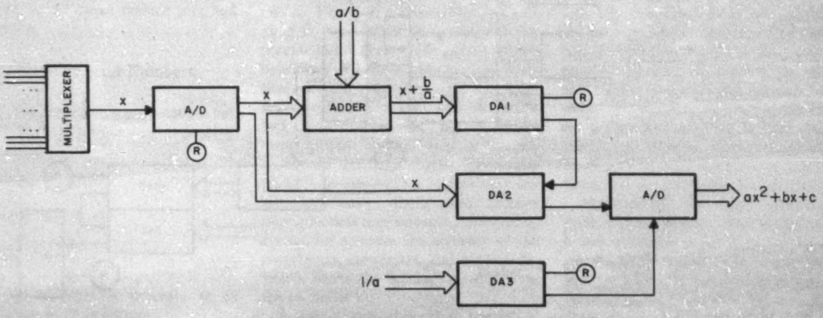

Fig. 7. Thermocouple (quadratic) linearization

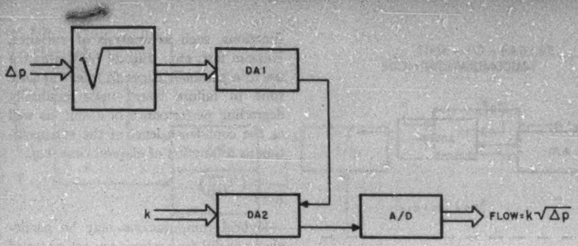

Fig. 8. Flow calculation

provided that

$$\Delta > \frac{\Delta^2}{2(X\pm\Delta)}$$

i.e., if

$$X > -\frac{\Delta}{2}; \text{ or } X > \frac{3\Delta}{2}$$

which is simply assured.

A simple principle permits obtaining $(X\pm\Delta)$, where $\Delta \leqslant X/40$, in a single addition and logic step from X^2. Since the square root of the exponent is exactly known, the principle is applied only to the significant digits. The argument term, X^2, is gated into $DA1$, "1/2" is gated into $DA2$, and the first approximation $(X\pm\Delta)$ is gated into $DA3$. Since the output of $DA2$ is the AD input and the output of $DA3$ is the AD reference, the coder digital output is the quotient, $1/2\ (X^2 \div (X\pm\Delta))$. When added to $1/2\ (X\pm\Delta)$, X is known accurately to about 1/3,120. Since the error is always positive, by subtracting 1/6,240, X is known to ±1/6,240, if necessary.

SINE FUNCTION, FIG. 5

A power-series approximation to sin $(\pi/2)\,x$, where $-1 \leqslant x \leqslant 1$, is $cx+bx^3+ax^5$, accurate to ±1/10,000, if enough digits are used. However, consistent with the use of 12 significant bits an accuracy of ±1/4,096 is adequate for most purposes. To calculate this algebraic form would require six cycles as shown; instead, the form

$$y=x\left(c+\frac{x^2}{1/a}\left(\frac{b}{a}+x^2\right)\right)$$

is used. First, x is gated into both $DA1$ and $DA2$. The AD output would be x^2 which is then added to b/a. The sum is then gated into $DA2$, x^2 is gated into $DA1$, and $1/a$ is gated into $DA3$. The AD output

$$a(x^2)\left(\frac{b}{a}+x^2\right)$$

is then added to c. The sum is placed in $DA1$, x is gated into $DA2$. The AD output is then the digital approximation to sin $(\pi/2)x$, ±1/4,096. Cos $(\pi/2)x$ may be similarly computed, or calculated as a function of sin $(\pi/2)x$.

POWER SERIES (GENERAL)

A power series may be developed term by term quite efficiently, since the hybrid basic operational sequence has the same form. However, as seen in the previous subroutine, the calculation form

$$\left(\left(\frac{xy}{q}+t\right)\frac{z}{p}+\ldots\right)$$

may be even more efficient.

RECIPROCAL FUNCTIONS

Sometimes it is desirable to multiply by the reciprocal of a number rather than use division, e.g., for an analog output preceded by "division." Reciprocal multiplication may be simply accomplished by using certain simple linear approximations of the form $y=(A-bx)$, computed by subtraction only, and improved by an iteration of the form $y(2-yx)=z$. As indicated, the product xy^2 is subtracted from $2y$. The resultant is equivalent to a cubic equation, but requires fewer computations than the power series. Reciprocal multiplication is used mostly on program constants, seldom on variables.

CONTINUED FRACTIONS

Continued fractions of the form $(a+b\div(c+d\div(\ldots)))$ are sometimes used for approximations. The calculation simply alternates division and addition. By factoring, addition may often be simplified by using a power of two as addend. A binary counter may then be used for addition.

For example:

$$e^x=1+\cfrac{x}{1-\cfrac{x}{2+\cfrac{x}{3\left(1-\frac{1}{3}\,\frac{(x)}{2+\ldots}\right)}}}$$

OTHER FUNCTIONS

Many other functions may be approximated with similar efficiencies. The best approximations for use with the hybrid computer predominate in multiplication and division. Finite difference techniques used are similar to those required for digital computers, or digital difference analyzers, except that a successive sampling may be used to obtain differences. Differential and integral equations are usually approximated by standard asymptotic, hypergeometric, and power-series expressions. For example, for small x,

$$J_P(x) \sim \frac{1}{2^P P!}\,x^P$$

is frequently used in solving second-order differential equations.

DATA FORMATS

Numerical bases other than 2 may be converted into binary form in the hybrid using standard conversion formulas. Likewise, fixed-point numbers may be converted into floating-point format. Outputs may be reconverted into other than floating-point formats, as required.

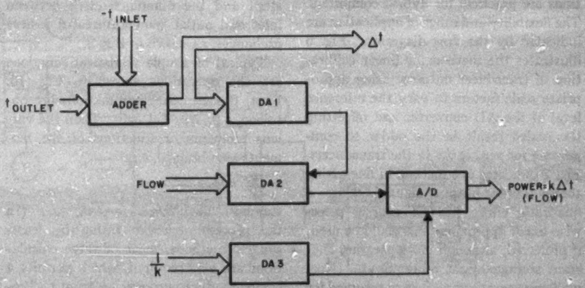

Fig. 9. Power calculation

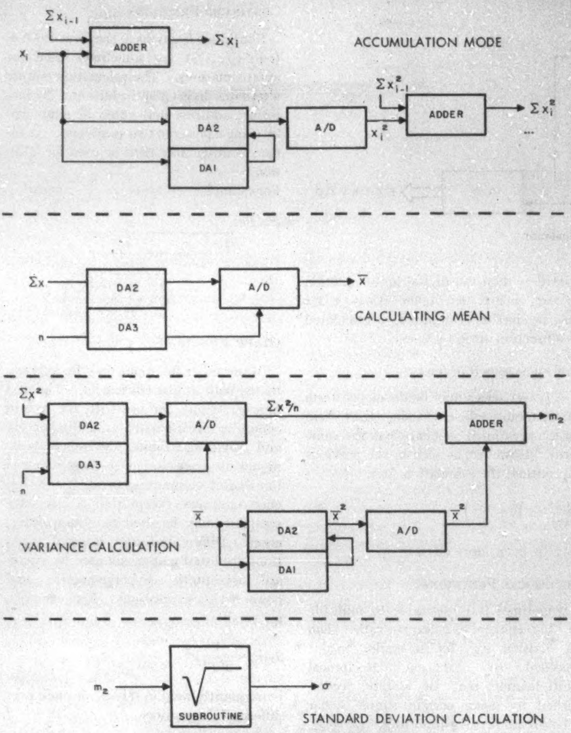

Fig. 10. Simple statistical calculations

The relative economy of multiplying and dividing may be utilized heavily in such conversions.

Applications

A wide range of process control operations are practical for hybrid computers. The flexibility and range of application are indicated by the flow diagrams. Fig. 6 illustrates the method for linear calibration of transducer outputs using appropriate scale factors to vary the reference level of the AD converter and offsetting the scaled result in the adder to compensate for zero shifts in the transducers. Fig. 7 indicates one method of linearizing thermocouple output signals, using a quadratic curve fit. Of course, piecewise linear approximations could be used, if preferred, although more program constant storage might be required. (Normalizing operations necessary assumed for all figures, although not specifically shown.) All basic units are used over and over, as in a digital computer.

Fluid flow through a system is sometimes calculated simply by an expression of the form $k\sqrt{\Delta p}$, as shown in Fig. 8. Power output is often calculated as the product of flow and some program constant and the difference (ΔT) between inlet and outlet temperatures of a heat exchanger, as shown in Fig. 9.

Typical of simple statistical functions are the operations shown in Fig. 10. First, the necessary summations are obtained, e.g., Σx, Σx^2, etc. Then the various moments or functions of the moments are obtained, e.g.,

$$\bar{x} = \Sigma x/n, m_2 = \Sigma x^2/n - \bar{x}^2$$

standard deviation $\sigma = \sqrt{m_2}$, ... (In the process of curve fitting by least-squares methods, most of these calculations are also required, which permits a compact dual-purpose program.) Programs are available for more complex functions, such as analysis of variance, Duncan test, etc. Fig. 11 illustrates the use of a parabolic curve fit to extrapolate time to failure based upon gradually degrading performance of a unit, as well as the confidence level of the extrapolation as a function of elapsed time, e.g.,

$$R = e^{-\left(\frac{t_f - t_i}{t_f}\right)}$$

Hybrid computations may be particularly useful for preliminary estimates of material requirements. As a somewhat oversimplified example, consider Fig. 12 which illustrates the estimation of the weight (*kg*) of fissionable nuclear material required for a 2-group 4-region cylindrical critical reactor. The weight in kilograms is given by:

$$\text{Weight} = x(\pi R^2)\rho H$$

where

x = volumetric fraction of fissionable material
R = core radius
ρ = density constant for pure fission material
H = reactor height

The volumetric fraction, x, of fissionable material, or the reactor dimensions, R and H, are assumed to have been previously estimated to a satisfactory accuracy, probably by an iteration between upper and lower limits based upon radial buckling, macroscopic cross sections, and reflector properties.

System Compatibility

Because of its converters, a hybrid computer is compatible with a wide range of analog and digital devices. As indicated under "Applications," conversion of digital formats is feasible. An unusual feature is the possibility for hybrid operations with a normalized "Grey" or permuted binary code. By use of odd-even parity information, a Grey-code hybrid system is feasible.

Hybrid computers will probably be used most widely for supplementing more expensive or slower systems, doing simple routine calculations more efficiently than other machines. For example, by linearizing data to calibrate transducer system outputs, the hybrid computer frees more expensive or slower digital machines for more complex calculations which require general-purpose or universal logic capabilities.

The recycling nature of hybrid operations and the availability of both analog and digital inputs and exists, give the hybrid computer an iterative or feedback characteristic, highly compatible with process control systems.

Conclusions

Advances in analog-digital-analog conversion devices led to the development of a hybrid (analog and digital) computer. Floating-point multiplication and division can be accomplished in bit and word conversion times, respectively. Many iterations, interpolations, series, and asymptotic approximations can be accomplished in two or three operational cycles using conventional AD conversion units.

The hybrid computer will be used largely for linear calibration and linearization in the immediate future, but will find restricted use in nuclear process monitoring and alarm systems, simple batch control, and other simple but very repetitive operations. A novel use may be automatic checking of system functions. By observing the effect of placing an analog component between the DA and AD converters, a trouble-shooting routine over a range of conditions is obtained. By varying the input digital patterns into the DA units, the variations in the AD output will provide a close look into analog unit variations under dynamic conditions. Likewise, the perturbations due to process parameter variations might be examined, perhaps with some measure of optimization control. As with all interdisciplinary engineering, the computer designer must learn more about users' needs before the real utility of hybrid computing will be realized.

Hybrid computation techniques are adaptable to the solution of many simple problems of process control and computation where on-line computing is desired. These techniques combine the performance of digital and analog equipment to produce a unique combination capable of operating at extremely high speeds and at high accuracies. The low cost, small size, and low power consumption permit on-line, economical use of hybrid computers at remote locations.

The accuracy of a hybrid computer is defined by the accuracies of available converters and system logic extensions. Partial-fraction techniques may be used for any desired degree of accuracy at the cost of increased logic complexity. Analog control units are more restricted in accuracies. In the sense that an analog computer or any analog device could be inserted between the DA units and the AD unit, and any digital device including a computer, can be inserted between the AD and DA units, the hybrid computer represents most data acquisition and data-reduction systems and therefore has extremely universal characteristics. The systems described in this paper are concerned with the basic hybrid computer requirements.

In terms of immediate applications, the hybrid systems described will supplement or replace analog equipment when automatic setup capability or increased accuracies are required. Likewise, expen-

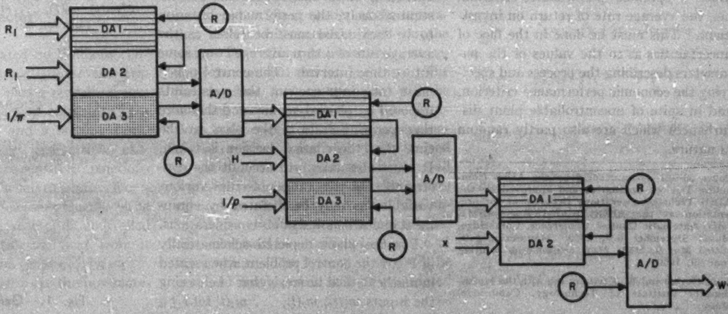

Fig. 12. Computation of $WT(K_e) = x \times (R_1^2/1/\pi)(H/1/\rho)$

sive digital computers will be relieved of routine linearizing and editing functions. The basic capability of a hybrid system is simple arithmetic transformation during its conversion from analog to digital or from digital to analog domains. If transformation from either domain to the other is needed in a system, then hybrid computing may be feasible.

The speed, accuracy, and flexibility requirements in an application establish basic hybrid system costs. A basic system requires one AD and three DA units, one significant digits adder, one exponent adder, one high-shift normalizer and one low-shift normalizer. Other system requirements determine information storage, gating, logic and programing needs. Obviously a hybrid system is most economical when its converters are required anyway. Parallel operations research, applications analysis, transducer design, and systems design programs will suggest better ways to utilize both analog and digital devices. The availability of both analog and digital process control information, derived from either analog or digital sources, should be a major advantage to some process control systems. Where such flexibility may be economically used will largely be determined by discussion with potential users of process control. Hybrid process control must be developed only where reductions of hazardous situations, relief of critical manpower situations, and increased yield-to-investment ratios are feasible.

Discussion

Floyd E. Nixon (The Martin Company, Orlando, Fla.): It is always difficult to tell how profound something is when you do not know your position in the forest. For example, techniques of computing which are very conventional and easy in digital computing will not appear profound to a digital man; but to accomplish these same mathematical objectives may be very difficult if analog computing techniques are used. Therefore, utilizing digital techniques might be extremely profound to an analog man. The same is true for reverse cases.

The technique of combining the most suitable analog or digital computing logic can and will lead to extremely profound results. Mr. Birkel is to be complimented for pointing out some of these areas; and both analog and digit circuit designers are to be alerted to the fact that they can develop significant computing devices by utilizing a combination logic to achieve their design.

George Birkel, Jr.: Mr. Nixon's discussion emphasizes critical points for today's (and tomorrow's) designers. Just as those of us who represent various aspects of the computer business should strive to understand other designers' viewpoints, just so the computer industry must look at process control from the users' viewpoints. In addition to advantages for some computing tasks, the use of hybrid computing tends to give designers a broader view of the whole system.

Although several new component and computer developments remain to be achieved, success in automating and controlling processes will lead us into a new era, an age of organization, adaptation, and application. As Mr. Nixon so aptly points out, successes will be bought at the cost of interdisciplinary understanding.

Dynamic Optimization and Control of a Stirred-Tank Chemical Reactor

L. A. GOULD
ASSOCIATE MEMBER AIEE

W. KIPINIAK
NONMEMBER AIEE

THE CONTROL of a chemical plant may be viewed as an attempt to vary the plant inputs in such a way as to maximize a specified performance criterion, i.e., the average rate of return on investment. This must be done in the face of uncertainties as to the values of the parameters describing the process and specifying the economic performance criterion, and in spite of uncontrollable plant disturbances which are also partly random in nature.

Since plant conditions and disturbances forever vary with time, and because the plant itself is a dynamic system whose operating state cannot be changed instantaneously, the performance criterion to be maximized must be taken as the average rate of return, averaged over some future time interval. The control policy must take into account the constraints imposed by plant dynamics and therefore the operating state of the plant at the time that the control decision is taken. It must also take into account the constraints on the range of the various variables as may be dictated by equipment limitations and safety considerations.

For the plant depicted schematically in Fig. 1 the control problem, when stated in mathematical terms, is that of choosing the inputs $m_1(t)$, $m_2(t)$, $\ldots$ $m_l(t)$ for $t \geq t_0$ to maximize the expected average rate of return $\mathcal{P}$, where

$$\mathcal{P}=E\left\{\frac{1}{t_e-t_0}\int_{t_0}^{t_e}[\mathcal{S}(q_1(t),q_2(t),\ldots q_k(t))-\mathcal{C}(m_1(t),m_2(t),\ldots m_l(t))]\,dt\right\} \qquad (1)$$

where

t_0 = present time, i.e., the time at which the control decision is taken
t_e-t_0 = time interval chosen for averaging rate of return
$\mathcal{S}[q_1(t), q_2(t), \ldots q_k(t)]$ = sales price of plant outputs $q_1, q_2, \ldots q_k$
$\mathcal{C}[m_1(t), m_2(t), \ldots m_l(t)]$ = cost of plant inputs $m_1, m_2, \ldots m_l$

Paper 60-982, recommended by the AIEE Computing Devices Committee and approved by the AIEE Technical Operations Department for presentation at the AIEE-AIChE-IRE-ISA-ASME Joint Automatic Control Conference, Cambridge, Mass., September 6–9, 1960. Manuscript submitted May 6, 1960; made available for printing June 29, 1960.

L. A. Gould and W. Kipiniak are with the Massachusetts Institute of Technology, Cambridge, Mass.

$\lambda_{Li} \leq m_i \leq \lambda_{Ui}$, $i=1, 2, \ldots l$, specify constraints on range of input variables

$dq_i(t)/dt = G_i(t;\ q_1, q_2, \ldots q_k;\ m_1, m_2, \ldots m_l)$, $i=1, 2, \ldots k$, represent dynamic relationships between system inputs and outputs

E = expectation operator indicating ensemble average over possible stochastic variations of cost functions $\mathcal{S}$ and $\mathcal{C}$, and of functions G_i, $i=1, 2, \ldots k$, which specify the system

Of the many methods available for solving this type of problem the approach of the calculus of variations is believed to be the most fruitful. It allows one to formulate the control problem for general performance criteria, subject to relatively weak restrictions on differentiability and concavity of the cost functions. The control law is then obtained in terms of the solutions of a boundary value problem associated with a set of ordinary differential equations. It is true that obtaining the solution is not a trivial matter and that it requires a considerable amount of computation, but it is well within the capabilities of modern computating devices. In many chemical processes, for example the one described below, the time scale is such that on-line solution of the control problem is feasible and the monetary gain is such as to justify considerable investment in the more sophisticated control equipment needed to perform such calculations.

It is not the purpose of this paper to discuss the variational method of control system synthesis in general; this has been done elsewhere.[1-3] Rather, an attempt will be made to show how this method is applied to a specific problem in chemical process control, namely, the control of the stirred-tank reactor postulated by Williams and Otto in their excellent paper.[4] This reactor is believed to represent a typical chemical process and the problems encountered in controlling it, typical of chemical process control in general.

The Williams Reactor

The plant postulated by Williams consists of a stirred-tank reactor fed two pure input streams plus a recycle stream and a separation section consisting of a distillation column and a settling tank. In the reactor three irreversible exothermic temperature-sensitive reactions take place to yield a mixture of six components in the reactor effluent. The temperature in the reactor is controlled by adding or subtracting heat from it through heating and cooling coils.

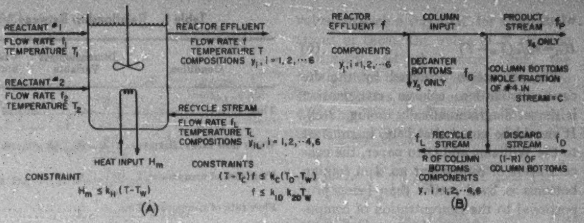

Fig. 2. Schematics of Williams plant. A—Reactor section. B—Separation section

Components 1 and 2 are the raw materials, no. 3 is an intermediate, no. 4 the desired product, no. 5 a tar, and no. 6 an inert substance. The tar is separated by cooling the effluent and allowing the tar, which is insoluble at low temperature, to settle. The desired product is then removed by distillation but the stripping is not complete because the product forms an azeotrope with column bottoms. The concentration of the inert is controlled by discarding a portion of the column bottoms while the remainder is recycled to the reactor. The supply of component 2 is assumed unlimited but the flow of component 1 is determined elsewhere in the plant and the reactor is required to process all that it receives.

The reactor through-put is limited by column capacity, which in turn depends on cooling water temperature. Reactor temperature and through-put are also limited by the ability of the cooler to reduce effluent temperature to the point where the tar will precipitate in the decanter. The rate of heat supply to the reactor, or its removal, is limited by the capacity of the reactor heating and cooling coils.

The above is an abridged description of the plant postulated by Williams. Reference is made to his paper for a more thorough description of the plant and for a derivation of the mathematical description of its behavior.[4]

In this study only the reactor will be considered. The operation of the separation section will manifest itself on the reactor only through limitations on reactor through-put and temperature. The recycle flow and composition will be assumed to be deterministic time functions independent of short-term fluctuations in reactor operation but constrained to satisfy, on the average, the over-all material balance. Thus, all the control settings in the recovery section, including the fraction of column bottoms being discarded, will be considered set at a constant value. The price structure will be assumed fixed and it will be postulated that the entire production of component 4 can be sold.

The reactor considered is shown schematically in Fig. 2(A) and the equations describing its behavior are listed in the following. The equations are all in normalized, dimensionless form and the relation between the normalized, dimensionless variables and those used by Williams is shown in Table I, together with the numerical values of the constants involved.

The reactions taking place are

$$
\begin{aligned}
&1(\text{no. }1)+1(\text{no. }2)\xrightarrow{r_1}2(\text{no. }3)\\
&1(\text{no. }2)+2(\text{no. }3)\xrightarrow{r_2}1(\text{no. }4)+2(\text{no. }6)\\
&2(\text{no. }3)+1(\text{no. }4)\xrightarrow{r_3}3(\text{no. }5)
\end{aligned}
\tag{2}
$$

The reaction rates are

$$
\begin{aligned}
r_1 &= y_1 y_2 e^{\alpha_1-\frac{\beta_1}{T}}\\
r_2 &= y_2 y_3 e^{\alpha_2-\frac{\beta_2}{T}}\\
r_3 &= y_3 y_4 e^{\alpha_3-\frac{\beta_3}{T}}
\end{aligned}
\tag{3}
$$

The material balance for each component is

$$
\begin{aligned}
\frac{dy_1}{dt} &= f_1+f_L y_{1L}-f y_1-r_1\\
\frac{dy_2}{dt} &= f_2+f_L y_{2L}-f y_2-r_1-r_2\\
\frac{dy_3}{dt} &= f_L y_{3L}-f y_3+2r_1-2r_2-2r_3\\
\frac{dy_4}{dt} &= f_L y_{4L}-f y_4+r_2-r_3\\
\frac{dy_5}{dt} &= -f y_5+3r_3\\
\frac{dy_6}{dt} &= f_L y_{6L}-f y_6+2r_2
\end{aligned}
\tag{4}
$$

The reactor heat balance is

$$
\frac{dT}{dt} = f_1 T_1+f_2 T_2+f_L T_L-fT+h_1 r_1+h_2 r_2+h_3 r_3+H_m \tag{5}
$$

where

$$H_m = k_H f_w (T_w - T) \qquad (6)$$

The separation achieved by the decanter-distillation column combination is shown diagrammatically in Fig. 2(B). It should be noted that here, in contrast to the Williams and Otto paper, the concentration of component no. 4 in column bottoms is fixed rather than being proportional to the concentration of component no. 6. Thus the various output streams are

$$f_P = f\left(\frac{y_4 - C(1-y_6)}{1-C}\right) \qquad (7)$$

$$f_G = f y_6 \qquad (8)$$

$$f_D = f(1-y_4-y_6)\left(\frac{1-R}{1-C}\right) \qquad (9)$$

The monetary rate of return is therefore

$$\mathcal{S} - \mathcal{C} = P_P f_P + P_D f_D + P_G f_G - P_A f_1 - P_B f_2 - P_U f - P_F \qquad (10)$$

In the above equations m(no. n) represents m units of component n; y_n = weight fraction of component no. n in the reactor, and y_{nL} = weight fraction in the recycle; r_i, $i = 1, 2, 3$ are the reaction rates, and h_i = corresponding amounts of heat liberated; f_1, f_2, and f_L = flow rates of components 1, 2, and of the recycle, and T_1, T_2, and T_L = the corresponding stream temperatures; f = effluent flow rate, and T = reactor temperature; H_m = heat input to the reactor; f_w = water or stream flow rates through the reactor cooling or heating coils, and T_w = corresponding temperature; f_P, f_G, and f_D = output flow rates of the product, the tar and the discard streams, and P_P, P_G, and P_D = sales values; P_A and P_B = costs of components no. 1 and no. 2, P_U = utility cost, and P_F = fixed plant charges; R = fraction of the column bottoms being recycled, and C = azeotrope point of no. 4 in column bottoms.

In order to achieve a satisfactory separation of component 5 in the decanter, the effluent temperature must be lowered to below a critical temperature T_c and $f(T-T_c)$ units of heat removed. The capacity of the effluent cooler can be expressed as $k_c(T_0 - T_w)$, where T_0 is the cooler outlet water temperature. This imposes a constraint

$$(T-T_c)f \leq k_c(T_0 - T_w) \qquad (11)$$

Similarly, column capacity can be represented as $k_{1D} - k_{2D}T_w$, which imposes a constraint

$$f \leq k_{1D} - k_{2D}\, T_w \qquad (12)$$

The reactor cooling-heating coils' capacity is represented as $k_H(T - T_w)$, which requires that

$$|f_w| \leq 1 \qquad (13)$$

Inequality constraints cannot be readily treated by the techniques of the calculus of variations, but their effect can be incorporated in the control law by including in the rate of return expression penalty functions which are analytic, and which subtract little from the return rate when the constraints are satisfied but a lot when they are exceeded. Ideally, these should represent the cast of the damage resulting from exceeding the set limits. In most cases, however, any convenient function which approximates this behavior can be used.

Thus in the following problem it is convenient to use a penalty function $F(x) = x^{16}$, whose argument is the ratio of the constrained variable to the constraint. The modified monetary rate of return is therefore written as

$$\mathcal{S} - \mathcal{C} - k_{p1} F\left(\frac{(T-T_c)f}{(T_0-T_w)k_c}\right) - k_{p2} F\left(\frac{f}{k_{1D} - k_{2D}\, T_w}\right) - k_{p3} F(f_w) \qquad (14)$$

and in this way the restrictions on the range of the system variables are effectively incorporated in the control problem.

The performance criterion to be maximized can now be written as

$$\mathcal{P} = \left\{\frac{1}{t_e - t_0}\int_{t_0}^{t_e}\left[P_P\left(\frac{y_4 - C(1-y_6)}{1-C}\right)\times f + P_D(1-y_4-y_6)\left(\frac{1-R}{1-C}\right)f + P_G y_6 f - P_A f_1 - P_B f_2 - P_U f - P_F - k_{p1}F\left(\frac{T-T_c)f}{(T_0-T_w)k_c}\right) - k_{p2} \times F\left(\frac{f}{k_{1D}-k_{2D}\, T_w}\right) - k_{p3}\, F(f_w)\right]dt\right\} \qquad (15)$$

The recycle flow rates and compositions

are treated as independent time functions, i.e., independent of reactor operation. They therefore have the status of disturbances. The function f_1 is also an independent time function determined elsewhere in the plant so that its variations are disturbances. Similarly, variations in the temperature of cooling water and feed streams are disturbances. It will be assumed, however, that they are all deterministic, so that the controller knows about them at least t_e-t_0 in advance. Under such circumstances the expectation operator can be dropped and the problem becomes purely deterministic at every time that a control decision is to be taken. (The design procedure being presented is capable of treating stochastic signals; this is one of its advantages. However, only the deterministic case will be treated here to keep the exposition simple.)

The system behavior for $t \geq t_0$ also depends on the current values of the state variables of the process. The state variables are those which cannot be altered instantaneously by any finite inputs and only their derivatives can change discontinuously. In this problem the reactor temperature T and the reactor compositions have this property, as shown in equations 4 and 5.

The control variables of the process are f_2 and f_w. The controller has to adjust them on the basis of its knowledge of the system state—values of $T(t_0)$ and $y_1(t_0)$, $\ldots y_5(t_0)$—and the values of disturbances for $t_0 \leq t \leq t_e$. The function which defines the value of $f_2(t_0)$ and $f_w(t_0)$ to be applied for the current system state and future disturbances is the control law. The object of the design procedure is to find the control law which maximizes $\mathcal{P}$.

Euler Equations for the Williams' Reactor

To maximize $\mathcal{P}$ as expressed in equation 15 by the variational calculus, one attempts to choose the time functions involved in such a way that, for small variations in them, the value of $\mathcal{P}$ remains stationary. At the same time, the relationships between the control and the state variables, as expressed by equations 4 and 5, must be maintained. To do this one forms a new performance criterion:

$$\begin{aligned}\mathcal{P}=\Bigg\{\frac{1}{t_e-t_0}\int_{t_0}^{t_e}\Bigg[\Bigg(&P_P\left(\frac{y_4-C(1-y_5)}{1-C}\right)+\\&P_D(1-y_4-y_5)\left(\frac{1-R}{1-C}\right)+\\&P_G y_5-P_U\Bigg)f-P_A f_1-P_B f_2-P_F-\\&k_{P1}F\left(\frac{(T-T_c)f}{(T_0-T_w)k_c}\right)-k_{P2}\times\\&F\left(\frac{f}{k_{1D}-k_{2D}\,T_w}\right)-k_{P3}F(f_w)+\\&\omega_1\,(-y_1'+f_1+f_L y_{1L}-fy_1-r_1)+\\&\omega_2\,(-y_2'+f_2+f_L y_{2L}-fy_2-r_1-r_2)+\\&\omega_3\,(-y_3'\quad+f_L y_{3L}-fy_3+2r_1-\\&\quad 2r_2-2r_3)+\\&\omega_4(-y_4'\quad+f_L y_{4L}-fy_4\ +r_2-r_3)+\\&\omega_5\,(-y_5'\qquad\quad -fy_5\quad +3r_3)+\\&\omega_6(-T'+f_1T_1+f_2T_2+f_LT_L)-\\&\quad fT+h_1\,r_1+h_2\,r_2+h_3\,r_3+k_Hf_w\times\\&\qquad\qquad (T_w-T)\Bigg]dt\Bigg\}\end{aligned} \quad (16)$$

and requires that $\mathcal{P}$ be stationary not only with respect to variations in $f_2, f_w, y_1, \ldots y_5, T$, but also with respect to variations in $\omega_1, \omega_2, \ldots \omega_6$. Clearly the only way $\mathcal{P}$ can be stationary with respect to variations in $\omega_1, \omega_2, \ldots \omega_6$ is for their coefficients to vanish, i.e., for the constraint equations to be satisfied. Furthermore, when the constraint equations are satisfied, $\mathcal{P}$ of equation 16 has the same value as $\mathcal{P}$ of equation 15. The variables $\omega_1, \omega_2, \ldots \omega_6$ so introduced are often called the Lagrange multipliers.[8]

Taking variations of $\mathcal{P}$ with respect to the time functions involved and equating them to zero, one obtains

$$\begin{aligned}\delta_{f_2}\mathcal{P}=0=-\omega_1y_1-\omega_2(y_2-1)-\omega_3y_3+&\\ y_4\left[P_P\frac{1}{1-C}-P_D\frac{1-R}{1-C}-\omega_4\right]+&\\ y_5\left[P_P\frac{C}{1-C}-P_D\frac{1-R}{1-C}+P_G-\omega_5\right]+&\\ \omega_6(T_2-T)-\Bigg[P_B+P_U+&\\ P_P\frac{C}{1-C}+P_D\frac{1-R}{1-C}\Bigg]-&\\ \frac{\partial}{\partial f}\left[k_{P1}\,F\left(\frac{(T-T_c)f}{(T_0-T_w)k_c}\right)\right]-&\\ \frac{\partial}{\partial f}\left[k_{P2}\,F\left(\frac{f}{k_{1D}-k_{2D}\,T_w}\right)\right]&\end{aligned} \quad (17)$$

$$\delta_{\omega_4}\mathcal{P}=0=-y_4'+f_Ly_{4L}-fy_4+r_2-r_3 \tag{28}$$

$$\delta_{\omega_5}\mathcal{P}=0=-y_5'\quad-fy_5\quad+3r_3 \tag{29}$$

$$\delta_{\omega_6}\mathcal{P}=0=-T'+k_Hf_w(T_w-T)+h_1r_1+h_2r_2+h_3r_3+f_1T_1+f_2T_2+f_LT_L-fT \tag{30}$$

where x' denotes dx/dt.

If one uses $F(x)=x^{16}$ as the form of the penalty function, equations 17 and 18 can be solved for f_2 and f_w, to yield

$$f_2=-f_1-f_L+\Bigg\{\Bigg[-\omega_1 y_1-\omega_2(y_2-1)-\omega_3 y_3+y_4\left(P_P\left(\frac{1}{1-C}\right)-P_D\left(\frac{1-R}{1-C}\right)-\omega_4\right)+y_5\left(P_P\left(\frac{C}{1-C}\right)-P_D\left(\frac{1-R}{1-C}\right)+P_G-\omega_5\right)-\omega_6(T_2-T)-\left(P_B+P_U+P_P\left(\frac{C}{1-C}\right)+P_D\left(\frac{1-R}{1-C}\right)\right)\Bigg]\Bigg/\left[16\,k_{P1}\left(\frac{(T-T_c)}{(T-T_w)k_c}\right)^{16}+16\,k_{P2}\left(\frac{1}{k_{1D}-k_{2D}T_w}\right)^{16}\right]\Bigg\}^{1/15} \quad (31)$$

$$f_w=\left\{\frac{\omega_6 k_H(T_w-T)}{16k_{P2}}\right\}^{1/15} \quad (32)$$

When these are substituted into equations 19 through 30 there results a set of 12 ordinary first-order differential equations in the state variables $y_1, y_2, \ldots y_5, T$, and the Lagrange multipliers $\omega_1, \omega_2, \ldots \omega_6$. These are the Euler equations for this problem.

The Euler equations are collectively of twelfth order and so 12 boundary conditions are needed to specify the solutions. The solutions represent the set of functions $y_1, y_2, \ldots y_5, T$, which for a specified change in operating state—from $y_1(t_0), y_2(t_0), \ldots y_5(t_0), T(t_0)$ to $y_1(t_e), y_2(t_e), \ldots y_5(t_e), T(t_e)$—maximize $\mathcal{P}$. At the time the control decision is taken, the present state of the system specifies $y_1(t_0), y_2(t_0), \ldots y_5(t_0), T(t_0)$. The conditions at $t=t_e$ and, for that matter, the value of t_e remain to be specified. Since the time over which the rate of return is to be averaged is probably many times the characteristic time constant of the system, t_e may be considered to approach infinity. If the expected values of the disturbances can be considered to approach constant values, the optimum solutions of the Euler equations must approach the steady-state optimum. Thus, at $t=t_e$, $y_1, y_2, \ldots y_5, T$ must all equal the values which yield a maximum of $\mathcal{P}$ in the steady state, and t_e must be large with respect to the characteristic time constants of the system.[2,3]

The boundary conditions on the solution of the Euler equations are specified at two points in time. Therefore, one must solve a 2-point boundary value problem. The values of the control efforts f_2 and f_w depend on $\omega_i(t_0)$, $i=2, \ldots 6$, and thus depend on the solution of the 2-point boundary value problem. Other ways of formulating the problem result in different specifications on $y_1, y_2, \ldots y_5, T$ at $t=t_e$, but in every case there results a 2-point boundary value problem. In every case, therefore, the control law is a function specified by the solution of a boundary value problem and the controller becomes a boundary-value problem solver.

Steady-State Optimization

Before solving the Euler equations and calculating the optimum control law, it was necessary to establish the desired values of the state variables at $t=t_e$, i.e., the values which result in maximum steady-state $\mathcal{P}$. For this purpose a computer program was written to map out the steady-state profit function for various operating conditions and to determine the optimum setting of the control variables f_2 and f_w for specified values of f_1 and cooling water temperature T_w.

To satisfy the steady-state material balance, the recycle flow rate and composition were made functions of reactor effluent flow rate and composition. Reference to Fig. 2(B) shows these relations to be

$$f_L=(1-y_4-y_5)\left(\frac{R}{1-C}\right)f \quad (33)$$

$$f_L y_{iL}=Ry_i f,\ i=1,2,3,\text{ and }6 \quad (34)$$

$$f_L\, y_{4L}=(1-y_4-y_5)\left(\frac{CR}{1-C}\right)f \quad (35)$$

and, since $f=f_1+f_2+f_L$, then

$$f=\frac{f_1+f_2}{1-(1-y_4-y_5)\left(\dfrac{R}{1-C}\right)} \quad (36)$$

In this way the over-all material balance is satisfied and variations in f_L considered in the dynamic optimization will be required to have an average value satisfying equation 33.

Examination of equation 5 indicates that the reactor itself is dynamically unstable. Therefore, it was not possible to simulate the reactor equations to compute $\mathcal{P}$ for various values of f_w. Instead, equation 4 was solved assuming T fixed, $\mathcal{P}$ was evaluated, and then f_w was chosen so as to satisfy equation 5 in the steady state.

Therefore the conditions to be satisfied in the steady state were

$$\begin{aligned}
&f_1-y_1(1-R)f && -r_1 &&=0\\
&f_2-y_2(1-R)f && -r_1-r_2 &&=0\\
&-y_3(1-R)f && +2r_1-2r_2-2r_3 &&=0\\
&-\left(y_4-(1-y_4-y_5)\ \frac{CR}{1-C}\right)f && +r_2-r_3 &&=0\\
&-y_5 f && +3r_3 &&=0
\end{aligned} \quad (37)$$

and

$$\mathcal{P}=\left(P_P\left(\frac{y_4-C(1-y_5)}{1-C}\right)+P_D(1-y_4-y_5)\times\left(\frac{1-R}{1-C}\right)+P_G y_5-P_U\right)f-P_A f_1-P_B f_2-P_F \quad (38)$$

In this way $\mathcal{P}$ was calculated for the set of cost functions given by Williams, a mean annual cooling water temperature of 0.8125 (dimensionless units) and a whole range of values for f_2 and T. This was repeated for $f_1=0.1292$, 0.1512, and 0.1722, corresponding to the average flow rate of f_1 and its extreme variations. The results are shown in Fig. 3, and the contours of constant profit $\mathcal{P}$ in Fig. 4. When the general character of the profit surfaces was established, "hill-climbing" techniques were used to find the optimum settings of f_2 and T, and therefore of f_2 and f_w. These are shown plotted in Fig. 5 for a cooling water temperature of 0.8125. Similarly, the optimum settings were determined at a cooling water temperature of 0.828125 and an inlet stream temperature of 0.84375 (this corresponds to the highest average temperature); the results are included in Fig. 5.

Examination of the response surfaces shows them to be smooth unimodal functions departing but little from a quadratic surface. Hence steady-state maximization was especially easy. Maximum achievable $\mathcal{P}$ for various values of f_1 vary relatively little, and variations in the optimum settings of f_2 and T are also small. Yet the optimum settings for one value of f_1 yield surprisingly poor values of $\mathcal{P}$ for a different value of f_1. Thus, at $f_1=0.1512$, choosing $f_2=0.3500$ and $T=1.02$ yields $\mathcal{P}=0.383$. At $f_1=0.1292$, $f_2=0.3295$ and $T=1.01$ gives a $\mathcal{P}$ of 0.395. Yet, at $f_1=0.1292$, using $f_2=0.3500$ and $T=1.01$, $\mathcal{P}$ is 0.331, i.e., a 16% reduction in profit! This can be taken as an indication of the necessity of precise process control. At the same time, $\mathcal{P}$ seems to be increasing as f_1 decreases, indicating the desirability of a larger reactor, i.e., longer residence time. It must be borne in mind that these conclusions are subject to the assumptions made in deriving the model of the process. For the actual plant, such conclusions

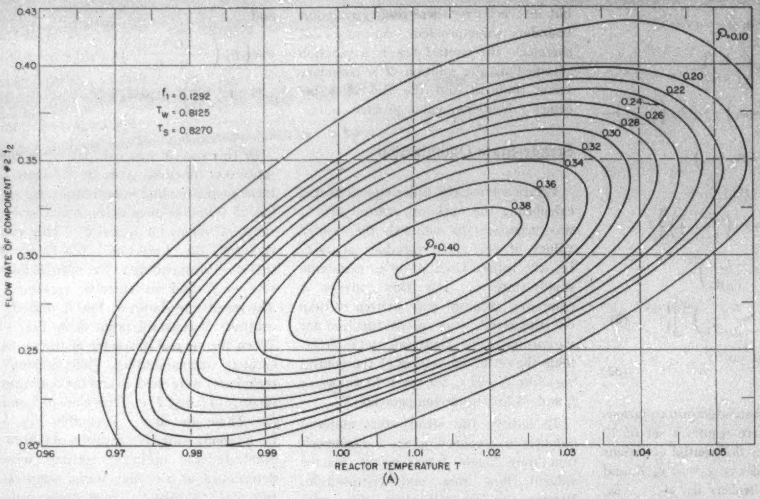

Fig. 4. Steady-state profit function contours A—At f_1= 0.1292. (For B and C see facing page)

may not be justified; they are presented here only as an indication of what can be determined in the initial stages of the optimization study. It must also be noticed that the optimum reactor conditions are not those specified by Williams, i.e., the profit functions do not agree with Figs. 20, 22, and 23 of his paper. One reason for this is that the azeotrope in the column was treated differently; another is that (in so far as is known to the authors) Williams' curves were obtained by varying one variable at a time, in particular by varying f_2 while keeping f_L fixed. In this problem f_L was tied to f_1 and f_2 by equations 33 and 36; hence the difference. Of course, for the conditions suggested by Williams, $f_1=0.1512$, $f_2=0.3475$, $T=1.00$, Fig. 4(B) indicates a $\mathcal{P}$ of 0.308 which is the same as shown by Williams. And yet the maximum $\mathcal{P}$ is found to be 0.383, an improvement of 24% or a monetary gain of $208,500 per year.

Calculation of the Control Law

The optimum control law for the reactor is given as a solution of the 2-point boundary value problem associated with the Euler equations; see equations 19 through 30. The boundary conditions are the values of the initial conditions of the system at $t=t_0$ and the optimum steady-state values of the variables at $t=t_e$. Therefore the controller has to choose a set of values, $\omega_1(t_0)$, $\omega_2(t_0)$, ... $\omega_6(t_0)$, which, for the existing state of the system $y_1(t_0)$, $y_2(t_0)$, ... $y_5(t_0)$, $T(t_0)$, will yield a solution of the Euler equation which satisfies the boundary conditions at $t=t_e$. Then, from the values of $\omega_i(t_0)$, $i=1,2$, ... 6, the controller can calculate the control variables $f_2(t_0)$ and $f_w(t_0)$. Unfortunately there is no direct method of choosing $\omega_i(t_0)$, $i=1, 2, \ldots 6$, since the equations are nonlinear and recourse to numerical trial-and-error solutions is necessary.

One possible method of solution makes use of the familiar hill-climbing techniques. The controller guesses a set of values of $\omega_i(t_0)$, $i=1, 2, \ldots 6$, and solves the Euler equations from $t=t_0$ to $t=t_e$. In general, the solution at $t=t_e$ will not satisfy the desired boundary conditions, so some criterion must be established to indicate how close to the desired point the solution passes. Since the primary objective of the solution is the maximization of $\mathcal{P}$, it is not reasonable to use the profit accumulated between t_0 and t_e as the indicator. Thus one attempts to find $\omega_i(t_0)$, $i=1, 2, \ldots 6$, to maximize

$$\mathcal{P}_a=\int_{t_0}^{t_e}(\mathcal{S}-\mathcal{C})\,dt$$

where the time functions y_1, y_2, ... y_5, T are the solution of the Euler equations with initial conditions $y_1(t_0)$, $y_2(t_0)$, ... $y_5(t_0)$, $T(t_0)$, $\omega_1(t_0)$, $\omega_2(t_0)$, ... $\omega_6(t_0)$. For sufficiently large t_e the values of $\omega_1(t_0)$, $\omega_2(t_0)$, ... $\omega_6(t_0)$ which maximize $\mathcal{P}_a$ approach those for which the solution of the Euler equations satisfies the desired end-point boundary conditions.

In this way the problem of finding functions $f_2(t)$, $f_w(t)$, $t_0 \leq t \leq t_e$, which maximize a functional, is reduced to a problem of finding variables to maximize a function, and this can be solved by any one of many hill-climbing techniques. Both the hill climbing and the solution of the Euler equations can be done "on line" by any of the modern computers.[2,3]

The above method of solution is a time-consuming process and would not normally be employed. Instead, one would obtain many solutions of the boundary-value problem and tabulate the values of $\omega_i(t_0)$, $i=1, 2, \ldots 6$, and therefore $f_2(t_0)$ and $f_w(t_0)$, as functions of $y_1(t_0)$, $y_2(t_0)$, ... $y_5(t_0)$, $T(t_0)$. To do this it has been found most efficient to generate solutions of the Euler equations from $t=t_e$ backward in time toward t_0. If $y_1(t_e)$, $y_2(t_e)$, ... $y_5(t_e)$, $T(t_e)$ are the set desired terminal conditions, then, for any set of $\omega_1(t_e)$, $\omega_2(t_e)$, ... $\omega_6(t_e)$, a solution will be generated which yields some $y_1(t_0)$, $y_2(t_0)$, ... $y_5(t_0)$, $T(t_0)$, $\omega_1(t_0)$, $\omega_2(t_0)$, ... $\omega_6(t_0)$, and the corresponding $f_2(t_0)$, $f_w(t_0)$. For this set of $y_1(t_0)$, $y_2(t_0)$, ... $y_5(t_0)$, $T(t_0)$ the corresponding $f_2(t_0)$ and $f_w(t_0)$ are the optimum settings of the control variables and so a point has been tabulated for the optimum control law functions

$$f_{2\,\mathrm{opt}}(t_0)=F_2[y_1(t_0), y_2(t_0), \ldots y_5(t_0), T(t_0)] \tag{39}$$

$$f_{w\,\mathrm{opt}}(t_0)=F_w[y_1(t_0), y_2(t_0), \ldots y_5(t_0), T(t_0)] \tag{40}$$

Thus, every time the Euler equations are solved, a point of F_2 and F_w is gen-

Fig. 4. B—At $f_1=0.1512$

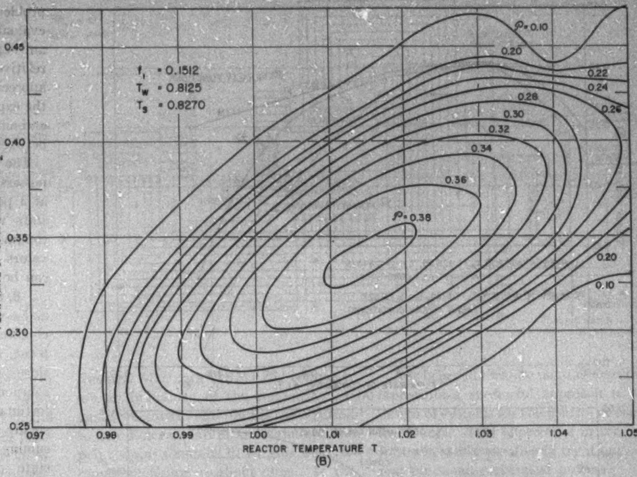

Fig. 4. C—At $f_1=0.1732$

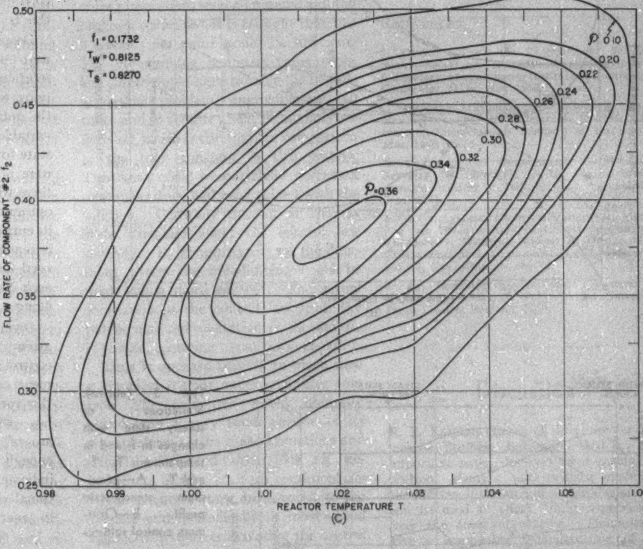

erated and in this way the complete tabulation can be obtained. Needless to say, the number of entries may be very large, but in such a case one would obtain polynomial approximations to F_2 and F_w, thereby characterizing them by a relatively small number of parameters.

Once the functions have been obtained, the controller measures $y_1(t_0)$, $y_2(t_0)$, ... $y_5(t_0)$, $T(t_0)$, and from these generates $f_2(t_0)$ and $f_w(t_0)$ according to F_2 and F_w. For use by a digital controller F_2 and F_w may be represented in terms of the coefficients of the describing polynomials; for use by an analog controller these may be synthesized by analog function generators.

Tabulation of the control function, though simple in principle, is nevertheless difficult to carry out in practice. The Euler equations are always inherently unstable whether solved forward or backward in time.[1-3] Small changes in the initial conditions at $t=t_s$ cause large changes in the values of the solution at $t=t_0$, so it is not easy to spot points in the region of the domain of F_2 and F_w that are of interest. This is further aggravated by the presence of constraint functions F with sharp cutoff characteristics. In the problem being presented this leads to the evaluation of $f_2+f_1+f_L$ as the 15th root of an expression involving differences of relatively large numbers. If $f_2+f_1+f_L$ is appreciably less than 1, then the value of the expression must be very small indeed and must be obtained as a small difference between large numbers.

The Euler equations are known to possess a saddle-point type of singularity at a point in the phase space for which state variables yield a steady-state optimum.[8] If the steady-state optimum values are known, Lagrange multipliers can be chosen to make $\omega_i(t_e)=0$, $i=1,2, \ldots 6$, thereby defining the singular point, and so all the conditions at $t=t_e$. By choosing small perturbations from this point, solutions which diverge relatively slowly are obtained, thereby keeping the solutions in the domain of interest. Unfortunately, in the current problem the steady-state optimum was chosen assuming f_L tied to f_1 and f_2. The steady-state optimum of the Euler equations corresponds to an independent f_L; hence this trick cannot be used.

Despite these difficulties, solution points were obtained and the corresponding solutions are shown in Fig. 6. The solutions, when plotted forward in time, show the optimum path along which the state variables would move from the current state to the steady-state optimum if there were no disturbances. Needless to say, there will always be disturbances and the optimum path will never be followed in its entirety until the steady-state optimum is reached (otherwise there would be no need for dynamic control), but following each disturbance the system is redirected along a new optimum path.

Owing to lack of computing time, no attempt was made to compile the entire control law table. Therefore no statement can be made about how severely the various variables affect the control law—which play a minor role and which are of predominant importance. Only enough solution points were obtained to indicate the feasibility of this computational scheme and the control approach in general.

Synthesis of Control System

The design procedure outlined above leads to the formulation and evaluation of the optimum control law for the system. The designer is allowed the freedom of choosing any system configuration to realize this law. Presented below is one such configuration for the control of the stirred-tank reactor, with a few comments on the problems of realization.

Fig. 7. Information flow in reactor control system

First, the control law is a function of the state variables $y_1(t_0)$, $y_2(t_0)$, ... $y_6(t_0)$. Ideally, composition measurements should be available to the controller but in practice this is very difficult. However, knowing reaction kinetics, reactor temperature, inlet and outlet flow rates, and composition, one may simulate the composition equations 4 to keep a running account of reactor composition. This is possible because the composition equations are stable and solution errors do not accumulate. Hence the simulation of the reactor equations must be an integral part of the controller.

The controller itself is the F_2 and F_w function generator; however, the domain of the function tabulation is limited. During start-up and emergencies, the state variables may be outside this domain and then the solution must be obtained from the boundary-value problem itself. Thus, in parallel with the F_2 and F_w function generator, a boundary-value problem solver must be incorporated. Since solution for a single set of state variables is required, the hill-climbing method of solution described in the section "Calculation of Control Law" would be most appropriate. The system would then be under the over-all control of a master monitor, which, on the basis of incoming economic data, results of further kinetic studies, and possibly weather information, updates the reactor model and recalculates the control law functions. Such an over-all control scheme and the information flow involved are shown in the diagram of Fig. 7.

Whether the over-all system is to be realized in terms of digital or analog components or in terms of a hybrid combination is an open question. Each method has advantages and disadvantages. The solutions of the control law as carried out on the International Business Machines (IBM) *704* computer are an indication of the computing capacity required. To obtain the solution to the Euler equation and tabulate one point, approximately 10 seconds were required including read-out time. If the output operations were eliminated and the program optimized, it is thought that 1 to 2 seconds per point would be sufficient. The hill-climbing boundary-value problem solver would have to solve the boundary-value problem approximately 40 times and so require about 80 seconds per decision, which is still small in comparison to the time constant of this system. This figure could be materially decreased once experience had been gained with the solution. Certainly not all of the six state variables affect the control law severely. By concentrating on the dominant effects the hill-climbing could be made much more efficient. The actual generation of the control law from the polynomial representation of F_2 and F_w is simple, requiring about 0.01 second.

Thus it appears feasible to place such a chemical reactor under computer control. The computer would normally spend only a very small portion of its time performing the control functions and would be free to do other jobs, e.g., accounting. Under start-up conditions its whole attention must be devoted to the process and, periodically, it must spend appreciable time recalculating the control laws.

It should be emphasized that the problem considered is 6-dimensional. No other schemes known to the authors were successful in handling nonlinear dynamic optimization problems of this many dimensions. Probably some of the variables are not important in affecting the control law; if this is true, tabulation of the control law function will make it evident.

It is believed that the method described represents a successful approach to the design of systems for the control of chemical plants. It is hoped that in the near future it will be possible to try it out on a real functioning chemical process.

Discussion

R. E. Kalman (Research Institute for Advanced Studies, Baltimore, Md.): This important paper deserves most careful attention. Using a quite realistic model for the process, it shows how a digital computer can be used to effect "tight supervision" over the chemical reactor. The authors give a convincing demonstration of the feasibility of computer control, a major step forward in research on process control which should impress engineers who like to "evaluate" research in terms of economic criteria.

Essentially the same problem, based on a simpler mathematical model, has been treated before by the discusser;[1] another application of the same technique has been described by R. E. Boydston, and was presented at the same session of the Joint Automatic Control Conference as the paper under discussion. Much of this stems from the pioneering work of Bellman.[3] Hence the statement "No other schemes known to the authors were successful in handling dynamic optimization problems of this magnitude" should perhaps be amended.

Concerning the mathematical side of their approach, the authors state that the approach of the calculus of variations is believed to be the most fruitful. But the calculus of variations, as the term is understood by mathematicians and physicists today, is not *an* approach but *the* approach to problems of optimization. The paper is based on the use of the Euler equation. This is but one (in fact, the oldest) aspect of the calculus of variations. The authors specifically exempt themselves from considering questions of a mathematical type associated with their technique. Nevertheless, a note of warning about the complexities of the calculus of variations may be useful at this stage, since much further work can be expected along this or similar lines.

The expositions of the calculus of variations usually found in engineering texts are badly lacking in rigor. In problems of classical theoretical physics, the rigorous details can usually be provided. This is not as easy in new types of problems such as occur in this paper. The following discussion is intended to point out that even in innocent-looking cases the rigorous application of the calculus of variations is far from being as simple as might appear.

There are only two modern, rigorous expositions in English to the best of my knowledge: Bliss[3] and the first two chapters of Morse.[4] These are not intended for the beginner but they contain a streamlined account of classical results.

Intuitively, the calculus of variations can be compared with finding the minima and maxima of a function $f(x_1, \ldots, x_n)$ of a finite number of variables. It is necessary that $\partial f/\partial x_i=0$ $(i=1, \ldots, n)$; the additional condition that the Hessian matrix $\partial^2 f/\partial x_i \partial x_j$ is negative (or positive) definite is then sufficient for a local maximum (or minimum). (The absolute maximum or minimum cannot be found by such simple means.) There are corresponding conditions in the calculus of variations which we shall now proceed to sketch.

Consider the problem of minimizing or maximizing the integral

$$V=\int_{t_0}^{t_1} L(x, \dot{x}, t)dt=\frac{1}{2}\int_{t_0}^{t_1} [x^2(t)\pm \dot{x}^2(t)]dt \quad (41)$$

subject to the constraint

$$\dot{x}=u(t) \quad (42)$$

Equation 42 represents a dynamical system: x is the state and u is the control variable; equation 41 defines the performance index. In general, though not always, one prescribes the initial and end points $x(t_0)$ and $x(t_1)$ of the desired motion of the system.

With the plus sign in equation 41 we are dealing with a conventional optimization problem. With the minus sign, equation 41 is intended to be a highly simplified version of equation 1: x^2 is the sales price of the output and u^2 is the price of the plant input.

Euler Equation. (See reference 3, page 12, and reference 4, page 3.) In analogy with the vanishing of the derivative of a function of finitely many variables, the first variation of the integral 41 is to vanish. In rigorous terms this is expressed as follows: Let $\xi(t)$ be a curve in the (x, t) plane for which the integral in equation 41 has an extremum (local minimum or maximum). Since the control variable in equation 42 might well be only a piecewise continuous function of time, we must admit curves with discontinuous tangents. The point at which $d\xi/dt$ is discontinuous is called a "corner." We have then the following necessary condition: Every arc of $\xi(t)$ not containing a corner must be a solution of the Euler equation. In other words, one can obtain extrema of the variational problem by means of solving the Euler equation only if it is known beforehand that the extremal curve $\xi(t)$ does not contain any corners.

The Euler equation is

$$\frac{d}{dt}(\partial L/\partial \dot{x})-\partial L/\partial x=0$$

or, for equation 41,

$$\pm d^2x/dt^2-x=0 \quad (43)$$

Weierstrass-Erdmann Corner Conditions. (See reference 3, page 12 and reference 4, page 3.) At a corner t_0 the extremal curve must satisfy the following condition:

$$\lim_{\tau\to 0} \partial L(\xi(t_0+\tau), \dot{\xi}(t_0+\tau), t_0+\tau)/\partial \dot{x}$$

$$= \lim_{\tau\to 0} \partial L(\xi(t_0-\tau), \dot{\xi}(t_0-\tau), t_0-\tau)/\partial \dot{x}$$

Legendre Condition. (See reference 3, page 23, and reference 4, page 6.) In general, the "loss function" L in the integral in equation 41 is a function of the vector variables $\mathbf{x}$ and $\dot{\mathbf{x}}$. Denoting the components of $\dot{\mathbf{x}}$ by $\dot{x}_1, \ldots \dot{x}_n$, can show that the integral will not have even a local maximum (or minimum) unless the matrix $\partial^2 L/\partial \dot{x}_i \partial \dot{x}_j$ is nonpositive (or nonnegative) definite. It should be emphasized that the Legendre condition must be considered in addition to solving the Euler equation.

Jacobi Condition. (See reference 3, page 26, and reference 4, page 8). It may happen that the second variation along any presumed extremal curve $\xi(t)$ (i.e., a solution of the Euler equation) vanishes. This can be shown to be equivalent to the following situation:

The Euler equation of the variational problem associated with the second variation has a solution which is zero at $t=t_0$ and $t=t_2>t_0$ but is not identically zero anywhere in the interval (t_0, t_2).

The point t_2 is called the conjugate point of t_0. The necessary condition of Jacobi states:

No curve $\xi(t)$ without corners, which is the solution of the Euler equation, can provide a (local) minimum or maximum if t_0 has a conjugate point in the interval (t_0, t_1).

As a matter of fact, one can show that if there is a conjugate point on $\xi(t)$, by introducing corners one can always modify $\xi(t)$ in such a way that the integral in equation 41 will assume a smaller or larger value.

It can be shown (see reference 3, page 43, and reference 4, page 16) that if the necessary conditions of Legendre and Jacobi are strengthened (the Hessian must be positive or negative definite, and no t satisfying $t_0<t\leq t_1$ is a conjugate point of t_0), then these conditions, together with the Euler equation, are also sufficient. It should be carefully noted that none of these results guarantee the existence of a minimum or maximum. The investigation of the existence question is a deep mathematical problem.

Now let us examine how these facts relate to our example and to equation 15. In all cases, the Weierstrass-Erdman corner conditions imply that there cannot be a corner. In our example this is obvious. In equation 15 it is brought about by the authors' method of "simulating" the constraints; see equations 11 through 13. Hence the extremal curves $\xi(t)$ (if they exist at all) must satisfy the Euler equation in the entire interval (t_0, t_1). The remaining part of the discussion will be carried out case by case.

Plus Sign in Equation 41. The strict Legendre condition is satisfied and shows that we can have only minima. The maximization problem has no solution (i.e., the maximum is infinite). The Euler equation can be shown have a unique solution connecting the arbitrary points $x(t_0)$ to $x(t_1)$ in any time interval (t_0, t_1). The proof of this is not trivial and leads to the concept of "controllability" introduced by the discusser.[5] This being the case, it is easy to prove also that there are no conjugate points. In fact, since L is quadratic, the Euler equation for the second variation is identical with equation 43; it follows that the only solution of this equation which links $x(t_0)=0$ with $x(t_1)=0$ (t_0, t_1 arbitrary) is the curve $\xi(t)\equiv 0$. More directly, one sees this by noting that, since L is positive definite, the second variation can never vanish. This is a case frequently encountered in classical physics. Since the three necessary conditions are also sufficient, it follows that the unique solution of the Euler equation is indeed the desired answer. Hence in this case one simply solves the Euler equation, forgets about all else, and comes out with a correct answer. The situation is different in the next case.

Minus Sign in Equation 41. The strict Legendre condition is satisfied and shows that we can have only maxima. The Euler equation can again be shown to have a unique solution corresponding to any pair of points $x(t_0,)$ $x(t_1)$, except for the pair 0,0, which can be connected by infinitely many solutions when $t_1-t_0=n\pi$ (n = positive integer). Since the Euler equation of second variation is again the same as equation 43, we see that t_0 has its conjugate points at $t=t_0\mp n\pi$. By the Jacobi condition, the unique solution of the Euler equation is a local maximum if $t_2<t_0+\pi$. But, if $t_1>t_0+\pi$, no curve $\xi(t)$ without corners can supply a maximum because of the presence of the conjugate point; on the other hand, curves with corners are ruled out for other reasons. Hence, if $t_1>t_0+\pi$, no maximum exists. One can show this directly as follows: Let $t_1=t_0+3\pi/2$. Connect $x(t_0)$ to any arbitrary point $y=x(t_0+3\pi/4)$ by means of the (unique) solution of the Euler equation. Similarly, connect $x(t_0+3\pi/4)$ to $x(t_1)$. Then the integral V in equation 41 will be a function of y. Take, e.g., $x(t_0)=1$ and $x(t_1)=0$. By an easy calculation, one sees that $V(y)\rightarrow\infty$ with $y\rightarrow\infty$, so that no maximum exists.

Equation 15. Even the verification of the Legendre condition is not a trivial matter here, but is probably true. On the other hand, the integrand in equation 15 is apparently not negative definite, so that conjugate points are not obviously ruled out. It may well be that the conjugate points have failed to show up only because of the relatively short time interval involved in the optimization; see Fig. 7. Unfortunately, it is difficult to give criteria as to how short this interval must be. Another question, by no means obvious, is: How do we know that any initial state in which the reactor might find itself can be transferred to the desired operating point in a certain fixed length of time? It is well known in the theory of saturating control systems that this is not always possible.

The difficulties sketched here have long been known and have led mathematicians to search for other approaches. The chief competitor or the Euler equation in this regard is the Hamilton-Jacobi theory, in particular, the partial differential equation bearing the same name. The existence of a solution of the Hamilton-Jacobi partial differential equation (with slight additions) guarantees the existence of a solution for the variational problem; as we have just seen, the same is by no means true of the Euler equation. In recent years, the Hamilton-Jacobi theory received splendid reaffirmation by the work of Bellman,[2] whose "dynamic programing" or "functional-equation" technique is based on the same general idea.[6]

The Hamilton-Jacobi equation for the example can be derived from the well-known "maximum" principle of Pontryagin.[6] Let p be the conjugate variable of x. We can eliminate equation 42 and write

$$L(x, u, t)=(x^2-u^2)/2=(x^2-\dot{x}^2)/2$$

(This elimination can be also carried out in the general case, obviating the authors' technique of considering the dynamical equations as constraints.) By virtue of the maximum principle, we select u in such a way as to minimize or maximize the Hamiltonian function

$$H(x, p, u, t)=L(x, u, t)+p\dot{x}=(x^2\pm u^2+2pu)/2$$

which yields

$$u_{\text{opt}}=k(x, p)=\mp p \tag{44}$$

The function k represents the "optimal control law." It specifies the mathematical form of the control system if one succeeds in expressing p as a function of x. (Incidentally, this derivation, with minor modifications, succeeds also when the control variables are constrained in amplitude,[6] which shows that the authors' belief that "inequality constraints cannot be readily treated by the techniques of the calculus of variations" appears to be incorrect.)

We now define the function

$$H^*(x, p, t)=H(x, p, u_{\text{opt}}, t)=(x^2\mp p^2)/2$$

The Euler equation 43 is then seen to be equivalent to the canonical (Hamiltonian) equations

$$\left.\begin{aligned}\dot{x}&=\partial H^*/\partial p=\mp p\\ \dot{p}&=-\partial H^*/\partial x=x\end{aligned}\right\} \tag{45}$$

We may consider V as a function of the initial point ξ_0, t_0 of the extremal curve. Since the initial point and time are arbitrary, we may drop the subscript zero, writing $V(\xi, t)$. Identifying p with $\partial V(\xi, t)/\partial\xi$, we are led to the Hamilton-Jacobi partial differential equation

$$\partial V/\partial t+H^*(x, \partial V/\partial\xi)=0$$

which in the example is given by

$$\partial V/\partial t+x^2/2\mp(\partial V/\partial\xi)^2/2=0 \tag{46}$$

Let

$$V(x, t)=\nu(t)\xi^2/2.$$

Substitution shows that this function satisfies equation 46 if the scalar ν is a solution of the ordinary differential equation of the Riccati type

$$-d\nu/dt=(1\mp\nu^2)/2 \tag{47}$$

The initial conditions of equation 47 are usually specified by letting $V(\xi, t_1)=0$. (This corresponds to a "free" end point of the motion at $t=t_1$; the case of "fixed" end point can be treated by similar methods.)

In case of equation 47, the initial condition is then $\nu(t_1)=0$. If the minus sign holds in equation 47 (i.e., the plus sign holds in equation 41), it can be readily shown that the unique solution of equation 47 starting at $\nu(t_1)=0$ exists for all $t<t_1$. This is not the case when the plus sign holds in equation 47 (i.e., when the minus sign holds in equation 41), because then the solution $\nu(t)$ will become infinite at some value of $t<t_1$. In fact, the solution of equation 47 is then given by

$$\nu(t)=\tan^{-1}(t_1-t)/2$$

and this solution becomes infinite when $t=t_1-\pi$, i.e., at the first conjugate point of t_1 on the left. We see therefore that the Hamilton-Jacobi technique allows one to conclude in this case the nonexistence of a solution for $t_1-t_0>\pi$, without any detailed knowledge of the classical necessary conditions.

One further point of both theoretical and practical importance: In the classical theory, one considers minimization of the integral in equation 41, with a loss function of type $L(x,\dot{x},t)$, and subject to a dynamic constraint, such as equation 42. But it is much simpler to use a loss function of type $L(x,u,t)$, in which case the differential equations of the plant are no longer constraints but are automatically considered in the derivation of the Hamiltonian. The LaGrange multipliers ω_i of equation 16 are then recognized as the conjugate variables p_i; the "maximum principle" of Pontryagin[6] follows naturally and the whole theory is greatly simplified. Details may be found in the discusser's forthcoming paper in the *Proceedings* of the RAND Symposium on Mathematical Optimization.

We emphasize again that if a solution of the Hamilton-Jacobi equation satisfying the appropriate initial conditions has been found, the variational problem is solved. One may regard solution of the Euler equation as an attempt to construct solutions of the Hamilton-Jacobi equation. (This is obvious from the fact that the Euler equations (in the canonical form 5 given by Hamilton) are just the equations for the characteristics of the Hamilton-Jacobi partial differential equation.) But the solution of the Euler equation does not automatically imply that there is a solution for the Hamilton-Jacobi equation (except for sufficiently short intervals of time) because of the conjugate point trouble. Hence in regard to theoretical questions, the Hamiltonian point of view is intrinsically the superior of the two.

The solution of the Hamilton-Jacobi equation completely specifies p as a function of the state; therefore, by equation 44, it also specifies the optimal control law as a function of the state. This may be more, however, than is really desired. It may be "cheaper" to specify the optimal control only for the given state of the system, rather than for all states. Under such circumstances, repetitive, real-time solution of the Euler equation, as used by the authors, may have appreciably advantages, provided of course that the Euler equation indeed provides the solution for the variational problem. In other cases, it might be better to solve the Hamilton-Jacobi equation directly, in terms of a family of orthogonal functions. In any case, one should guard against too hasty generalizations concerning the "engineering" merits of the Euler point of view.

The foregoing may be summarized roughly as follows:

1. Solution of the Euler equation provides a necessary but not a sufficient condition.

2. The solution of the Hamilton-Jacobi equation (or, equivalently, dynamic programing) provides a condition which, with slight additional requirements, is also necessary. This point of view is used in reference 1 and also by Boydston.

3. The computational advantages of the Euler point of view depend on the problem at hand and the requirements of control. It is primarily preferable in cases where the control law is to be determined step by step as the need arises, rather than all at once.

4. A brute-force numerical attack on the problem is bound to run into difficulties unless the existence of the optimal system is established in advance. It is by no means obvious that an extremum of the integral exists for any time interval (see equation 41 with minus sign) or that any state can be transferred to the desired final state.

None of the difficulties raised is insurmountable from the engineering point of view, but neither is the problem as simple as might be surmised by a quick reading of the paper.

L. A. Gould and **W. Kipiniak:** The authors appreciate Dr. Kalman's comments. There is no question that the method requires a rigorous foundation and that care is needed in applying the technique. This paper was presented to show how the method could be used on a realistic engineering problem, in a situation in which the questions of existence and uniqueness of an optimum can be resolved on physical grounds. At present, not all of the mathematical restrictions on the application of the method are completely known; investigation of these restrictions is now under way.

With regard to the example presented in the discussion in which the Euler equations did not define an optimum, we should point out that it does not represent a realistic control problem. In practice, the performance criterion represents a balance between the cost of tolerating an error and the cost of exerting control effort to correct it. That is, the integrand is either concave in both the state variables and their derivatives or convex in both. In Dr. Kalman's example in which a plus sign was used, the above criterion is satisfied and no difficulties result. The example with a minus sign corresponds to a criterion convex in the state variable but concave in its derivative and it is not surprising that the stationary point defined by the Euler equation is a point of inflection and not an optimum.

As far as is known to the authors (reference 1 of the discussion included), the dynamic optimization problems treated so far have been either of small dimensionality or based on a linear model and a quadratic performance criterion. We know of no other scheme successfully used for dynamic optimization of a nonlinear reactor model.

It must be emphasized that in contrast to Bellman's and Kalman's work, the optimization procedure is based on Euler differential equations of the calculus of variations rather than on the functional equations of dynamic programing. Although both approaches are, to a large extent, theoretically equivalent, computationally they present different problems. In our experience the variational approach has been found to possess some advantages.

The authors have always felt that all of the various optimization techniques have their place and that more applications of these methods are needed, to demonstrate their power both mathematically and in practical problems. This paper attempted to show one of these methods applied to a realistic engineering problem.

On the Response of Linear Systems to Periodic Excitations

W. R. LEPAGE
MEMBER AIEE

R. McFEE
MEMBER AIEE

THE PROBLEM of finding the periodic response of a linear system to a nonsinusoidal periodic excitation is of continuing interest.[1–6] The following constitutes a brief summary of the existing methods of solving such problems:

1. The Fourier series.
2. Infinite series summation of transients.
3. Solution of a differential equation subject to matching conditions at the beginning and end of a cycle.
4. Computation of the periodic response in closed form, for the duration of the first cycle, by subtracting the transient part of the response from the total response.
5. Use of the modified Z-transform to obtain the closed form solution for one cycle of response, in the limit, as t approaches infinity.

Methods 1 and 2 are of such classic nature as to need no comment, other than the well-known observation that they are seldom useful for computation. Method 3 is satisfactory only in simple cases, for which Laplace techniques are not needed. A variety of justifications for method 4 will be found in the literature[4–7] and method 5 has been expounded in a recent communication by Jury.[8] Method 5 is conceptually satisfying, to the degree that its procedure is closely identified with the definition of the periodic response as that part of the response which remains after the transient has died out. However, with respect to the amount of manipulation required to solve a specific problem, method 4 is probably not exceeded in simplicity by any of the other methods.

Attention will be devoted to presenting a new proof of the validity of the usual procedure for identifying the periodic and aperiodic parts of the response in method 4. All methods of justifying this procedure involve an interpretation of the inversion integral

$$y(t)=\frac{1}{2\pi j}\int_{Br} H(s)X(s)e^{st}ds$$

where $y(t)$ is the system response, $X(s)$ is the Laplace transform of the periodic driving function, $H(s)$ is the system function, and Br is the Bromwich contour. $X(s)$ has an infinite unbounded set of poles; and for a lumped system $H(s)$ is rational, having a finite number of poles. All procedures classified in method 4 recognize that residues due to poles of $H(s)$ constitute the transient response, and residues due to poles of $X(s)$ constitute the periodic response. However, a difficulty arises when the poles of $X(s)$ are used to identify the periodic response, because of the need to justify a term-by-term integration over an infinite set of poles. This problem has been attacked on the one hand by defining a special steady-state transform,[6] and also by using the conventional Laplace transform, while paying attention to the relatively difficult mathematical problem of justifying a term-by-term integration of an infinite series.[5]

It is the purpose of this paper to show that adequate theorems exist to demonstrate the validity of procedure 4 without defining a special transform, or without dealing with the infinite unbounded set of poles of $X(s)$ in the evaluation of the inversion integral.

The Basic Derivation

We are given a stable lumped linear system with a rational system function (ratio of Laplace transforms of output to input) $H(s)$. The system is initially without stored energy, and is excited at $t=0$ by a piecewise continuous periodic driving function $x(t)$, having period T. It is assumed that $x(t)$ and $H(s)$ meet conditions sufficient to ensure existence of the response function $y(t)$. Then $y(t)$ is given by

$$y(t)=\mathcal{L}^{-1}[H(s)X(s)] \tag{1}$$

The periodic input $x(t)$ has a transform[9]

$$\mathcal{L}[x(t)]=X(s)=\frac{X_0(s)}{1-e^{-sT}} \tag{2}$$

where by definition

Paper 60-1288, recommended by the AIEE Basic Sciences Committee and approved by the AIEE Technical Operations Department for presentation at the AIEE Fall General Meeting, Chicago, Ill., October 9–14, 1960. Manuscript submitted July 12, 1960; made available for printing August 19, 1960.

Vol.
Pt. 1
196

$$X_0(s)=\mathfrak{L}[x_0(t)]=\int_0^T x(t)e^{-st}dt \qquad (3)$$

and where

$$\begin{aligned} x_0(t)&=x(t), \quad 0\leq t\leq T \\ &=0, \quad T<t \end{aligned} \qquad (4)$$

Since the integral in equation 3 has finite limits, and $x(t)$ is bounded, this integral is differentiable with respect to s for all finite s. Thus, $X_0(s)$ is an entire function, and $X(s)$ is singular only at the simple poles which arise from the zeros of $1-e^{-sT}$. These zeros occur on the imaginary axis at $\pm 2n\pi/T$, where $n=0, 1, 2, \ldots$. The transform of the output is

$$Y(s)=H(s)X(s)$$

or

$$Y(s)=\frac{H(s)X_0(s)}{1-e^{-sT}} \qquad (5)$$

$H(s)$ is a rational function, which is usually regular at infinity. However, there are certain degenerate cases for which $H(s)$ can have a pole at infinity. This possibility will be treated later; for the present, assume that $H(s)$ is regular at infinity.

The function $Y(s)$ has simple poles at the zeros of $1-e^{-sT}$ and is also singular at poles of $H(s)$, which are not necessarily simple. To distinguish between these two sets of poles, we now define $A(s)$ as the sum of the principal parts of $Y(s)$ due to the poles $s_1, s_2, \ldots s_N$ of $H(s)$. Then the function

$$P(s)=Y(s)-A(s) \qquad (6)$$

will have poles only at the zeros of $1-e^{-sT}$. These poles can be placed in evidence by writing

$$P(s)=\frac{P_0(s)}{1-e^{-sT}} \qquad (7)$$

where $P_0(s)$ is defined by equations 6 and 7, and may be written

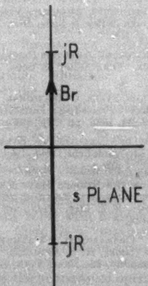

Fig. 1. Definition of the Br contour

$$P_0(s)=H(s)X_0(s)-A(s)+e^{-sT}A(s) \qquad (8)$$

Since $A(s)$ is a sum of a finite number of principal parts such as

$$\frac{b_m}{(s-s_1)^m}+\frac{b_{m-1}}{(s-s_1)^{m-1}}+\ldots+\frac{b_1}{s-s_1}$$

it follows that $A(s)$ has an inverse

$$a(t)=\mathfrak{L}^{-1}[A(s)] \qquad (9)$$

which is aperiodic if each pole has a nonzero real part. Since the physical conditions of the problem have been stipulated to ensure existence of $y(t)=\mathfrak{L}^{-1}[Y(s)]$, it follows that

$$p(t)=\mathfrak{L}^{-1}[P(s)] \qquad (10)$$

exists.

We suspect that $p(t)$ is periodic, and offer the following conjectural arguments in support of this statement. $P(s)$ is known to be singular only at the zeros of the denominator of equation 7, and so it is evident that $P_0(s)$ is an entire function. In view of the similarity with $X_0(s)$, which also is an entire function, and the similarity between equations 2 and 7, it is reasonable to expect $p(t)$ to be periodic.

To prove that $p(t)$ is periodic, we demonstrate first that, if $p_0(t)$ is zero for $t<0$ and $t>T$, then $p(t)=(pt-kT)$, where k is an integer; i.e., it is shown that the above conditions on $p_0(t)$ are sufficient to make $p(t)$ periodic. It is then shown that $p_0(t)$ meets the above conditions. Parenthetically, it is emphasized that we are now discussing sufficiency of a condition on $p_0(t)$ to ensure periodicity of $p(t)$. Necessity of the above condition on $p_0(t)$ has already been established in the discussion pertaining to equation 4.

On the basis of the above information, pending proof that $p(t)$ is periodic, the following may be written:

$$y(t)=a(t)+p(t) \qquad (11)$$

where $p(t)$ is periodic, and $a(t)$ is not periodic.

Proof that p(t) is Periodic

The following proves that $p(t)$ is periodic if $\mathfrak{L}^{-1}[P_0(s)]$ is zero when t is outside the interval from 0 to T:

To discuss $p(t)$, as given by equation 10, where $P(s)$ is given by equation 7, assume that $p_0(t)$ is zero when t is outside the interval from 0 to T. It is readily seen that the function

$$\sum_{k=0}^{\infty} p_0(t-kT)$$

is periodic, having the transform

$$\frac{P_0(s)}{1-e^{-sT}}$$

where $P_0(s)=\mathfrak{L}[p_0(t)]$. Thus, by virtue of uniqueness of transform pairs, it follows that

$$p(t)=\sum_{k=0}^{\infty} p_0(t-kT) \qquad (12)$$

is the inverse of $P(s)$, as given by equation 7, and is periodic if $\mathfrak{L}^{-1}[P_0(s)]$ exists and is zero outside the interval from 0 to T.

The following proves that $\mathfrak{L}^{-1}[P_0(s)]$ is zero when t is outside the interval from 0 to T:

The existence of $\mathfrak{L}^{-1}[P_0(s)]$ is assured because each term on the right of equation 8 has an inverse transform. Furtheremore, this inverse transform is given by the integral

$$p_0(t)=\frac{2}{2\pi j}\int_{Br} P_0(s)e^{sT}ds \qquad (13)$$

where Br is the path of integration obtained by allowing R to approach infinity in Fig. 1. In the general case of this inversion integral, path Br must be to the right of all singular points, but since $P_0(s)$ is an entire function, Br can coincide with the imaginary axis, as shown. Now consider the individual terms of equation 8.

To show that $p_0(t)$ is zero for $t<0$, it will be recalled that $x_0(t)=\mathfrak{L}^{-1}[X_0(s)]$ is zero for $t<0$; thus either from physical considerations, or the convolution integral

$$\int_0^t x_0(\tau)h(t-\tau)d_\tau$$

where $h(t)=\mathfrak{L}^{-1}[H(s)]$, it is evident that $\mathfrak{L}^{-1}[H(s)X_0(s)]$ is zero for $t<0$. Also, from standard Laplace transform theory, it is known that $\mathfrak{L}^{-1}[A(s)]$ and $\mathfrak{L}^{-1}[e^{-sT}A(s)]$ are both zero for $t<0$.

It is more difficult to prove $p_0(t)$ is zero

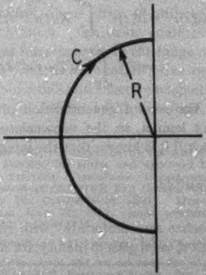

Fig. 2. A contour equivalent to Br when there are no left half-plane poles, and when conditions of Jordan's lemma apply to the left half-plane

for $t>T$. To accomplish this, we write the integral of equation 13 in the form

$$\int_{Br} P_0(s)e^{st}ds = \lim_{R\to\infty}\int_C P_0(s)e^{st}ds \tag{14}$$

where C is the semicircle of radius R shown in Fig. 2. Assuming that the limit on the right exists, this change is permitted because $P_0(s)$ has no finite-plane singular points. The nature of the singularity of $P_0(s)$ at infinity determines whether the limit exists. It can be shown that the right side of equation 14 is zero for $t>T$ by means of Jordan's lemma, which in one form states that

$$\lim_{R\to\infty}\int_C F(s)e^{su}ds=0$$

when $u>0$, if $F(s)$ approaches zero uniformly with respect to ang s, as $|s|$ goes to infinity, for $Re\ s \leqq 0$. Since we are interested in the response for $t>T$, it is convenient to write

$$\int_C P_0(s)e^{st}ds = \int_C P_0(s)e^{sT}e^{s(t-T)}ds$$

$$= \int_C P_0(s)e^{sT}e^{su}ds \tag{15}$$

Thus, in order to apply Jordan's lemma, we must show that

$$P_0(s)e^{sT} = H(s)X_0(s)e^{sT} - A(s)e^{sT} + A(s)$$

approaches zero as $|s|$ goes to infinity, uniformly in the region defined above. From the description of $A(s)$ as a sum of principal parts, it is evident that $A(s)$ goes to zero at least as fast as $1/s$, which goes to zero uniformly for $0 \leqq \text{angle } s \leqq 2\pi$. For the term $A(s)e^{sT}$, the exponential causes the region of uniform approach to zero to be reduced to $\pi/2 \leqq \theta \leqq 3\pi/2$ (or $Re\ s \leqq 0$).

To deal with the remaining term, observe that

$$H(s)X_0(s)e^{sT} = H(s)e^{sT}\int_0^T X_0(t)e^{-st}dt$$

$$= H(s)\int_0^T x_0(T-\tau)e^{s\tau}d_\tau \tag{16}$$

By the second generalization of Riemann's lemma, in the nomenclature of Doetsch,[10] it is known that the integral

$$\int_0^A f(x)e^{zx}dx$$

approaches zero uniformly* with respect to angle z, as $|z|$ goes to infinity, for $Re\ z \leqq 0$ provided that $f(x)$ is piecewise continuous. The factor $H(s)$ at most approaches a constant at infinity, and hence the last integral in equation 16 has the proper behavior at infinity. Thus, all terms of $P_0(s)e^{sT}$ approach zero in the proper manner for Jordan's lemma to be applicable; thus it follows that

$$\lim_{R\to\infty}\int_C P_0(s)e^{sT}e^{su}ds=0$$

when $u>0$, and hence, referring to equation 15

$$\lim_{R\to\infty}\int_C P_0(s)e^{st}ds=0$$

when $t>T$.

It has now been established that

$$\mathcal{L}^{-1}[P_0(s)]=0$$

when $t<0$, and when $t>T$. Furthermore, in the previous section it was shown that this condition, along with other conditions already established, is sufficient to make $p(t)$ periodic.

Case of H(s) with Pole at Infinity

As yet the proof is valid only for the case where $H(s)$ is regular at infinity. Now, suppose $H(s)$ has a kth order pole at infinity. Two cases are open to consideration:

1. The excitation is of such a form that the response includes impulse terms.
2. The excitation is smooth enough so that the response is free of impulse terms.

Case 1 can always be considered a limiting form of case 2, by using a symbolic notation where 1, s, s^2, etc., are interpreted respectively as symbolic transforms of the unit impulse, the unit doublet, etc. Therefore, we turn our attention to case 2.

It can be shown, either from physical or mathematical considerations, that if the response is to be free of impulses, $x_0(t)$ must have $k-1$ continuous derivatives, all of which will be zero at $t=0$. To simplify the analysis, assume the kth derivative as piecewise continuous. This being true, from the theorem for the transform of a derivative

$$X_0(s)=\frac{1}{s^N}X_k(s) \tag{17}$$

where

$$X_k(s)=\int_0^T \frac{d^k x_0(t)}{dt^k}e^{-st}dt \tag{18}$$

Note that $X_k(s)$ is an entire function, since the derivative is piecewise continuous. In place of equation 5 we can now write

$$Y(s)=\frac{H(s)}{s^k}\,\frac{X_k(s)}{1-e^{-sT}} \tag{19}$$

All arguments previously applied to $X_0(s)$ and $H(s)$ are now respectively applicable to $X_k(s)$ and $H(s)/s^k$. Since $X_k(s)/s^k = X_0(s)$, there is no difference between equations 5 and 19 in so far as the functions $A(s)$ and $P(s)$ derived from $Y(s)$ are concerned. Therefore, although equation 19 is conceptually necessary for carrying out the proof, in a numerical problem this case is handled by the procedure already described.

Summary

As pointed out at the start of the paper, the analysis presented leads to the well-established procedure for solving for a periodic response. The claim is made, however, that the subject becomes conceptually simpler with the realization of the following: In addition to the recognized fact that if $p(t)$ is periodic its transform has the form

$$\frac{P_0(s)}{1-e^{-sT}}$$

we can also say that if $P_0(s)$ meets certain conditions, the inverse transform of the above form exists and is periodic. This fact allows us to deal only with $P_0(s)$ and its inverse, thereby avoiding complexities arising from the infinite set of poles occurring at the zeros of $1-e^{-sT}$.

* Riemann's theorems have the physical interpretation that the frequency spectrum of any piecewise continuous function eventually becomes zero as frequency approaches infinity. However, this physical interpretation does not take cognizance of the uniform approach to zero, which is an important aspect of Riemann's lemma.

Discussion

E. I. Jury (University of California, Berkeley, Calif.): The authors are to be commended for their brief summary of methods and concise proof of the validity and ramifications of method 4. The discusser agrees that methods 4 and 5 show more promise in application than the others. In the following methods 4 and 5 are briefly compared, so that the reader may judge the difference between the various manipulations required to obtain the steady-state response. A brief summary of the steps involved in each of these methods is included.

In method 4, the process of obtaining the steady-state response denoted as y_{ss}, the following integrals which are equivalent to the inverse of equation 8 for $0 \leq t < T$, should be evaluated.[1]

$$y_{ss} = \frac{1}{2\pi j}\int_{C_1} H(s)X_0(s)e^{st}ds - \frac{1}{2\pi j}\int_{C_2} \frac{H(s)X_0(s)}{1-e^{-Ts}}e^{st}\,ds,\ 0 \leq t < T \quad (20)$$

The first integral is at the right of the poles of $H(s)X_0(s)$. The second integral encloses the poles of $H(s)$.

In evaluating the first and second integral the residues at the poles of $H(s)X_0(s)$ [for the various regions[1] of $X_0(s)$] and $H(s)$ are to be evaluated respectively. The steady-state output y_{ss} is obtained by subtracting the second integral (the transient response for the duration of the first cycle) from the first integral (the total response for the first cycle).

In method 5 with the use of the modified z-transform, the steady-state response is given.[3]

$$\begin{aligned} y_{ss} &= \lim_{z\to 1} \frac{z-1}{z}\left.\frac{Z_m[H(s)X_0(s)]}{(1-z^{-1})}\right|_{z=e^{Ts}} \\ &= \lim_{z\to 1} HX_0^*(z,m) \\ &= \lim_{z\to 1}\frac{1}{2\pi j}\int_{C_1} H(p)X_0(p)\left.\frac{e^{mpT}}{1-e^{-T(s-p)}}dp\right|_{z=e^{Ts}} \end{aligned}$$

$$0 \leq mT \leq T \quad (21)$$

The integral is at the right of the poles of $H(s)X_0(s)_{s=p}$.

To evaluate the integral of the modified z-transform $HX_0^*(z, m) = Z_m[H(s)X_0(s)]$, it should be observed that only the residues at the poles of $H(s)X_0(s)$ [for the various regions[2] of $X_0(s)$] are required.[2,3] Thus in this procedure the steady-state response is obtained in one step and by the evaluation of one integral.[3] The amount of manipulation required to solve for the steady-state using methods 4 and 5 can be easily compared by solving a specific problem. The limit $z = 1$ could also be inserted inside the integral in equation 21 which probably simplifies the manipulations required in obtaining the steady state.

Knowing the modified z-transform of $Y(s)$, one can readily obtain the total response (if desired) in a closed form using the following relation:[2,3]

$$y(n, m)T = \frac{1}{2\pi j}\int_{\Gamma} Y^*(z, m)z^n dz$$

The integral encloses the poles of $Y^*(z, m)$.

$t = (n+m)T$

n = positive integer

$0 \leq m \leq 1$

Furthermore, by expanding $zY^*(z, m)$ in powers of z^{-1}, the piecewise response for each period can also be obtained. As a final remark, utilizing the equivalence between methods 1 and 5, closed expressions of infinite Fourier series are obtainable.[3] Similarly, one could use the procedure of this paper for closing such series form.

In conclusion, the discusser deems it pertinent to mention that it is possible to combine the two integrals in equation 20 into a form equivalent to equation 21 (provided z is replaced by unity in the integrand of the latter). Thus method 4 reduces to method 5 or vice versa.

However, the availability in the literature[3] of extensive tables of the modified z-transform lends its application for obtaining the steady-state response conveniently.

W. R. LePage and **R. McFee**: The authors are glad to acknowledge Prof. Jury's comments, with which they find no significant disagreement. We wish to point out, however, that the discussion pertains only to our comment concerning the amount of work involved in solving a numerical problem. The main point of our paper is to show that the correctness of method 4 can be established without consideration of the difficult problem of evaluating the inversion integral when the integrand has an infinite set of poles.

Magnetic Memory Drum Design

E. B. CARNE
ASSOCIATE MEMBER AIEE

Synopsis: A magnetic memory drum is a convenient, relatively cheap storage device of moderate speed and of large capacity. It comprises a cylindrical rotor, whose surface is coated with a magnetic material, rotating within a shroud which supports salient heads. Proper design requires an appreciation of the effect on performance of such factors as rotor eccentricity, head-setting variations, head manufacturing tolerances, and storage surface variations. Equations are developed to describe the signal-to-noise ratio of a typical drum and the threshold (switching) voltage appropriate to the read amplifier for reliable operation. Material selection is approached on the basis of stress calculations and it is concluded that *2014-T6* aluminum is the best rotor material for general-purpose applications. It is shown that, for any rotor with a given degree of unbalance, there is a maximum stable operating speed. Problems associated with thermal mismatch of materials are discussed, and the necessity of operating large drums in a stable temperature environment is pointed out.

A MAGNETIC memory drum comprises a cylindrical magnetic surface rotating in close proximity to a number of magnetic heads. Information is stored on the surface by energizing a head with a suitable current pulse and producing a magnetized area on the rotating surface. Reading is achieved by noting the voltage produced at the output terminals when the magnetized area passes under a head. Because of the air gap between the head and the recording surface, the readback voltage is necessarily small; this presents a problem in terms of noise and spurious signal pickup when a large number of heads are involved. Nevertheless, magnetic memory drums have assumed an important place in data-processing systems, and are currently used where a convenient, potentially large, relatively cheap, permanent-storage device of moderate speed is required.

The storage surface may be fine iron-oxide particles held together by an organic binder or a very thin deposit of two or more metals, such as nickel and cobalt, plated simultaneously on the rotor cylinder. The former comprises micron-size powder in a resin matrix which, after appropriate curing, can be ground to a thickness of one-half to one mil (inches × 10^{-3}). The latter comprises a plated deposit, approximately 80% cobalt and 20% nickel, about 20 to 40 millionths of an inch thick. For oxide coatings, the coercive force may be in the range of 200 to 300 oersteds with an effective permeability of 2 to 3 and effective magnetic induction of 500 to 1,000 lines/cm² (per

E. B. CARNE is with Melpar, Inc., Falls Church, Va.

The author would like to acknowledge the help rendered by A. S. Berson, of Melpar, Inc., in the discussion of electrical results and in providing the experimental values of head crosstalk voltages; also the assistance of J. A. Ward and F. A. Shultz, of the Remington Rand Division of the Sperry Rand Corporation, Utica, N. Y., in the formulation of the mechanical problem.

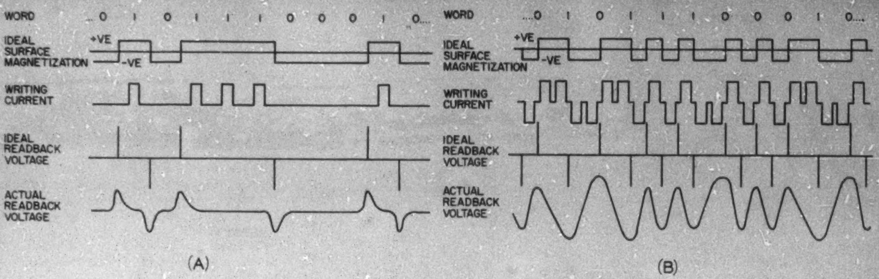

Fig. 1. Recording waveforms. A—NRZ. B—Phase-modulation

centimeter^2). For a typical Ni-Co (nickel-cobalt) deposit, the coercive force may be 200 to 800 oersteds, effective permeability 20, and magnetic induction 10,000 lines/cm^2.

In a typical system the air gap between the rotor and heads may be 0.001 inch. So that this dimension may be maintained with reasonable accuracy, the rotor diameter must be machined to a tolerance of ±0.0001 inch, and the mechanical stability of the bearings and housing must be perfect. A factor K_e will be introduced to represent the air-gap variation (rotor eccentricity) in such a way that

$$d_a' = d_{a0}(1 \pm K_e) \qquad 0 \leq K_e \leq 1 \tag{1}$$

where d_a' is the effective air gap between the storage surface and the head and d_{a0} is the nominal air gap. Expressed another way

$$D' = D_0 \pm d_{a0}K_e \tag{2}$$

where D' is the effective rotor diameter and D_0 is the nominal rotor diameter. Departures from the nominal air gap give rise to modulation of the maximum readback signal and variations in the length of the recorded pulse x_p.

A further important source of variation is the magnetic head used for writing and reading. K_g will be introduced to represent the variation in effective pole face gap, in such a way that

$$g' = g_0(1 \pm K_g) \qquad 0 \leq K_g \leq 1 \tag{3}$$

where g' is the nominal pole face gap. While it is usual to establish this dimension by means of nonmagnetic foil of closely controlled thickness, subsequent finishing operations can degrade the sharp corners and increase the effective gap width. This will affect the size of the magnetized area recorded on the storage surface.

Other discrepancies occur in the manufacture of the head, such as variation of the number of turns of wire in the energizing coil and variation of the parameters of the head magnetic circuit material. A factor K_m will be introduced to represent the effect of these manufacturing tolerances. There will also be a variation in the setting of the head relative to the storage surface. A factor K_a will be used to represent this kind of variation. Its value will depend on the style of head used, and on the way in which the heads are set. Finally, the magnetic playback will depend on the quality of the magnetic surface, which will depend very critically on the quality of the substrate and the homogeneity of the storage material.

For all practical purposes digital systems utilize two methods of storage: nonreturn-to-zero (NRZ) saturation recording, or phase modulation saturation recording. In the first, 0 and 1, are represented by negative and positive saturation of the recording surface, while in the second a double mark is used with 0 being represented by negative saturation followed by positive saturation, and 1 being represented by positive saturation followed by negative saturation. It will be appreciated that the terms positive and negative, 0 and 1, are conventional and that they denote opposites. Fig. 1 compares the two systems on the basis of recording current, storage surface magnetization, and readback voltage. It is assumed that the storage surface employing NRZ recording has been "erased" by uniformly magnetizing the medium to negative saturation (0 state). Information is then inserted by pulsing the recording head so as to change the state of magnetization of the storage surface for a 1. The recording head is left quiescent for a 0. In phase modulation recording, the initial state of the surface is not important since the desired information can be written over whatever digit may be stored. If erasing is required this can be achieved by writing 0's in each cell. The process of interpreting the readback voltage and reconstructing the information to recognizable digital form will be discussed in a later section.

Electrical Design Considerations

ACCESS TIME

The usefulness of a magnetic drum is as great as its ability to perform the required system function of storing a known quantity of data in discrete blocks and to recall them in a given time. The total number of bits N, the number of discrete stores (tracks) n, and the approximate

Table I. Access Time (3% Slip) as Function of Motor Speed and Number of Heads Per Track

Motor			Access Time, Milliseconds		
Supply Frequency, Cps	No. of Poles	Synchronous Speed, Rpm	1 Head Per Track	2 Heads Per Track	4 Heads Per Track
60	2	3,600	17	8.6	4.3
	4	1,800	34	17	8.6
	8	900	69	34	17
	16	450	140	69	34
400	2	24,000	2.6	1.3	0.64
	4	12,000	5.1	2.6	1.3
	8	6,000	10	5.1	2.6
	16	3,000	21	10	5.1
1,000	2	60,000	1.03	0.51	0.26
	4	30,000	2.06	1.03	0.51
	8	15,000	4.12	2.06	1.03
	16	7,500	8.24	4.12	2.06

access time t_a' are defined by system considerations. By the judicious choice of the number of poles and the supply frequency for the drive motor it is usually possible to tailor the system requirements to utilize 60,400 or 1,000 cps (cycles per second) power. Table I shows representative values of access time for drums driven by induction motors utilizing these frequencies. It will be observed that the use of several heads synchronized mechanically to sample a single track can achieve access times as short as 240 μsec (microseconds). As an alternative, the same acess time will be achieved if one head is used and the information is written a number of times around the rotor circumference. Such times, however, are achieved only with a corresponding loss of storage capacity.

Recorded Pulse Length

The total amount of information which can be stored depends on the length of the individual bits recorded on the drum surface and on the rotor diameter. While it is possible to write with a pulse density greater than that naturally associated with the writing head pole gap and the head-to-storage surface separation, this results in a decrease in readback voltage and degeneration of resolution. Karlquist[1] has computed the magnetic field at the surface of the recording medium under stationary conditions. For large values of pulse length (as compared with $d_a'g'$) the exact expression can be approximated as

$$H_x = H_0 d_a' g' \mu' / \pi x^2 \tag{4}$$

where H_x is the magnetizing force at a point on the storage surface in the direction of the storage track, distant x from the center of the recording gap; H_0 is the magnetizing force in the recording gap; g' is the effective recording head pole gap; and μ' is the effective permeability of the storage medium. Writing $x_p = 2x =$ pulse length, and assuming a square-loop recording medium for which the coercive force is H_c at the writing frequency, yields

$$x_p = 2\left(\frac{H_0}{H_c}\,\frac{d_a'g'\mu'}{\pi}\right)^{1/2} \tag{5}$$

Since H_c is difficult to determine under practical writing conditions, a reasonable expedient is to define an arbitrary percentage of the maximum field strength as determining pulse length. If $H_x = 0.2\,H_0$ (20% point) equation 5 can be written as follows:

$$x_p = 2.53(d_a'g'\mu')^{1/2} \tag{6}$$

For an oxide surface, $\mu' \simeq 3$ and for a Ni-Co surface $\mu' \simeq 20$, so that

$$x_p = 4.37(d_a'g'\mu')^{1/2} \quad \text{(oxide)}$$

$$x_p = 11.3(d_a'g')^{1/2} \quad \text{(Ni-Co)} \tag{7}$$

Comparing two surfaces, for the same pulse length

$$d_{a1}'g_1' = (\mu_2'/\mu_1')d_{a2}'g_2' \tag{8}$$

In order to achieve the same packing density on drums of equal size but with different storage surfaces, the recording head pole gap and the head-to-storage surface separation must be decreased in the drum having the greater effective permeability. Alternatively, equal pulse length can be achieved with the same recording head and head-to-storage surface separation if the coercive force of the storage surface is increased, i.e.,

$$H_{c2} = H_{c1}(\mu_2'/\mu_1') \tag{9}$$

It should be remembered that equations 5 through 9 are only as valid as equation 4, which in turn is limited to the domain in which the integral expressions obtained by Karlquist in reference 1 can be replaced by the first term of an asymptotic series. They may be regarded as qualitative indication of the influence of storage surface properties on pulse length.

In a practical system, both d_a' and g' will vary. If $d_a' = d_{a0}(1 \pm K_s)$ and $g' = g_0(1 \pm K_g)$, using equation 6 yields

$$x_p' = 2.53\left(1 \pm \frac{1}{2}K_s \pm \frac{1}{2}K_g\right)(d_{a0}g_0\mu')^{1/2} \tag{10}$$

If "smearing" of the recorded data is to be prevented, the write current pulse period must be sensibly shorter than the time required for the recorded bit to pass under the writing head. This will ensure that the storage surface remains approximately stationary during the writing operation. The rise time of the writing pulse is relatively unimportant under this condition. As a practical convenience the writing current pulse width can be made 20% of this period, i.e.,

$$t_p = 0.2nt_a/N \tag{11}$$

For maximum readback voltage, the recording surface diameter should be capable of accommodating N/n bits per track having maximum length, i.e.,

$$D_0 = Nx_p'/\pi n = 0.8\frac{N}{n}\left(1 \pm \frac{1}{2}K_s \pm \frac{1}{2}K_g\right) \times (d_{a0}g_0\mu')^{1/2} \tag{12}$$

In certain applications, two or more heads are mounted to read information on the same track. If the two heads represent the extremes of head pole-gap variation, if they read what the other has written, and if they are located so that the maximum air-gap variation exists between them at the same time, the difference in recorded pulse length is

$$x_{p1} - x_{p2} = 2.53(K_s + K_g)(d_{a0}g_0\mu')^{1/2} \tag{13}$$

The variation between the leading edges of the two extreme pulses will be one half of the value given in equation 13. Expressed as a fraction of the nominal pulse length, this becomes

$$(x_{p1} - x_{p2})/2x_p = \frac{1}{2}(K_s + K_g) \tag{14}$$

representing a time difference of

$$t_d = \frac{1}{2}(K_s + K_g)nt_a/N \tag{15}$$

which must be taken into account when the use of multiple-headed tracks for fast access applications is considered. If $K_s = 0.1$ and $K_g = 0.2$, it will be seen that the maximum time delay will be 15% of the total pulse period.

Head-to-Storage Surface Separation

In a recent paper, Miyata and Hartel,[2] have shown that, for practical head-to-storage surface separations, the maximum readback voltage can be represented by

$$e_{\max} = C \log_e\left(1 + \frac{d_s}{d_a - a}\right) \tag{16}$$

where $e_{\max}$ = peak readback voltage, C = constant for a particular storage surface and running conditions, d_s = storage surface thickness, d_a = head-to-storage surface separation, and a = recording constant.

The value of the recording constant a varies with the type and thickness of the magnetic surface and with head-to-storage surface separation. For modern oxide coatings and separations of the order of 1 or 2×10^{-3} inches, $a \simeq 0.2$. Similar information is not available for Ni-Co surfaces. It will be assumed, therefore, that the results derived for oxide surfaces can be applied qualitatively to the Ni-Co case.

Rewriting equation 16, differentiating, and putting $K_s = \Delta d_a/d_a$ gives

$$\frac{\Delta e_{\max}}{e_{\max}} = K_s \times \left[\frac{d_a d_s}{(d_a - a)(d_a + d_s - a)}\,\frac{1}{\log_e\left(1 + \dfrac{d_s}{d_a - a}\right)}\right] = \alpha K_s \tag{17}$$

or

$$e_{\max}' = e_{\max}(1 \pm \alpha K_s) \tag{18}$$

The maximum output voltage will be affected in a similar manner by head-setting tolerances, i.e.,

$$e_{\max}' = e_{\max}(1 \pm \alpha K_a) \tag{19}$$

Values of α, computed from equation 17, for representative values of d_a, d_s, and a are as follows:

d_s	d_a	α
0.50	0.50	1.06
	1.00	1.00
	1.50	0.99
	2.00	0.98
	2.50	0.98
0.75	0.50	0.95
	1.00	0.91
	1.50	0.92
	2.00	0.93
	2.50	0.94
1.00	0.50	0.87
	1.00	0.86
	1.50	0.88
	2.00	0.90
	2.50	0.92
1.50	0.50	0.77
	1.00	0.77
	1.50	0.81
	2.00	0.83
	2.50	0.86

The value of a is 0.2 throughout.

HEAD CROSSTALK

The magnetic field of an energized recording head in the plane of the storage surface is approximately that of a small dipole. Other heads in the immediate vicinity will be affected by that component of the field which lies perpendicular to the pole gap faces. In the case of a magnetic drum, all of the heads are oriented in the same direction, i.e., with pole gaps parallel to the axis of rotation. With the use of elementary properties of a small dipole, it can be shown that the component of the writing head field perpendicular to this direction is

$$H_x = \frac{M}{r^3}(1+3\cos^2\theta)^{1/2}\cos\frac{3\theta}{2} \qquad (20)$$

where M is the magnetic moment of the dipole, r is the distance between the dipole center and the receiving point, and θ is the angle between the dipole axis and a line joining the center of the dipole to the receiving point. Equation 20 can be interpreted in terms of the noise voltage induced in a head by another writing in close proximity, i.e.,

$$e_{nc} \propto \frac{e_1}{r^3}(1+3\cos^2\theta)^{1/2}\cos\frac{3\theta}{2} \qquad (21)$$

where e_1 = voltage developed across the writing head by the writing current. Table II compares values of experimentally determined crosstalk with equation 21. It will be observed that agreement is excellent when $\theta=0$ degrees and $\theta=90$ degrees but that the experimental technique shows a zero occurring about $\theta=45$ degrees, while theory predicts that it should occur at $\theta=60$ degrees. This discrepancy may be due to lack of sensitivity in the voltage-measuring equipment and distortion of the simple dipole pattern. Fig. 2 shows experimental values of crosstalk voltage as a function of head separation. The variation from a 3-power law is illustrated by the inclusion of an arbitrary cubic curve.

Table II. Head Crosstalk as a Function of Orientation

Values Compared With a Theoretical Dipole Field

Angle, θ Degrees	Crosstalk: Observed Voltage, $V(\theta)$, Mv	Crosstalk: Observed $\frac{V(\theta)}{V(\theta=0)}$	Crosstalk: Theoretical $\frac{V(\theta)}{V(\theta=0)}$
0	140	1	1
45	0	0	0.234
60			0
90	50	0.357	0.353

Head separation 0.25 inch.

NUMBER OF HEADS

If a proportionality constant K_c is introduced, which may be determined from measurements made when $\theta=0$ degrees, and expression 21 is rewritten in terms of r, it becomes

$$r^3 = \frac{K_c e_1}{e_{nc}}(1+3\cos^2\theta)^{1/2}\cos\frac{3\theta}{2} \qquad (22)$$

Putting $\theta=0$ degrees, $\theta=90$ degrees gives

$$r^3(\theta=0°) = \frac{2K_c e_1}{e_{nc}};\; r^3(\theta=90°) = \frac{K_c e_1}{\sqrt{2}e_{nc}} \qquad (23)$$

i.e., for a given value of e_1/e_{nc}

$$r(\theta=0°) = \sqrt{2}\,r(\theta=90°) \qquad (24)$$

Now, as a good approximation, the effective track width may be considered to be the width of the pole piece d_p together with a width equivalent to the pulse length x_p, i.e.,

$$d_t = d_p + x_p \qquad (25)$$

If the number of heads in any one circuit of the drum is n_h, and the crosstalk contributions of circumferential and axial heads are made equal, then

$$n_h d_t = r(\theta=90) = \frac{1}{\sqrt{2}}r(\theta=0) = \frac{1}{\sqrt{2}} \times \left(\frac{2K_c e_1}{e_{nc}}\right)^{1/3} \qquad (26)$$

Introducing the diameter of the drum yields

$$n_h = \pi D_0/r(\theta=0) = \pi D_0\left(\frac{e_{nc}}{2K_c e_1}\right)^{1/3} \qquad (27)$$

Combining equations 26 and 27 yields

$$n_h^2 = \frac{1}{\sqrt{2}} \cdot \frac{\pi D_0}{d_t} \qquad (28)$$

or

$$n_h = 1.49\sqrt{D_0/d_t} \qquad (29)$$

NOISE

The readback signal is affected by noise due to inhomogeneities and discontinuities in the storage surface. Two major types of noise voltage can be recognized. The first is due to the discrete nature of the surface which gives rise to a typically random noise pattern when viewed on an oscilloscope connected to the read head. The second, which is truly a macroscopic case of the first, is due to relatively large nonmagnetic inclusions which generate single recognizable interfering voltages. In the worst case these may be complete holes in the storage surface. The magnitude of this voltage can be approximated as a percentage of the maximum readback voltage e_{max}. Since a complete void is associated with a sudden change of magnetization from saturation to zero, it is reasonable to expect that this will give rise to a voltage of $1/2e_{max}$. For nonmagnetic inclusions which represent a fraction χ of the total storage surface volume per bit, this voltage will be approximately $1/2\chi e_{max}$. Combining the two effects yields the nominal maximum noise voltage due to the recording surface:

$$e_{ns} = e_{max}\left[\eta(1-\chi)+\frac{1}{2}\chi\right] \qquad (30)$$

where η represents the noise due to microscopic effects. This will be modified by air-gap eccentricity, manufacturing tolerances, and head setting variations so that the effective maximum noise voltage due to surface variations will be

$$e_{ns}' = [1+\alpha(K_s+K_a)](1+K_m) \times \left[\eta(1-\chi)+\frac{1}{2}\chi\right]e_{max} \qquad (31)$$

In addition to noise generated by the magnetic recording surface, the reading head is subject to the influence of other heads which may be writing in its vicinity.

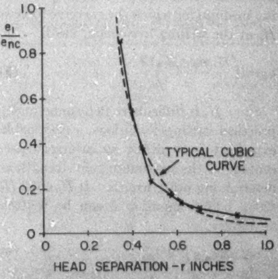

Fig. 2. Typical head crosstalk characteristic

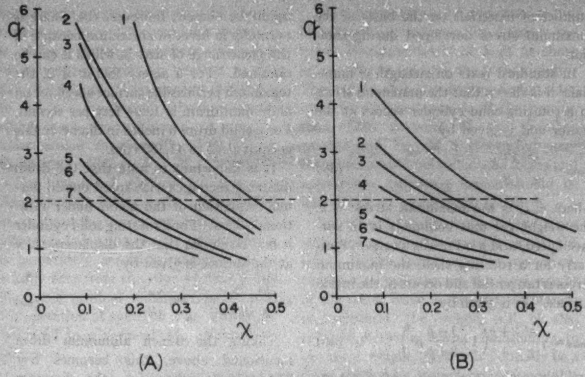

Fig. 3. Variation of signal-to-noise ratio (q) with volume of nonmagnetic inclusion expressed as a fraction of the total storage surface volume per bit (χ)

Curves in A—no interfering writing heads
1—ideal
2—$\alpha=0.91$, $K_a=0.05$, $K_m=0.05$, $K_s=0.05$
3—same as curve 2 except $K_s=0.1$
4—same as curve 2 except $K_s=0.2$
5—$\alpha=0.91$, $K_a=0.2$, $K_m=0.25$, $K_s=0.05$
6—same as curve 5 except $K_s=0.1$
7—same as curve 5 except $K_s=0.2$
Curves in B—one interfering writing head
1—ideal with $(e_1/e_{max})K_c(r\theta)=0.1$
2 through 7—same as curves in A with addition of writing head interference term

For convenience, equation 22 can be written

$$e_{nc}=K_c(r,\theta)e_1 \tag{32}$$

In the general case of a number of heads

$$e_{nc}=e_1[K_c(r_1\theta_1)+K_c(r_2\theta_2)+\ldots] \tag{33}$$

Under normal conditions a certain amount of cancellation between these quantities may exist.

SIGNAL-TO-NOISE RATIO

Just as the noise voltage due to surface inhomogeneities is affected by a number of tolerances, the signal voltage due to recorded data is affected by these quantities also. In computing signal-to-noise ratio, the minimum value of signal should be considered, so that

$$e_{max}'=[1-\alpha(K_s+K_a)](1-K_m)(1-\chi)e_{max} \tag{34}$$

Combining equations 31, 33, and 34 to give signal-to-noise ratio under the worst conditions yields

$$q=e_{max}'/(e_{nc}'+e_{ns}')$$
$$=\frac{[1-\alpha(K_s+K_a)](1-K_m)(1-\chi)}{[1+\alpha(K_s+K_a)](1+K_m)\left[\eta(1-\chi)+\frac{1}{2}\chi\right]+[K_c(r_1\theta_1)+K_c(r_2\theta_2)+\ldots]} \tag{35}$$

For a typical system

$\alpha=0.91$ when $d_a=0.001$ inch; $d_s=0.00075$ inch; $a=0.2$
$K_a=0.05$ for heads set individually
$K_a=0.20$ for heads set collectively
$K_m=0.05$ for selected heads
$K_m=0.25$ for heads taken indiscriminately over the full manufacturing range
$\eta=0.08$
$\frac{e_1}{e_{max}}K_c(r,\theta)=0.1$ for a typical head when $r=0.75$ inch and $\theta=0$

Fig. 3(A) shows the variation of q with χ and K_s for the case when $K_a=0.05$, $K_m=0.05$, and the case when $K_a=0.20$, $K_m=0.25$, when there are no interfering writing heads. The former corresponds to a drum in which selected single heads are set individually, the latter to a drum in which random heads are set collectively by a mechanical expedient. Fig. 3(B) shows the variation of the same quantities in the case when a typical head is writing in proximity to the read head. In both figures the characteristic curves for a mechanically perfect drum are given as reference. If a value of 2 is considered desirable for signal-to-noise ratio, it will be observed that the operating margin is much greater with individually set, selected heads. Indeed, this is essential if simultaneous reading and writing are performed.

READ AMPLIFIER DESIGN

The signals depicted in Fig. 1 are reconstructed into digital information by means of the read amplifier and associated circuits. Typically, the amplifier will consist of a linear amplifier section followed by a nonlinear amplifier-switching section. When several amplifiers are interrogated in parallel, or when it is essential to reproduce the information with an accurate time period, a strobe is usually generated from an accurate clock recorded on the drum surface, and is used to gate the outputs of the read amplifiers. A typical system is shown in Fig. 4(A) and a representative read amplifier design is given in Fig. 4(B). The reconstruction of digital information from the signals shown in Fig. 1 is depicted in Fig. 5.

The important design parameter char-

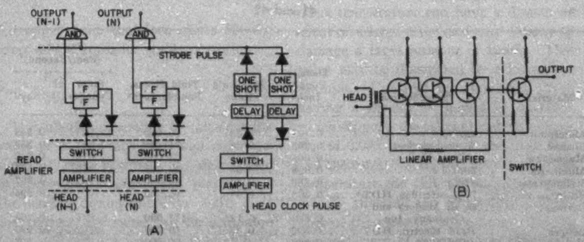

Fig. 4. A—Typical read amplifier and strobe system. B—Typical read amplifier

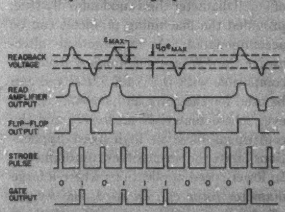

Fig. 5. Reconstruction of NRZ information

acterizing the response of the read amplifier is the input voltage at which full output voltage is generated. Consistent operation can be obtained if this value is chosen so that it is greater than the maximum noise voltage but less than the minimum signal voltage minus the maximum noise voltage, i.e.,

$$e_{nc}'+e_{ns}'<q_0e_{\max}<e_{\max}'-(e_{nc}'+e_{ns}) \qquad (36)$$

where $q_0e_{\max}$ is the threshold voltage of the amplifier. If $q_0e_{\max}$ is designed to be intermediate between these limits, expression 36 reduces to

$$q_0=\frac{e_{\max}'}{2e_{\max}}=\frac{1}{2}[1-\alpha(K_e+K_a)]\times (1-K_m)(1-\chi) \qquad (37)$$

In this case reliable operation can be assured only if the strobe is generated at the peak of the readback signal. This presents serious errors in strobe timing. A better criterion is to design the threshold voltage so that it is midway between the maximum noise signal and some fraction τ of the readback signal less the maximum noise signal. In this case

$$q_0=\frac{1}{2}\tau[1-\alpha(K_e+K_a)](1-K_m)(1-\chi) \qquad (38)$$

Mechanical Design Considerations

In this discussion, interest is limited to a drum comprising a rotor positioned by ball bearings in a stationary shroud which supports salient heads. While many believe that such a drum must run with its axis of rotation vertical, very successful units have been built in which the axis of rotation is horizontal. In either case, the general features of the construction are the same and it should be assumed that the following remarks apply to either unless specific exception is made.

MATERIAL SELECTION

As a first approach to material selection it would seem that, since the bearing rings are normally made from chrome-steel (*SAE 52100*, for example), a number of problems might be solved if the entire unit were made from this material. For drums of small diameter this is undoubtedly true, provided the machining problems can be accommodated. As a practical alternative the *400* series of stainless steels are compatible with the *SAE 52100* and can be used for the rotor and shroud. However, these materials are heavy and the centrifugal force in high-speed applications limits the permissible drum diameter. In lower-speed applications where a large diameter rotor can be used, the weight affects bearing life. In view of these limitations it is instructive to compare a number of materials on the basis of the maximum stress developed during rotation.

In standard texts on strength of materials[3] it is shown that the maximum stress in a rotating solid cylinder occurs at the center and is given by

$$\sigma_{\max}=\gamma\frac{v^2}{g}\,\frac{3+p}{8} \qquad (39)$$

where $\sigma_{\max}$ is the maximum stress, γ is the weight per unit volume, v is the surface speed, and p is Poisson's ratio. Similarly for a rotating shell, the maximum stress is tangential and occurs at the inside surface. It is given by

$$\sigma_{\max}=\gamma\frac{v^2}{g}\,\frac{3+p}{4}\left(1+\frac{1-p}{3+p}\beta^2\right) \qquad (40)$$

where $\beta=a/b$, a is the inner radius of shell, and b is the outer radius of the shell. It will be noted that the maximum stress occurring in a solid cylinder is approximately one half of the stress produced in a hollow shell of the same outside diameter. If σ_{yp} represents the yield point stress and K_{SF} denotes the safety factor employed, equations 39 and 40 may be written

$$v^2=8g\sigma_{yp}/K_{SF}\gamma(3+p)\ \text{(solid)} \qquad (41)$$

$$v^2=4g\sigma_{yp}/K_{SF}\gamma(3+p)\left\{1+\frac{1-p}{3+p}\beta^2\right\}\ \text{(shell)} \qquad (42)$$

If K_{SF} be taken as 2 and $\beta=0.8$, the numerical values of these expressions are compared in Table III on the basis of the square of the linear surface speed. Aluminum can be used to the highest speed, followed by Inconel X and magnesium. Because of its weight (3×Al, 4.5×Mg), and machining properties, Inconel cannot be considered seriously as a general-purpose material for drum construction. In applications in which weight is of paramount importance magnesium is the obvious choice. At lower speeds any of the materials listed might be chosen; however, the choice is normally in favor of aluminum because of the great range of sizes in which it can be obtained. For a safety factor of 2, the maximum permissible surface speed for an aluminum drum is 1,294 feet per second. For a solid drum 6 inches in diameter this is equivalent to 41,180 rpm.

It is important to note that the drum diameter increases with speed due to normal expansion of the metal under rotational stress. For a rotating solid cylinder it can be shown that the displacement u at the surface is given by

$$u=\frac{b^2}{8}\,\frac{2}{1+p}\,(1-p^2)\,\frac{\gamma\omega^2}{gE} \qquad (43)$$

Taking the 6-inch aluminum drum mentioned above, this becomes $u=27.65\times10^{-3}$ inches, i.e., the diameter will increase by some 55 mils when a nominal 6-inch-diameter aluminum drum is rotated at 41,180 rpm. It is essential that any static method of head setting compensate for this growth.

BALANCING

Because of manufacturing tolerances, inhomogeneities in the material, etc., unbalance will be present in a drum rotor and will give rise to radial forces acting on the bearings. The worst case will be that of unbalance occurring at one end of the rotor so that all of the out-of-balance force is applied to one bearing. If bearing considerations limit the maximum permissible radial force to $F_r(\max)$, the maximum permissible out-of-balance moment is

$$M(\max)=\frac{g}{\omega^2}F_r(\max) \qquad (44)$$

If the natural out-of-balance condition of the manufactured rotor is greater than this, it must be balanced to a value less than $M(\max)$. For low-speed applications, it is perfectly satisfactory to subtract weight by drilling the rotor at

Table III. Square of Maximum Surface Speed of Various Materials Computed From Equations 41 and 42

Material	Specification	Density, Pound/Inch³	Poisson's Ratio	Yield Stress, Pounds/Inch²	V²×10⁻⁶, (Feet/Second)² Solid Cylinder	Shell
Aluminum	*2014-T6*	0.101	0.33	60,000	1,903	0.843
Inconel	*X*, cold-worked	0.298	0.33	175,000	1.881	0.834
Magnesium	*AZ80A-T5*	0.065	0.35	34,000	1,675	0.742
Aluminum	*6061-T6*	0.098	0.33	40,000	1.307	0.581
Stainless steel	*440C*	0.280	0.30	60,000	0.692	0.307
Brass	70% cartridge, HDT*	0.308	0.33	64,000		0.294

Copper	*B188* Electro, HDT	0.322	0.33	50,000		0.220
Stainless steel	*303 (18–8)*	0.290	0.30	30,000	0.334	0.148

* Hard-drawn tubing.

appropriate points; however, high speeds require greater precision and it is desirable to utilize balancing members which can be moved accurately in relation to the axis of rotation. A convenient method is to utilize a number of balancing screws which can be screwed in and out in radial holes similar to conventional gyroscope balancing techniques.

For high-speed applications it is also desirable that balancing be accomplished at or near the operating speed so that adequate balancing can be achieved with a moderately sensitive machine. It is readily seen from equation 44 that if the allowable residual unbalance in a rotor for operation at speed ω_2 is M_2 it must be balanced to a moment M_1, at speed ω_1, given by

$$M_1 = M_2\omega_2^2/\omega_1^2 \tag{45}$$

In the case of a rotor intended for operation at 24,000 rpm, but balanced at 2,000 rpm, the implication is that the sensitivity of the balancing machine must be 144 times better than would be necessary if balancing were done at the operating speed. Under normal conditions such an increase in sensitivity is not practical.

MECHANICAL STABILITY

Suppose a force F_B, applied at the center of the rotor, deflects the center of gravity a distance d from the axis of rotation when the rotor is supported at the bearings; then, for small displacements

$$F_B = K_r d \tag{46}$$

where K_r will be called the coefficient of rigidity of the rotor. If the rotor is rotating, and has a total weight W_r, this deflection will produce a centrifugal force. The rotor will be stable or unstable as

$$K_r > \frac{W_r}{g}\omega^2 \quad \text{(stable)} \tag{47}$$

or

$$K_r < \frac{W_r}{g}\omega^2 \quad \text{(unstable)}$$

An upper limit therefore exists for the speed of the rotor for stable operation:

$$\omega_{\max}^2 = \frac{K_r g}{W_r} \tag{48}$$

It is almost impossible to calculate the value of K_r for any particular rotor design; it can, however, be determined experimentally. Since the majority of the bending occurs where the shafts meet the spinner, its value can be estimated fairly well, once a few models have been tested.

As a consequence of equation 48, in high-speed applications, the distance between bearings should be kept as short as possible to enhance the rotor rigidity. This means that the driving motor rotor must be attached outside of the bearing span. The presence of this member cantilevered beyond the bearing may introduce additional unbalance forces and appropriate balancing means should be introduced to compensate for them.

The size of the bearing selected for use will depend on the orientation of the rotor. If the axis of rotation is vertical, one bearing will support the total weight of the rotor, while if the axis of rotation is horizontal, the weight will be distributed between them. In addition to the rotor weight there will normally be a force applied by springs or other suitable means to the rotor in the direction of the axis of rotation to stabilize the balls in the bearings. This "preload" force will act equally on both bearings in either system. The choice of actual bearing size is best left to the recommendation of the bearing manufacturers since specific operating conditions may require special consideration. Experience has shown that their recommendations in regard to bore alignment and bore tolerances should be followed accurately for reliable service and long life.

THERMAL STABILITY

An important aspect of drum design is thermal mismatch between members constructed of different materials. This is particularly true with the advent of solid-state computers. Previously, air conditioning was provided to keep the operating temperatures low enough to achieve proper cooling of solid-state components in the presence of vacuum-tube circuitry. As a secondary effect, drums were operated in a stable temperature environment. However, with the elimination of vacuum tubes by solid-state devices, air conditioning is unnecessary and the drum must operate under natural conditions. Sudden changes in environment temperature can have a disastrous effect on a large drum and may destroy or damage a large number of heads. This point may be illustrated by a numerical example. Consider an aluminum drum having a shroud 24 inches in diameter which supports the salient head with an air gap of 0.001 inch between the head face and the rotor. A sudden drop in external temperature can chill the shroud without greatly affecting the temperature of the bulk of the rotor for some time. Taking the coefficient of expansion of aluminum as 13×10^{-6} inches per inch per degree Fahrenheit (F), a sudden change of 6.4 F in the temperature of the shroud will cause the heads to touch the storage surface.

If aluminum is chosen as the rotor material a mismatch in thermal coefficients of expansion occurs between the aluminum shaft and the chrome-steel inner race of the bearing and between the chrome-steel outer race and the aluminum housing. For a moderate rise in temperature, bearings with a large radial clearance should be chosen so that there is adequate margin for expansion of the inner race by the expansion of the aluminum shaft. The stress produced can be computed from expression 5:

$$\tau_{\max} = \delta c^2 \left\{ \frac{b}{E_r}\left(\frac{b^2+c^2}{c^2-b^2} + p_r\right) + \frac{b}{E_s}(1-p_s) \right\}^{-1} \tag{49}$$

where $\tau_{\max}$ is the maximum shear stress, δ is the magnitude of the interference fit between the inside diameter of the bearing race and the outside diameter of the shaft, b is the outside diameter of the shaft, c is the inside diameter of the bearing races, E_s, E_r are the values of Young's modulus for the shaft and the race, and P_s, P_r are the values of Poisson's ratio. The shear stress should be kept below the manufacturer's recommended value.

Conclusions

It should not be assumed that successful drum construction is solely a simple application of the principles enumerated. As with any electromechanical device, much depends on the skilled hands of the mechanic making and fitting the parts, as well as on the experience of the designer. Attention to fine detail cannot be overstressed. The "roundness" of the bearing spots, the fit of the outer race in the bores, the quality of the finish grind on the rotor, the precision of balancing, the relief of the machining stresses after boring the shroud, are all examples of items as essential to success as the proper choice of bearings or the right size of driving motor.

Viewed simply as a precision mechanical device, a memory drum is an impressive unit in which a highly machined, precise rotor rotates at several thousand rpm within 0.001±0.0001 inch from as many as 500 separate heads. From a chemical viewpoint, the preparation of the magnetic surface poses many problems, particularly in the case of plated deposits in which subtle amounts of addition agents and the temperature of deposition may have a profound effect on the magnetic properties of the deposit.

Lest the task appear too difficult, it should be said that each of these difficulties can be overcome by employing special techniques. Machining a rotor at running speed to correct for deformations due to the dynamic forces present is one example. The discovery of broader range additives for the control of the plating bath is another. As with any complex technical process, tight control at every step is the secret of success, with as much detailed attention being given to the measurement of quality as to the production of the item itself.

A well-made, reliable magnetic drum is capable of many years of faultless service at a cost per bit which gives it premier place as a medium-speed high-capacity storage device. At the upper end of the storage spectrum it is flanked by ferrite cores, cryogenic devices, and thin films; at the lower end it yields to disk memories and magnetic tapes. In applications of moderately fast data rate (up to 500 kc) and medium access time (in milliseconds), the magnetic drum has established its utility and will be a part of the computer designer's repertoire for a long time to come.

Nomenclature

a = recording constant: inner radius of shell
b = outer radius of shell: shaft diameter
B_0 = nominal magnetic induction in storage medium
B' = effective magnetic induction in storage medium
c = inside diameter of bearing race
C = constant
d = deflection
d_{a0} = nominal air gap
d_a' = effective air gap (also d_{a1}', d_{a2}')
d_p = width of recording head pole piece
d_s = thickness of storage surface
d_t = width of storage track
D_0 = nominal rotor diameter
D' = effective rotor diameter
e_{max} = nominal peak voltage at readback head
e_{max}' = effective peak voltage at readback head
e_{nc} = peak voltage due to crosstalk between heads
e_{ns} = peak voltage due to magnetic surface noise
E_r = Young's modulus for bearing race
E_s = Young's modulus for shaft
F = centrifugal force
F_B = bending force
$F_r(\max)$ = maximum permissible radial force
g = acceleration due to gravity
g_0 = nominal recording head pole gap
g' = effective recording head pole gap (also g_1', g_2')
H_0 = maximum magnetizing force in recording gap
H_c = coercive force of storage medium (also H_{c1}, H_{c2})
H_x = magnetizing force at point distant x along storage track from center of pole gap
I_m = intensity of magnetization in storage surface
K_a = factor defining variation in head readback voltage due to head-setting variations
K_c = crosstalk coefficient; also $K_c(r_1\theta_1)$, $K_c(r_2\theta_2)$
K_e = factor defining air-gap variation (rotor eccentricity)
K_g = factor defining variation of recording head pole gap
K_m = factor defining variation of recording head output voltage due to manufacturing tolerances
K_r = coefficient of rigidity
K_s = factor defining variation of magnetic properties of storage surface
K_{SF} = safety factor
M = magnetic moment of dipole equivalent of recording head: unbalanced moment; also $M(\max)$
n = number of recording tracks
n_h = number of heads in one complete turn around drum
N = total number of bits stored
P = Poisson's ratio (also P_r, P_s)
q = minimum signal per maximum noise
q_0 = read amplifier threshold level
r = radius: distance
t_a = access time
t_a' = approximate access time
t_d = maximum time delay (skew) between pulses in register tracks
t_p = duration of writing current pulse
u = displacement of rotor surface due to centrifugal force
v = surface velocity
W = unbalanced weight
x_p = recorded pulse length (also x_{p1}, x_{p2})
x_p' = effective pulse length
$\beta = a/b$
γ = weight per unit volume
δ = interference fit between shaft and bearing race
η = noise voltage due to microscopic effects
θ = angle
μ' = effective permeability of storage surface (also μ_1', μ_2')
σ_{max} = maximum stress
σ_{YP} = yield point stress
τ = maximum shear stress
χ = volume of nonmagnetic inclusion as a fraction of total storage surface volume per bit
ω = radial velocity (also ω_1, ω_2)

A New Function Generator

C. W. EGGERS
NONMEMBER AIEE

T. W. SZE
MEMBER AIEE

IN ANALOG COMPUTING technology as well as in the laboratory study of control instrumentation or simulation systems, it is frequently desirable to be able to provide a given arbitrary periodic function as a forcing function. However, no device will reproduce exactly every arbitrary function which might be required. For this reason, considerable effort has been applied toward the development of devices which will reproduce an approximation to a wide variety of functions. The term, "function generator" has been given to devices of this type.

The existing function generators may be separated into the following:

1. Analytic function generator. These generators employ the property that a certain number of analytic functions are the known solutions of differential equations. For example, a sinusoidal function may be generated by setting up an ordinary differential equation using three operational amplifiers.[1]

2. Diode function generator. This is the most widely used type in present-day analog computing facilities. In these devices, an input variable, x, produces an output, $F(x)$, which consists of a number of straight line segments between break points, which may be fixed or variable. The change in slopes is accomplished by biasing a number of diodes, each to one of the break points.

3. Tapped potentiometers. If a potentiometer is rotated with the angular position proportional to a variable, x, the wiper

This work is partially based on an *M. S. Thesis* by C. W. Eggers at the University of Pittsburgh.

voltage will vary approximately linearly with x between the voltages applied to the two ends of the potentiometer. In the tapped potentiometer used for function generation, the voltages at a number of taps along the potentiometer are forced to specified values and, as the wiper is rotated between any two points, $F(x)$ will vary linearly between the two corresponding voltages. In this manner, a curve of $f(x)$ versus x may be approximated by straight line segments, and functions of time may be obtained by generating x proportional to time.

4. Follower-type function generator. An example of this is the photoformer, in which a mask is placed on a cathode-ray tube and a servosystem with a photosensitive pickup forces the trace to follow the mask.

5. Function generation by synthesizing harmonics.[3] Since any periodic function may be written as the sum of a finite or infinite number of harmonics, an arbitrary periodic function may be synthesized by producing and combining a number of harmonics with proper amplitude and phase relationships.

A new function generator has been developed, constructed, and tested successfully by the authors, and results will be presented in this paper. This function generator employs the combined design techniques of digital circuits and analog computing circuits.

Development of the New Function Generator

Theory of Operation

The problem to be considered is the generation of an approximation, $F(t)$, to a function of time, $f(t)$, which is valid for $0 \leq t < T$. The function may be periodic with period T, or it may be aperiodic where $0 \leq t < T$ is the region of interest.

The following scheme of approximation is used in developing the new function generator. The period T is divided into equal intervals. In each interval, the function is approximated, either by a constant value, by a constant slope, or by a curve having some higher derivative constant. A commutating device is developed and used to generate constant voltages in each interval. The constant voltages are then integrated the required number of times to produce the approximation.

In the approximation process the period T is first divided into n equal intervals in an analytic or graphical representation of the function. Within each interval, say the ith interval, the approximation of the function may be written as

$$F_i(t) = K_i\left[t - \frac{(i-1)T}{n}\right]^p + F_{i-1}\left[\frac{(i-1)T}{n}\right]$$

for

$$\frac{(i-1)T}{n} \leq t < \frac{iT}{n} \tag{1}$$

and

$$F_i(t) = 0$$

for

$$t < \frac{(i-1)T}{n}$$

or

$$t \geq \frac{iT}{n}$$

with

$$F_0 = f(0)$$

where p may be any positive integer including zero. Finally,

$$f(t) \approx F(t) = \sum_{i=1}^{n} F_i(t) \tag{2}$$

The exponent, p, and the set of constants, K_i, are chosen for the best approximation to the function, $f(t)$, and these choices form the mechanics of the setup procedure. The exponent, p, must first be chosen on the basis of the general form of $f(t)$ and on the desired degree of accuracy of approximation for a given number of interval divisions. For example, if the function consists of a series of steps, the choice is $p=0$ so that the approximation will consist of a series of steps of magnitudes K_i. If a good approximation of function consists of a series of segments of constant slopes, the case of $p=1$ applies. The approximation is then made by straight line segments, and

$$F_i(t) = K_i\left[t - \frac{(i-1)T}{n}\right] + F_{i-1}\left[\frac{(i-1)T}{n}\right] \tag{3}$$

for

$$\frac{(i-1)T}{n} \leq t < \frac{iT}{n}$$

and the constants, K_i, are obtained as the slopes of F_i in the ith interval. That is,

$$K_i = \frac{dF_i}{dt} \tag{4}$$

The result of this set of calculations is the formation of a staircase function

$$c(t) = \sum_{i=1}^{n} c_i(t) \tag{5}$$

where

$c_i(t) = aK_i = C_i$ within the ith interval

and

$c_i(t) = 0$ in all other intervals (6)

and a is a constant scale factor. The steps in the formation of this function are shown in Fig. 1.

For the cases of $p \geq 2$, the approximation of $f(t)$ is made by segments of parabolic arcs (for $p=2$), or of higher order. Procedure for $p \geq 2$ is similar to that for $p=0$ or $p=1$ in principle, but the actual process of finding K_i for each interval becomes quite difficult except for an analytic function, instead of an arbitrary function.

Implementation of the Function Generator

The theory just presented has involved the mathematical procedures for the approximation of a function. To generate a known but arbitrary time function, one will first calculate $c_i(t)$ for each interval, equations 6. The different $c_i(t)$ are sampled, one at a time and in sequence, by a commutating device to form $c(t)$ or equation 5. Then finally, this function $c(t)$ is integrated p times, and multiplied by the scale factor a^{-1} to produce the approximation

$$F(t) = a^{-1} \int \int \ldots \int c(t)\,dt\,dt \ldots dt$$

and

$$F(t) \approx f(t) \tag{7}$$

These steps are indicated by the block diagram of Fig. 2. The potentiometers in Fig. 2 supply the voltages C_i, which are sampled in sequence by the commutating device. The integration may be per-

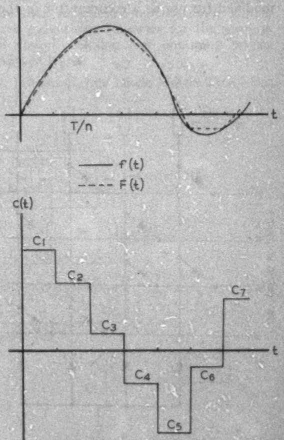

Fig. 1. Process of approximation and formation of staircase function

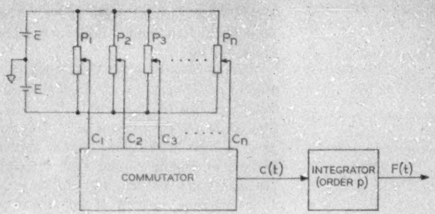

Fig. 2. Block diagram of a function generator using a commutating device

formed by an operational amplifier appropriately connected as an integrator.

The function generator may be made periodic by making the commutating device periodic. On the other hand, if an aperiodic operation is desired, the commutating device is designed to sample the c_i's only once.

Commutating Diode Matrix Tree

An essential element of the new function generator is the commutating device. Commutating devices used in function generators and in other applications have been reported previously.[2-9] The function generator presented in this paper employs a modified diode matrix as a commutating device.

The diode matrix and its variations (diode pyramid and diode rectangle) are well known to the digital circuit designers.[10] Such circuits have been widely used in the design of combinational logic networks such as the encoding and the decoding networks in a digital computing system. The basic structure of a diode matrix is modified for use as a commutator in the development of the new function generator.

The commutator actually used in the function generator is a 4-input diode matrix tree capable of commutating 16 segments. Its principle of operation, however, may be more easily explained by using a 2-input diode matrix, capable of commutating only 4 segments. Fig. 3 is a basic diode matrix for use as a commutator. This may be developed from a static diode matrix by the following modifications:

1. The switching voltages applied to the terminals A, A', B, B' have waveforms as shown in Fig. 4(a). Notice that the voltage waveform applied at B or B' has a frequency of twice that at A or A'. Furthermore, the voltages at A and A' and at B and B' are logically complements of each other. Therefore, these voltages are the outputs of a binary counter, with a count pulse train having the same frequency as B or B'.

2. The load resistors, instead of being connected to a common constant voltage as in the normal operation of a diode matrix, are individually connected to the wipers of potentiometers as shown in Fig. 2. Examples of the waveforms of voltages at these points are shown in Fig. 4(b).

3. The outputs of the diode matrix: e_1, e_2, e_3, e_4, are mixed by an OR gate to produce $c(t)$.

The principle of commutation is based on two facts of the diode logic circuits (assume ideal diodes):

1. In a diode AND logic circuit, the output voltage is equal to *the most negative one* among the input voltages and the supply voltage, which are either zero or positive.

2. In a diode OR logic circuit, the output voltage is equal to *the most positive one* among the input voltages, which are either zero or positive.

Based on the former, the waveforms of e_1, e_2, e_3, e_4, which are really outputs of AND gates, can be drawn as shown in Fig. 4(c). Based on the latter, $c(t)$ is then produced by mixing e_1, e_2, e_3, and e_4. This is equivalent to saying that the commutating diode matrix has sampled the c_i in sequence for $i=1,2,3,4$, etc. If the switching voltages are periodic, the sampling will also be periodic.

To commutate and sample 2^k segments, a k-input commutating diode matrix which contains $(k+1)2^k$ diodes is required. Here is seen a basic weakness of a diode matrix, namely that the number of diodes rises sharply as k increases. Variations of the diode matrix, such as the diode pyramid and the diode rectangle[10] have been developed with the number of diodes

used substantially reduced. The function generator presented in this paper uses a variation of the diode matrix which is more economical than a diode pyramid or a diode rectangle of the same commutating and sampling capacity. This variation is referred to here as a commutating diode matrix tree, and is shown in Fig. 5 for 16 segments or $k=4$. In this scheme the 16 segments are divided into 4 groups of 4 segments each. A commutating diode matrix is used for each group, and a fifth commutating matrix is used to commutate from group to group. The economy of such a scheme is shown in Table I in which the number of diodes is compared. Note that the number of diodes refer to the *commutating* diode matrix rather than the conventional *static* diode matrix.

Table I. Comparison of Number of Diodes Required for Variations of Commutating Diode Matrix

* Same as that required for a matrix.

Laboratory Model

A laboratory bench model of the function generator based on the principle presented here was designed, built, and tested successfully at the University of Pittsburgh. This generator was designed as an additional equipment for the existing analog computing facilities.

Design Considerations of the Laboratory Model

Fig. 6 shows a front and rear view of he laboratory model. Fig. 7 shows the block diagram for the function generator. Some of the design considerations will be described briefly as follows:

1. Timing Circuit. The laboratory model was built for a function approximation using 16 segments. To supply the switching voltages for the commutating diode matrix tree, a 4-bit binary counter, with a trigger flip-flop supplying the count pulses, is provided. The counter outputs are then separated from the diode matrix tree by cathode followers for the purpose of circuit isolation and obtaining proper voltage levels.

commutating 16 segments, the commutating matrix used is the one shown previously in Fig. 5. The input voltages are taken from the wipers of the potentiometers. It should be noted that these input voltages correspond to the slopes of the approximated function for the case $p=1$. It follows that these voltages may be positive or negative. However, with positive switching voltages, the input voltages must all be positive or zero. To overcome this problem, the d-c level of the inputs is raised by E_c volts so that all increased inputs are now positive or zero. After commutation, the d-c level is restored at the output of the commutator.

3. Integrator. Since the function generator was designed and constructed as an auxiliary equipment of the existing analog computing facilities, one operational amplifier of the computer was assigned and used as an integrator.

OPERATING PROCEDURE

The use of the function generator to produce an arbitrary function involves essentially two main series of steps:

Preliminary steps. The preliminary steps are mainly mathematical steps taken to determine the settings of the controls of the function generator. As a first step, it may be convenient to consider a normalized function $Nf(x)$, where N is a constant and x is an independent variable. This function may be either of tabulated form or a graphical plot. One period of the function is divided into n segments, and each interval Δx is designated as one unit.

Next, the approximated function, $NF(x)$, consisting of a straight line in each interval, is formed, and the slope of each line is calculated as

$$\frac{\Delta[NF_i(x)]}{\Delta x}=\Delta[NF_i(x)]=NF(i)-NF(i-1) \tag{8}$$

If better accuracy of approximation is desired, techniques of curve fitting may be used to minimize the error.[11,12]

After the calculation of the increments from the normalized function, the actual constants, K_i, may be calculated by taking into account the factors N and T/n. Thus,

$$K_i=\frac{\Delta F_i(t)}{\Delta t}=\frac{\Delta[NF_i(x)]}{NT/n} \tag{9}$$

The scale factor, a, is obtained next. It may be conveniently set to the scale factor of the integrator so that $a=RC$, where R and C are the resistance and the capacitance respectively, used in a conventional connection of an operational amplifier as an integrator. The choice of R-C must, in turn, depend upon the possible range of C_i, and the necessary range of K_i. The range of C_i is set by that of the diode matrix which has some limiting outputs, E_{max} and E_{min} respectively, so that

$$|E_{max}-E_{min}|=|C_{imax}-C_{imin}|\geq RC|K_{imax}-K_{imin}| \tag{10}$$

The range indicated by equation 10 also determines the magnitude of E_c. Although this voltage may be set in any manner so long as the diode matrix inputs become all positive, E_c is preset here to allow equal range of C_i of both signs. It follows that

$$|E_c|=\frac{1}{2}(E_{max}+E_{min}) \tag{11}$$

so that the range of C_i may be rewritten

$$-\frac{1}{2}(E_{\max}-E_{\min}) \leq C_i \leq \frac{1}{2}(E_{\max}-E_{\min}) \tag{12}$$

With these values fixed, equations 5 and 6 are determined for a given arbitrary function. Now, it may be written that the diode matrix output for any interval is

$$E_i = C_i + |E_c| \tag{13}$$

where E_c is the artificial d-c level change and is restored before the integrator stage, see Fig. 7.

Set-up steps. The mechanical steps of setting up the generator are quite simple. They are essentially the adjustment of the potentiometers so that equation 13 is satisfied for each interval i. The counter is provided with a manual advance so that the inputs may be sampled one at a time at the leisure of the operator. This allows the voltage for each interval to be measured by the precision instrument available on the analog computer, and has the advantage of bypassing some of the effects of the nonideal components in the diode matrix. Alternately, the negative voltage E_e may be combined ahead of the voltage measurement which is then made to satisfy equation 6 and no calculation of E_i is necessary. When the potentiometer adjustments are completed, the function generator output should be the approximated function.

TEST RESULTS

The oscillograms in Figs. 8 and 9 are samples from the very large group of functions that the function generator is capable of generating. In each case of Fig. 8, a staircase waveform of slopes, $c(t)$, and the generator output, $F(t)$, are shown. Fig. 9 shows some other waveforms generated by the function generator.

DISCUSSION OF ACCURACY

The experimental model of the function generator was constructed using only commercial, nonprecision, and inexpensive components. For example, all 60 diodes required for the commutating diode matrix tree are *1N34A*, one of the most inexpensive types available, 39 cents each. With such low-cost components, concern may arise as to the accuracy attainable by the use of the function generator.

Two possible sources of error exist in the generation of an approximation to an arbitrary function. The first is the approximation itself while the second is the implementation of the approximation. When, in the set-up procedure, the voltages, C_i, are precisely measured, the characteristics of the diodes and the potentiometers become unimportant and and errors of implementation are comparable to those in the analog computing equipments. The errors of the first type are, for the same number of segments, comparable to those in any function generator employing an approximation by straight line.

To study the magnitude of the error involved, a sine wave was approximated so that the desired function is $f(t)=\sin wt$ while the generated function is $F(t)$. The per-cent error is defined here as

$$\frac{\int_0^T |f(t)-F(t)|\,dt}{\int_0^T |f(t)|\,dt}$$

and computation for the sine wave example yields an error of 1.29 per cent. For comparison, a calculation based on the definition of Hamer[12] yields a maximum per-cent difference between $f(t)$ and $F(t)$ as 1.93 per cent. Finally, actual measurement of harmonic distortion was made with the generator generating the approximated sine wave. When a single integration was used ($p=1$), the generator output shows a harmonic distortion of 4.07 per cent. When a double integration was used ($p=2$), the generator output shows a harmonic distortion of 1.24 per cent. These figures of errors include errors of both types.

Summary

The primary purpose of the function generator is to provide an approximation to a specified function as a forcing function to an actual or a simulated system. Consequently, the function generater developed here is used as a part of existing analog computing facilities. However, aside from this primary application, the new function generator can be particularly well-suited to the following applications because of its flexibility and low cost:

1. For computer study of transient response of systems, the function generator can provide an arbitrary but known forcing function other than a step function or a ramp function. This may be accomplished when the new function generator is on "one shot" operation instead of periodic operation.

2. As a college laboratory instrument, the new function generator may be used for a number of standard functions which normally require a separate instrument for each function. This is especially convenient when the potentiometers are replaced by precalibrated plug-in resistor cards.

3. If the integrator of the generator is bypassed (or $p=0$) so that $c(t)$ is taken as the output of the generator, the function generator becomes well suited for the studies of discrete signal systems. Several examples are:

   (*a*). With all inputs but one set to zero, the output is a pulse of width T/n and an amplitude determined by a single input. If a time varying signal is applied to that input, the amplitude of that pulse will be modulated by the signal. The modulating signal could be obtained from a second function generator. This will allow the extension of studies on pulse amplitude modulation beyond the use of a single frequency sine wave.

   (*b*). If all potentiometers are set to nonzero values, the voltages, $e(t)$ and $c(t)$, are of the same form as the output of a holding circuit in a sampled-data control system. Thus the function generator may be used in a computer study to simulate the output of a holding circuit.

   (*c*). The function $c(t)$ may be so adjusted that it can be used to represent the forcing function of a difference equation. The use of this function and this function generator would allow the simulation of certain digital systems on an analog computer.

4. If there are two such function generators available at the computer, they may be designed to allow for an adjustable delay between their time scales. Calculation of correlation functions, which involves delay, may be easily carried out with such analog computing equipment.

5. The concept of a matched signal or a matched filter suggests that, for optimum freedom from noise, the signal component of the input be $h(-t)$ for a system with an impulse response of $h(t)$.[13] With the new function generator, it is of no difficulty to generate $h(-t)$ once the waveform of $h(t)$ is known and the time scale is shifted.

6. The function generator may also be used in simulating environment in certain equipment tests. One such example is the radar test in which a vehicle at various ranges, velocities, and accelerations is to be simulated. One instrument that is used for such testing[14] provides for an input from a function generator to simulate a maneuver. The use of the function generator should add to the versatility of the radar tests made with the instrument.

The design of the new function generator makes use of both digital and analog circuit design concepts. As a result, the function generator is useful in both digital and analog simulations. It thus further expands the capacity of an existing analog computer to include the study of discrete or digital systems.

Nomenclature

$A, B, \ldots, X$ = logical variables
$A', B', \ldots, X'$ = negations of the logical variables
a = a scale factor used in approximating a function
$c(t)$ = a variable voltage, the output of a commutator
$c_i(t)$ = the part of $c(t)$ corresponding to interval i

C_i = a constant voltage associated with the interval i
$e(t)$ = a variable voltage, the output of the diode matrix
e_i = a variable voltage associated with the interval i
E = a constant power supply voltage
E_c = a change of d-c voltage level
$f(t)$ = a time function to be generated by the function generator
$F(t)$ = the time function generated by the function generator
i = an integer, the number of a segment or an interval along the time axis
K_i = a constant, equal to the derivative of $F_i(t)$
N = a number, a normalizing scale factor used in approximating a function
n = an integer, the number of segments to be commutated by the commutator
P_i = a potentiometer associated with interval i
t = time variable
T = the period of a periodic function
x = a dependent variable

Current-Operated Diode Logic Gates

HENRY REINECKE, JR.
NONMEMBER AIEE

THE LITERATURE contains many articles on the design of voltage-operated diode logic gates. Perhaps the major disadvantage of this type of gate is the restriction of the design to two or three stages which does not, in general, allow realization of minimal networks or which alternately requires the insertion of a gain device to re-establish the voltage levels. This paper formulates the general realization procedures applicable to the synthesis of current-operated diode logic networks. The current-operated gate is essentially the dual of the voltage-operated gate; this relationship is established to substantiate the utilization of existing synthesis methods. Two distinctly different realization procedures are described, both equally general, and the choice is usually dictated by the nature of the specific transmission function. The Boolean operations of addition and multiplication (commonly referred to as OR and AND respectively) are more conveniently realized with the use of the "dual method." The operation of sum modulo two (or function selection) is more economically synthesized using the "lattice method." For a further discussion of the terms see the section on add and multiply, reference 1.

The operation of complementation assumes a unique meaning in current-operated systems because the reversal of a current may be accomplished by simply transposing the two lines connecting the gate output and the load.

A static multiplier capable of simultaneously multiplying two 4-bit binary numbers was designed employing current-operated techniques exclusively. This particular type of multiplier was selected because it advantageously utilizes both realization methods and requires the synthesis of a wide variety of transmission gates.

Preliminary Derivational Steps

Conventions and Dual Relationships

The realization procedures for current-operated diode logic gates may be derived from the rules employed for voltage-operated gates, using the principles of duality. Table I lists the pertinent standard dual relationships and Table II summarizes the conventions applied to voltage-operated gates and the corresponding conventions for the current-operated gates.

In accordance with these conventions, the 2-input add and multiply (alternately referred to as OR and AND respectively) gates and their respective duals are shown in Fig. 1. For background information on duality and the construction of dual graphs see references 2 and 3. The polarity of the current sources is established by employing the convention; when the dashed line connecting points a and b, which intersects the voltage source, is traversed in the direction from a to b and the voltage source is polarized to the right (or the normal direction of current flow

INPUTS SHOWN FOR STATE A=B=1

Fig. 1. Basic add and multiply gates

is clockwise), the current source in the dual circuit is confluent on *a*. Conversely, if the voltage source is polarized in the opposite direction the corresponding current source is confluent on *b*. Similar conventions apply in determining the polarity of the diodes. Traversing the dashed line from *a* to *b*, crossing the diodes, if the preferred direction of conduction is to the right (or clockwise), the diode in the dual circuit points toward *a*. If the preferred direction of conduction is to the left (or counterclockwise) the diode then points toward *b*.

In practice, the load resistor associated with the add gate is generally returned to a voltage more negative than the magnitude of the voltage used to represent a low (or 0) input; the current source shunting the load resistor in Fig. 1(A) is merely the Thévenin equivalent of this situation. The converse is true for the multiply gate shown in Fig. 1(C), and hence the current source is reversed.

Basic Add and Multiply Gates

All diodes shown in Fig. 1 are ideal and the inputs are shown for the state $A=B=1$. The voltage source in the current-operated gates serves to reverse-bias all diodes not forward-biased by their associated current sources. Also, the load conductance is high, and proportional to the load resistance of the voltage-operated gate. Determination of the transmission of the gates is readily accomplished by considering the four possible combinations of the inputs. The add circuit is redrawn for all four input states and a reasonable set of network parameters is shown in Fig. 2; idealized results are included. In addition, the various mesh currents and their associated paths are shown to indicate the direction of the load current. In general, the current paths are obvious by inspection, although some elaboration on Fig. 2(B) may be beneficial. Both current sources appear to be in the direction to forward-bias the diodes. However, the voltage drop across the load is 0.2 volt which subtracts from the 1.0-volt source. The remaining 0.8 volt is sufficient to reverse-bias the diodes and direct the current as shown.

Using the convention that current down through the load represents a 1 (one), we may deduce that the transmission is represented by $T=A+B'$. The above procedure may be repeated for the multiply gate which has a transmission of $T=AB'$. A few preliminary conventions may now be stated: 1. Diodes in series pointing up represent elements of add gates. 2. Diodes in series pointing down represent elements of multiply gates. 3. If the input current source points up when the variable is in state 1, the input is represented by the unprimed literal; conversely, if the input current source points down when the variable is in state 1, the input is represented by the primed literal. 4. Current down through the load represents a transmission of 1.

Directing our attention to the diodes at this point, which in the nonideal situation will exhibit a voltage drop of a few tenths of a volt when conducting, and observing that this voltage would be of the same polarity as the auxiliary voltage source, it appears that the series bias-voltage source might be eliminated.

Realization and Design of Current-Operated Gates

Dual Method of Realization

The dual method of realizing current-operated diode logic networks utilizes to advantage the diode voltage drop. The general principles of realization are established by analyzing the simple multistage network of Fig. 3 which represents the transmission function $T=AB+A'C$. The networks of Fig. 3(A) and Fig. 3(B) are dual and use ideal diodes. As suggested above, if the ideal diodes were replaced by nonideal diodes it might be possible to eliminate the three bias-voltage sources shown in Fig. 3(B). Using an ideal diode, in series with a voltage source as the equivalent circuit of a nonideal diode, accounts for the forward drop of real diodes and may suffice as a first-order approximation. The characteristics of a germanium junction diode and the proposed equivalent circuit are shown in Fig. 4 for comparison. It was previously

mentioned that G_1, G_2, and G_3 are relatively high conductances and hence virtually short circuits. They perform no logical function and may be eliminated but actually it is desirable to retain G_3 to provide means of sensing the load current.

The network of Fig. 5 is derived from that of Fig. 3(B). This can be done after all the suggested substitutions have been made and the bias-voltage sources (E_1, E_2, and E_3) and conductances (G_1 and G_2) removed. A complete analysis of this circuit is required to justify the previous steps. Since the system contains three variables, there are eight distinct input states for which the circuit operation must be determined. The nonideal diode equivalent circuit consists of an ideal diode in series with a 0.24-volt source, which corresponds to the voltage drop across a *CTP-521* (germanium diode) at a current of 1.0 ma (milliampere). Although the logic level is 0.5 ma, it is shown below that any conducting diode always operates at a current equal to twice the logic level. The current sources are typically 0.5 ma and the load resistance is equal to 40 ohms. Using these values, the various voltages were calculated (or assumed, in the cases where the values are known to be indeterminate, by considering all similar elements identical), and tabulated on the diagram. The bottom values represent the measured data and are included to facilitate comparison of the results. The arrowheads indicate the reference directions of the branch voltages.

Referring to Fig. 5 and Table III(a), the first input state to be considered is $A=B=C=0$, and the polarity of the current sources correspond to the convention that the source points up when the literal is in state 1. Current source A' points up, which causes diode c to conduct, and allows the current to circulate in this mesh. The second mesh current of interest is described by a path linking current sources A and B, conducting diode c, and current source C, and is completed via the load. Diodes a, b, d, e, and f remain essentially nonconducting because of the bias applied across their associated branches. Kirchoff's voltage law requires that the algebraic sum of the voltages around any closed loop must equal zero. To meet this requirement the terminal voltages of sources A, B, and C must assume the values indicated. The voltage at the node joining diodes a and b is indeterminate, but if the diodes are assumed to be identical, the voltage across each would be the same. Ideally, the load current would be 0.50 ma; the reduced magnitude of the measured value is due to the deviation of the actual diode characteristics from that of the assumed equivalent circuit. The transmission is zero because the output current is directed up through the load.

Circuit operation for the remaining input states will be discussed more briefly. In particular, to eliminate extensive repetition, the meshes will be described by indicating the sources and/or diodes which they include, using only the letter associated with each, and ordering the letters to correspond to the direction of current flow. The two mesh currents in Table III (b) are *A-B-e* (this abbreviated form is used to indicate that the current from source *A* flows through source *B* and finally returns via diode *e*) and *C-A′-e*-load. Diodes *a*, *b*, and *f* are obviously nonconducting, but diodes *c* and *d* shunt sources *A′* and *C* respectively. These diodes would ideally be nonconducting but, owing to the bias present, a small amount of current will flow. The effect of such shunt paths is to reduce the actual output current. The transmission is 1 because the output current is down through the load.

Three meshes are established in Table III(c). The two minor ones are: *B-b* and *A′-c*; the one including the load is *A-b-c-C*-load. The transmission is zero and no significant "shunt paths" exist for this configuration. The three meshes present in (d) are: *B-b*, *A-b-e* and *C-A′-e*-load and diodes *c* and *d* shunt a fraction of the current in a manner similar to that discussed for (b). However, the direction of the current in the load shows the transmission to be 1 as required. Operation of circuits of (e) through (h) are very similar to the previous circuits as may be determined by comparing (e) and (a), (f) and (c), (g) and (b), and finally (h) and (d). In general, the function of the upper and lower halves of the circuits has been interchanged but the configuration of the meshes having circulating currents is the

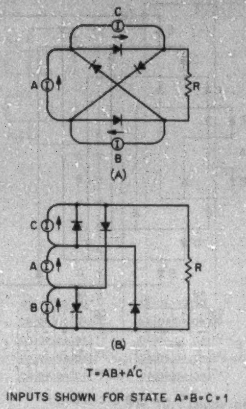

Fig. 7. Generalized current-operated lattice network

same. For completeness, the conducting meshes are tabulated below:

Table III

Line Designation	Conducting Meshes
(e)	*A-a*; *a-B-A'-C*-load
(f)	*A-a*; *C-d*; *a-B-A'-d*-load
(g)	*A'-C-f*; *f-B-A*-load
(h)	*C-d*; *A'-d-f*; *f-B-A*-load

In general, the calculated voltages are in excellent agreement with the measured values, except in the cases where the voltages were indeterminate. Since the voltage across the 40-ohm load (a ±0.50 millimeter) never exceeds 0.02 volt, it is a sufficiently good approximation to a short circuit with respect to the 0.24-volt drop across a conducting diode.

Reviewing the results of Fig. 5 and Table III, it is concluded that the auxiliary series bias-voltage sources and the intermediate conductances may be eliminated. Furthermore, this realization demonstrates the method of combining stages, and points out the similarity between multistage voltage-operated and current-operated gates. The two terms of the minimum-sum function are separately realized with the use of multiply gates. The term AB is obtained by applying current sources A and B to two diodes in series pointing down. Similarly, the term $A'C$ is formed by applying current sources A' and C to two diodes in series pointing down. The output of these gates is a current which has a specified direction depending on the state of the inputs. Addition of the two terms is accomplished by a 2-input add gate which requires two series-connected diodes pointing up. The outputs of the two multiply gates serve as inputs to the add gate which completes the realization.

The operation of complementation has a unique meaning in current-operated systems. Clearly, if the output lines of the network in Fig. 3(B) were transposed without changing the position of the load, the current would flow through the load in the opposite direction. Retaining the original convention that current down through the load represents a transmission of 1, it would be concluded that the transmission of the gate was the complement of the realization intended. Another approach to this problem is the realization of the complementary transmission function. If this is carried out the resulting network will be identical to that of Fig. 3(B) revolved 180 degrees about a horizontal center line. This reorientation of the circuit reverses the direction of the sources and the diodes, and interchanges the add and multiply gates, but the network remains unaltered. Hence, the realization of any specified transmission function is unique but indistinguishable from its complement. This property results from the fact that the output current is not referred to a specified reference current, as is the output voltage in voltage-operated systems.

The 4-stage circuit of Fig. 6 illustrates the application of the design techniques and the method of interconnecting the diodes to accomplish "logical" addition and multiplication. All current sources have been omitted, the appropriate convention being that the implicit current source points up when the associated literal is in state 1; conversely, the source points down when the associated literal is in state zero. Hence, for the state $A=B=C=D=E=1$, all current sources are directed upward except those represented by primed literals. In this diagram, the rectifier symbol represents the actual diode and replaces the previously used equivalent circuit of an ideal diode in series with a voltage source. The given transmission function is realized by considering the more subordinate portions first, which in this case corresponds to $A'B$. This term is realized by a basic multiply gate.

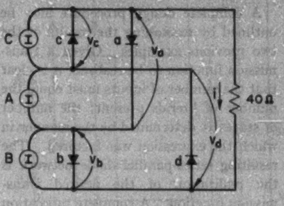

Fig. 8. Experimental results of lattice network gate calculations

Each remaining term is subsequently synthesized and the outputs to these stages may be employed as inputs to succeeding stages in a manner identical to that for which the input is a primary current source. A ±0.50-ma center-reading milliameter, having an impedance of approximately 40 ohms, was used to make the measurements and it also constituted the output load resistance. The measured output currents for the 32 input states are tabulated with the use of Karnaugh maps[4]; a positive current represents a transmission of 1 and a negative current represents a zero transmission. The minimum-sum form of the transmission equation may be written directly from the maps as $T=A'BDD'+A'BE+CD'+CE+ABD$, which is the desired result. A 2-stage realization would require 18 diodes, in contrast to the 13 diodes used in the multistage network.

(g)	1	1	0	+0.01 −0.01	+0.01 +0.03	+0.24 +0.24	−0.26 −0.26	+0.50 +0.50	1
(h)	1	1	1	+0.01 +0.04	+0.01 −0.02	−0.01 −0.01	−0.01 −0.01	+0.50 +0.50	1

A complete design procedure may be outlined by examining the results of the two previous examples. Given a transmission function to be realized, it is clear that the number of inputs must equal the number of literals present; the number of stages is determined by the manner in which the expression was factored. The resulting series-parallel diode network is the realization of the desired transmission function. A complete tabulation of the design procedure is included in Appendix I for convenient reference.

LATTICE METHOD OF REALIZATION

The lattice method of realizing current-operated diode logic networks uses four diodes connected in series to form a ring as the basic building block. The unique transmission characteristics of this configuration will be discussed for the generalized case. A 4-diode lattice network is shown in Fig. 7(A) and is redrawn in (B) to resemble more closely the previous diagrams and to facilitate the application of the established conventions to this method. All rectifier symbols represent nonideal diodes and the load impedance is low, effectively a short circuit, as was the case for the previous method.

The lattice structure is a general 3-input network and its transmission is represented by $T=AB+A'C$. All conducting meshes for the eight input states may be determined from the tabulated data of Fig. 8 and Table IV, and are listed below:

Table IV

Line Designation	**Conducting Meshes**
(a)	*C-A-B*-load
(b)	*A-B-d, d-C*-load
(c)	*B-b; C-A-b*-load
(d)	*B-b; A-b-d; d-C*-load
(e)	*C-c; A-c-a; a-B*-load
(f)	*A-C-a; a-B*-load
(g)	*C-c; B-A-c*-load
(h)	*B-A-C*-load

It is interesting to note that diodes *a* and *c* remain nonconducting for the four input states when current source *A* is in state zero; and that diodes *b* and *d* remain nonconducting for the four input states when current source *A* is in state 1. Inspection of the output state column of Fig. 8 and Table IV, reveals the fact that the realization satisfies the desired transmission function.

The principle of operation parallels that of networks realized with the use of the dual method, where it was observed that current circulates in various meshes, thereby establishing the direction of the current in the mesh which includes the load; current down through the load signifies a transmission of 1. All conducting diodes are observed to link two meshes and the current in each is equal to twice the logic level. The eight measured values of output current are all equal to 0.50 ma, and were obtained using the ±0.50-ma center-reading milliameter.

The design rules depend primarily on the relative directions of the current sources with respect to each other. For the general lattice transmission function, $T=AB+A'C$; either of two conventions may be chosen because of the symmetry of the network. Referring to Fig. 7(B), if current source *A* points up when in state 1, the two product terms will be *AB* and *A'C* respectively, if current sources *B* and *C* point up when their inputs are in state 1. Addition of the terms is inherent in the lattice network which realizes the entire transmission function.

Complementation of any of the variables contained in the function requires reversal of its associated current source. To complement the transmission, the entire network may be revolved 180 degrees about a horizontal center line or the output lines may be transposed. As noted in the discussion of the dual method, the realization is unique and identical to that of the complemented function.

The design procedures for realizing lattice networks are summarized in Appendix I. Comparing this lattice realization with the dual realization of Fig. 3(B) for the same transmission function, a marked reduction may be observed in the number of diodes required. This economical feature is one of the primary advantages of the lattice network. One obvious difference in this method is that current source *A* is not associated with a specific diode, and it performs basically a function of path selection. Substituting a current source B' for the current source *C* yields a transmission of $T=AB+A'B'=A\oplus B'$. This function represents the operation of sum modulo 2 (alternately referred to as ring sum, circle sum, or "exclusive or") and finds many useful applications in digital systems.

Multistage gates may be realized by cascading a number of lattice networks, or by employing the outputs of lattice networks as the inputs to another lattice network (i.e., replacing current sources *B* and *C* in Fig. 7 by the outputs of lattice networks). A more general form of the transmission equation is $T=T_aT_b+T'_aT_c$, where the subscripts correspond to the input positions designated by the capital letters in the previous expression. This expression indicates that the inputs are not restricted to simple current sources; they include currents derived from gate outputs. The operation of sum modulo 2 on five literals is accomplished by cascading four lattice configurations as shown in Fig. 9.

10	− .40	+ .40	− .40	+ .40

Fig. 9. Multistage lattice networks and measured load currents

The measured output currents are tabulated using two Karnaugh maps from which the transmission function may be directly determined as $T=A\oplus B\oplus C\oplus D\oplus E$. The magnitude of the output current for all 32 input states is equal, which is apparently a result of the symmetry of the network. A 2-stage voltage-operated gate would require 96 diodes, in contrast to the 16 used in the cascaded lattice realization.

HYBRID AND MULTIPLE OUTPUT CIRCUITS

In general, any arbitrary transmission function may be realized using either the dual or the lattice method, although the number of diodes required may be different. Therefore, in the interest of economy, it may be advantageous to consider hybrid realizations which result in more minimal networks. The standard minimizing techniques currently in use reduce the transmission function to its minimum-sum or minimum-product form. This is satisfactory for the realization of 2-stage gates which are extensively used in voltage-operated systems. No practical procedure has been devised which will always result in the simplest transmission expression of any order, where order is synonymous with the number of stages required in the realization. In addition, it would be advantageous to have a method of minimization based on the three binary operations add (+), multiply (·), and sum modulo 2

Fig. 11. Multiple output realization

(⊕). Curtis describes a procedure based on this approach.[5]

Two examples of hybrid realizations extracted from the series of carry and sum gates used in the static multiplier are included. The transmission function of Fig. 10(A) is realized with the dual method employed, and the circuit uses as one of its inputs the output of two cascaded lattice networks. Remarks describing the significance of the diodes, drawn in dashed lines, are contained in the following section. The network of of Fig. 10(B) is essentially a cascaded lattice structure whose inputs represent dual realizations of the product terms represented by Cb and Da.

A single example of a multiple output realization will be presented to clarify the definition and to demonstrate the design technique. The particular pair of transmissions chosen for this illustration are the sum and carry functions associated with a parallel binary adder. If A_i and B_i are the addend and augend bits in the ith binary position, the sum S_i and carry C_i may be expressed as follows, using C_{i-1} as the carry from the adjacent column toward the least-significant-bit end of the word.

$$\begin{aligned} S_i &= A_i \oplus B_i \oplus C_{i-1} \\ &= C_{i-1}'(A_i \oplus B_i) + C_{i-1}(A_i \oplus B_i)' \\ C_i &= A_iB_i + A_iC_{i-1} + B_iC_{i-1} \end{aligned}$$

Expanding in terms of sum modulo 2 yields

$$\begin{aligned} C_i &= A_i(A_i'B_i' + A_iB_i) + C_{i-1}(A_i'Bl + \\ &\qquad A_iB_i') \\ &= A_i(A_i \oplus B_i)' + C_{i-1}(A_i \oplus B_i) \end{aligned}$$

The sum modulo 2 of A_i and B_i, and its complement, are both present in the carry and the sum; therefore we may realize this portion of the functions separately and use it as a common input. A simple lattice network having this transmission is shown in Fig. 11, with its output applied to the inputs of two other lattice networks. Straightforward realization produces the sum and carry as shown. Since the first lattice is required to supply current to two lattices in parallel, the logic levels in the first lattice (i.e., the magnitude of current sources A_i, B_i and B_i') must be doubled at all three inputs. This output current then divides equally, producing the proper output levels for the sum and carry networks. The usefulness of this arrangement is enhanced when we evaluate the relative economies of this realization as opposed to the 2-stage voltage-operated gates. For the latter, a total of 25 diodes are required; 16 diodes for the sum and 9 for the carry. A saving in excess of 50% is achieved with the use of the multiple output lattice network consisting of 12 diodes.

PRACTICAL DESIGN CONSIDERATIONS

There are a number of practical problems associated with the design of current-operated diode logic gates. These include modified realization techniques in special cases, requirements imposed on auxiliary circuits, and general restrictions present in any nonideal system. A pertinent question arises concerning multiple inputs which are dependent on a common variable, where "multiple inputs" refers to either the number of times a specific literal and its complement are repeated for a single gate realization or throughout the entire system. In voltage-operated equipment, all inputs requiring the same literal (or function) are connected to a common point which may be a flip-flop or gate output. Existing digital components usually exhibit low output impedance characteristics and are capable of driving many inputs. The requirements for current-operated systems are markedly different. Components are needed which have a number of high-impedance outputs. These outputs should preferably be isolated, and identical in their performance. Neither devices nor circuits which meet all these specifications are presently available, although a reasonable approximation may be derived with the use of standard components.

Using a conventional flip-flop or a differential amplifier as shown in Fig. 12, both the output and its complement may be paired and connected to all inputs dependent on this binary variable. Conversion of this voltage into many identical current sources is accomplished within the gate circuits in the manner illustrated in Fig. 13. Since the impedance presented to any input current source is relatively low, either a single conducting diode or a series circuit of conducting diodes and current sources, a good approximation to a current input is achieved by inserting series resistance between the network and the $A(1)$ and $A(0)$ voltage inputs. Clearly, the potential difference between

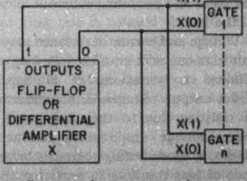

Fig. 12. System wiring scheme

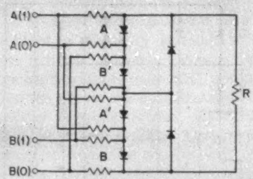

Fig. 13. Implementation of current sources

$A(1)$ and $A(0)$ should be large in comparison to the voltage across one or more conducting diodes which constitute the current source load.

Examining Fig. 13 reveals that both A and its complement are required as inputs to the network. Current source A is derived by inserting a resistor between $A(1)$ and the anode of the diode, and an equal resistor between $A(0)$ and the cathode. The complemented current source is obtained by interchanging the connections to $A(1)$ and $A(0)$, effectively inverting the source and reversing the current with respect to current source A. Inputs B and B' are obtained in a similar manner. It should be pointed out that the load on any flip-flop depends only on the number of inputs it must supply, and is independent of the state of the flip-flop. The load reflected by the parallel resistor-diode branches is essentially constant and balanced; the state of the input merely determines the direction of the current.

Another important factor is the determination of the magnitude of the current to be used to represent the logic levels. This problem is slightly more involved. Actual diode volt-ampere characteristics must be considered because severe current and voltage imbalances may result in marginal circuit performance. This item will be more fully discussed below. In equipment constructed to date flip-flops and current buffers were employed having outputs of ±5 volts, and providing a voltage difference of 10 volts. All series resistors were 10 kilohms with the result that the logic level was 0.50 ma. This set of values proved to be very satisfactory from the standpoint of loading by the gates and providing sufficient current in the load.

Voltage and current imbalance may result from one or more of the following conditions: 1. variations in flip-flop or buffet output voltages, 2. nonuniformity of resistors due to their tolerances, 3. finite voltage drop across conducting diodes, 4. diode leakage currents or presence of bias resulting in partial conduction, and 5. loading by the detector which senses the output current. In general, the effect of these imbalances is a reduction in magnitude of the zero and 1 current outputs. A few typical examples will be discussed which illustrate the practical problems involved in designing current-operated diode logic circuits.

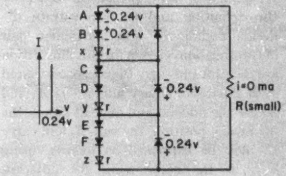
A simple 2-input add gate, shown in Fig. 2(B), serves to illustrate the effect of unequal current sources. Assume the inputs as indicated on the diagram, but let the magnitude of source A be 0.4 ma, and determine the remaining currents. The diode opposite source A will remain nonconducting, but the output current will be reduced to 0.4 ma because source A is in series with the load. Current source B' will deliver its specified 0.5 ma, of which 0.4 ma must flow through the load and 0.1 ma must flow through the diode faced by the source. This diode will conduct, although theoretically it is to remain nonconducting. For this simple network the effect of the unbalanced current is almost trivial; it simply reduces the output current. In more elaborate networks the conducting diodes would establish "sneak paths" which could adversely affect the performance of the circuit. No reason was given for the inequality in the assumption made earlier, that the currents were unequal. When the inequality was due to unequal input voltages or currents, the previous arguments would apply only if the errors were symmetrical. This brings up the problem of errors due to voltage imbalance, which is perhaps the more serious problem because it applies to all types of networks.

If the currents are derived as was suggested, with flip-flops and series resistances, all current sources will essentially be commonly connected. Assume the flip-flop outputs to be +E and −E, symmetrical about zero volts or ground, connect identical resistances to each output and then connect these resistances to a load. If the load were a short circuit, the potential of this point with respect to ground would be zero volts. Hence, if the inputs are symmetrical with respect to ground it would be desirable to have all portions of the network at this potential. This requirement cannot be satisfied for all input states of a network due to the finite voltage drop exhibited by a conducting, nonideal diode.

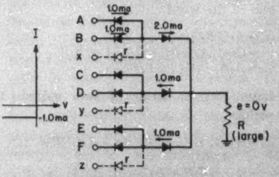
To emphasize this condition, consider a 20-input multiply gate of which 19 inputs are in state 1. The cumulative voltage across the 19 conducting diodes would be approximately 4.5 volts. It is obvious that this would severely unbalance the currents if the input voltage were ±5.0 volts. Furthermore, the terminal voltage of the current source associated with the zero input would have to exceed this voltage (and be of opposite polarity) to cause the current in the load to flow in the proper direction. A solution to this problem, using a multistage network, consists of dividing the network into several multiply gates each having only four or five inputs. The second stage would also be a multiply gate, and its inputs would be the outputs of the first-stage gates. In terms of circuit particulars, equal groups of diodes would be shunted by a single diode, pointed in the same direction. This procedure could be extended to several stages if necessary.

Multistage networks are generally formed by cascading alternately add and multiply gates. The circuit will therefore contain several columns of diodes, those in adjacent columns oppositely polarized. Over-all voltage imbalance is usually less severe in the typical case because the voltage drops across the diodes pointed up will tend to be canceled by the drops across diodes pointed down. It has been demonstrated that practical multistage networks can be designed by means of current-operated techniques.

Factored transmission expressions require fewer literals than the equivalent lower-order functions. Since each literal represents a required current source input, higher-order functions require fewer inputs. Any reduction in the number of inputs is advantageous in limiting the detrimental effects of voltage and current imbalance. All items discussed thus far may be classified as engineering prob-



(A)CURRENT-OPERATED GATE



(B) VOLTAGE-OPERATED GATE

Fig. 14. Realization requiring redundant diodes

lems. In most cases several acceptable solutions exist and consideration must be given to the specific application or requirement.

A second category of problems requires modification of the realization rules because the resulting networks fail to meet the transmission specifications. In particular, the output currents may be of the wrong polarity or greatly reduced in magnitude. Why do the realization rules fail? Previous discussion has indicated that the auxiliary series bias-voltage sources shown in Fig. 3(B) could be eliminated because the voltage drop across conducting diodes is of sufficient magnitude to reverse bias diodes which are to remain nonconducting. The elimination of the bias-voltage sources is usually valid and the practical advantages of a technique which employs diodes only but does not require numerous floating voltage sources is obvious. Although the elimination of the bias-voltage sources is valid for all single-stage gates it is not valid for all multistage gates.

To review the requirements of multistage gates, it will be recalled that the output of all stages must effectively represent current sources (for every possible state of the inputs) to drive the succeeding stages properly. The output of a stage will fail to represent a current source if for any specified input state all diodes in the stage become conducting. The current sources forward-bias the diodes in an attempt to establish sufficient terminal voltage (of the proper polarity) to cancel opposing voltage drops present in the mesh of interest. This voltage must be supplied by the current sources in order to establish current flow in the correct direction. Current-operated diode logic gates exhibiting the conditions outlined above may not satisfy the desired transmission specifications.

However, experience gained in designing the static multiplier (mentioned at the start of the paper), and numerous other gates, indicates such difficulties to be the exceptions and not the rule. Furthermore, if only minor network modifications are required to correct the transmission, it is simpler to treat malfunctioning realizations as special cases. The remedy usually requires the addition of one or more diodes strategically located. These additional diodes will be referred to as redundant diodes because they perform no "logical" function. In certain instances, the addition of a redundant diode permits, oddly enough, the omission of another diode which appears to be "logically" required. Diodes which may be omitted without affecting the transmission of the gate will be referred to as superfluous diodes.

The first class of networks to be discussed is that of 2-stage realizations representative of the minimum-sum or minimum-product forms of the transmission function. Fig. 14(A) shows the current-operated realization of the function $T = AB + CD + EF$; a sketch of the $V-I$ characteristics representing the equivalent circuit of a nonideal diode is included for reference. The dual of this network is found in Fig. 14(B) which includes a sketch of the V-I characteristics of the equivalent "dual diode." This hypothetical element conducts for all values of positive applied voltage and exhibits a constant "leakage current" for negative voltage. An equivalent circuit of this device consists of an ideal diode in parallel with a constant current source, polarized in the direction to cause the diode to conduct. If a practical device having these characteristics were available, voltage-operated gates could be realized in a manner dual to that suggested for current-operated gates.

The reason for introducing this hypothetical diode and the corresponding network is to provide an alternate approach to clarify the following discussions. The networks are identical to the circuits of voltage-operated gates with all stage load resistors omitted. Familiarity with voltage-operated gate circuits greatly simplifies the problem of determining the proper location of redundant diodes.

Return to Fig. 14(A) and assume the input state $A = B = 1$ and $C = D = E = F = 0$. The output should be 1, because of current down through the load. The measured output current of this circuit will be approximately zero for this particular input state, in accordance with the idealized calculations. For current to flow down through the load, the cumulative terminal voltage of current sources A and B must exceed 0.48 volt to overcome the voltage drop of the two conducting diodes in the second stage. However, the diodes faced by sources A and B will conduct as soon as the terminal voltage equals 0.24 volt, and will limit the terminal voltage to this value. Therefore, the voltage drops across the conducting diodes will exactly cancel and no current will flow in the load. The identical results will be obtained if only C and D or E and F are equal to 1.

Several solutions suggest themselves; one is to use six silicon diodes in the first stage and three germanium diodes in the second stage. A second method requires the addition of three redundant diodes, one in each first-stage gate. These diodes are shown by dashed lines in Fig. 14(A); the r indicates that they are redundant. The associated sources are labeled x, y, and z for identification, to facilitate discussing the various ways in which they may be used. The diodes effectively simulate the bias-voltage sources which were previously eliminated.

To complete this simulation, sources x, y, and z could simply be unit current sources causing the associated diodes to conduct, exhibiting a voltage drop of 0.24 volt. Other alternatives exist: source x could be either a second source A or B, source y could be either a second source C or D, and source z could be either a second source E or F. Any of the suggested solutions are satisfactory; the decision is left to the designer.

For those more familiar with voltage-operated gates a brief discussion of Fig. 14(B) will demonstrate the utility of the analogy. Assume the same input state as before. For ease of calculation let the current sources shunting the ideal diodes be equal to 1.0 ma, and determine the output current. The diodes connected to voltage sources A and B are both reverse biased. A current of 1.0 ma will flow bypassing the diodes (due to the current sources) with the result that 2.0 ma will enter the next stage. The 1.0 ma associated with the diode in the second stage is confined to circulate in a mesh which consists of this diode and its corresponding source and does not enter into the calculations.

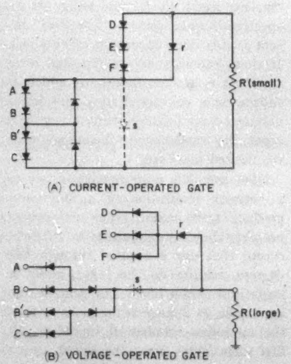
Voltage sources C, D, E, and F hold their respective inputs low, and allow the diodes to conduct. However, the 2.0 ma leaves the top diode in the second stage, and divides as shown. Each of the 1.0-ma currents again divides and enters its respective voltage source. The load current is zero and no output is obtained. If these calculations are repeated after the three redundant diodes are added as shown, each connected to a unit input voltage source or duplicating an existing input, the transmission will conform with the desired function.

Obviously, the same remarks apply to a network realization of a minimum-product transmission. The uniqueness property shows the circuits to be identical except that one is rotated through 180 degrees, relative to the other, about a horizontal center line. The general rule applicable to 2-stage realizations is that the minimum number of inputs to all first-stage gates must be equal to or greater than the number of inputs to the second-stage gates. From a geometrical standpoint this implies that there must be at least as many series-connected diodes in each gate in the first column as there are diodes in the second column.

The second class of networks includes all multistage realizations which do not satisfy the desired transmission specifications because the series bias-voltage sources were eliminated. This miscellaneous category also includes networks which may be further minimized, not by algebraic methods but from operational considerations which show that a particular diode is not required to conduct for any state of the inputs. The network in Fig. 15(A) and its dual in Fig. 15(B) will be used to illustrate these points. These circuits each contain a diode which is superfluous, and is shown by dashed line and designated by an *s*. In the current-operated gate this diode may be removed and replaced by an open circuit, and in the voltage-operated gate it may be removed and replaced by a short circuit.

Experimentation showed this gate to malfunction for the input state $A=B=C=0$ and $D=E=F=1$. The desired transmission function is $T=DEF\,(AB+B'C)$ and for the given input state the transmission should be equal to zero but was found to be 1. The reason for the malfunction is that insufficient voltage was established by the first stage sources, due to the presence of the two series diodes in the second stage, to overcome the cumulative voltage developed across the conducting diodes faced by generators *D*, *E*, and *F*.

Again, many acceptable solutions exist and the designer must be cautioned against overlooking the simple approach. A straightforward solution is obtained by expanding the function and then synthesizing the result, $T=DEFAB+DEFB'C$. This requires two more diodes and three additional inputs. The solution shown in the diagram was selected because the network is more minimal and it illustrates the presence of a superfluous diode. Adding the redundant diode solves the problem because it reduces, by a factor of three, the voltage across the three input diodes faced by sources *D*, *E*, and *F* when all inputs are in state 1.



(A) CURRENT-OPERATED GATE

(B) VOLTAGE-OPERATED GATE

Fig. 15. Realization requiring redundant elements and detection of superfluous diodes

The superfluous diode, "logically" required by the realization rules, may be eliminated since all four input sources *A*, *B*, *B′*, and *C* cannot simultaneously be equal to 1 requiring the presence of the path provided by this diode. Currents flowing between the nodes to which the superfluous diode is connected are required to choose paths established in the network to the left of this diode because of the disjunctive nature of the function. The net result of this solution requires no more diodes but corrects the malfunction. Analysis of the voltage-operated gate parallels that of the previous discussion and is left to the reader.

One last remark concerning this realization must be made because it occurs frequently. If a hybrid realization were considered, the portion of the function represented by $AB+B'C$ could be synthesized with the use of a lattice consisting of four diodes. This in addition to the four diodes required to form the term *DEF* would complete the circuit. The hybrid circuit was constructed and the transmission experimentally verified. It satisfied the desired transmission equation with a total of eight diodes. Experience has proved, in many instances, that the more minimal network operates satisfactorily, whereas a less minimal realization may exhibit malfunctions for certain input states.

Construction of a Static Multiplier

A static multiplier is a device capable of simultaneously multiplying two numbers without recourse to the accumulation of partial products or shifting operations. Signals representing the multiplicand and the multiplier are simultaneously applied to the logic gate inputs and, after the transients in the system have disappeared, signals representing the product appear at the outputs. It was decided that the design of a static multiplier would provide ample opportunities to evaluate both the design techniques and the advantages of current-operated gates. To achieve this goal, a device capable of multiplying two 4-bit binary numbers was designed and built.

				A	B	C	D
				a	b	c	d
				Ad	Bd	Cd	Dd
			Ac	Bc	Cc	Dc	
		Ab	Bb	Cb	Db		
	Aa	Ba	Ca	Da

K_{72}	K_{62}	K_{52}	K_{42}	K_{32}	K_{22}		
S_8	S_7	S_6	S_5	S_4	S_3	S_2	S_1

Fig. 16. General procedure for binary multiplication

The operation of the multiplier is conceptually simple because it parallels the familiar decimal system method. Fig. 16 illustrates the general procedure, and Appendix II lists the pertinent carry and sum functions. The first form of the expressions is derived by inspection, using Fig. 16, and the second form is the result after minimizing, and represents the transmission function actually realized. In order to limit the number of current buffers required, the minor products were not separately formed with the exception of *Dd*, which is the first sum digit.

Two auxiliary functions were incorporated to reduce the complexity of three gate networks; the functions involved are K_{42}, K_{44}, and S_4. Several redundant superfluous diodes were incorporated, in the networks which represented the realization of K_{42}, K_{44}, and K_{02}, which were not specified by straightforward application of the realization rules. However, the modified circuits performed satisfactorily. Approximately 270 diodes were required to construct the 20 gates used in the static multiplier. A total of four redundant diodes were included to correct malfunctions exhibited in special cases. To balance this number exactly, it was found that four diodes could be omitted because they were superfluous. The previous statements are submitted as evidence that malfunctioning realizations are infrequently encountered and that the network modifications which may be required are usually minor.

The static multiplier block diagram of Fig. 17 indicates the flow of information and depicts the major areas included in the system. Static tests performed on the equipment indicated that all gates operated satisfactorily for the 256 different inputs, thus verifying the correctness of the functions, the minimization steps,

Vol.
Pt. 1
1960

the realization rules, the actual circuits, and the wiring. Dynamic tests were made with a single flip-flop operating in the commutative mode to obtain data on carry propagation time to ascertain the maximum operating speed of the static multiplier.

As always, it is a difficult matter to specify the "worst case" situation. It was found that the significant delays could be attributed to the response time of the current buffer circuit. Therefore, the propagation times were measured for those input combinations which required the greatest number of current buffers to change state. The longest delay measured was 2.4 μsec (microsecond) for a combination which required 12 current buffers to change state. Using the 0.2-μsec delay figure, determined from tests of the current buffer, and multiplying this by 12 because of the number of buffers which made a transition, a total delay of 2.4 μsec is obtained. This value is in agreement with the experimental results. From these data it may be deduced that the maximum reliable operating speed of the static multiplier is approximately 3.0 μsec, which corresponds to 333,000 multiplications per second.

Conclusions

Two realization methods have been presented which are applicable to the design of current-operated diode logic gates. The dual method, as the name implies, consists of a set of rules which are analogous to the procedures employed for voltage-operated circuits. In single-stage gates obtained by using the dual method the input current sources are connected in shunt with their respective diodes, and the diodes are connected in series to constitute the network. The state of a variable is represented by the direction of the current. The output of the gate is also a current which may be used as an input to a succeeding state.

Multistage networks may be realized by series-parallel arrays of basic gate circuits. The lattice method, which has no voltage-operated counterpart, is based on the transmission characteristics of a lattice network of four series-connected diodes. The general form of the transmission function realized by the lattice is $T=T_aT_b+T'_aT_c$. It is observed that the operation of T_a is one of selection. For the special situation where $T_c=T'_b$, the lattice performs the operation of sum modulo 2. Multistage networks may be obtained by cascading a number of lattice circuits. Hybrid realizations which combine the advantages of both procedures, generally require fewer diodes than networks obtained by either method alone. Discriminating application of the current-operated realization rules, which offer numerous synthesis alternatives, should yield more minimal networks than heretofore possible using voltage-operated techniques.

It has been shown that the realization of a transmission function is identical to the realization of the complement of that function by current-operated methods. This unique property exists because the direction of the output current is functionally related to the direction of the input currents.

Although current-operated techniques are not the "last word" in the realization of switching functions using diode networks, this approach does suggest some new and interesting possibilities.

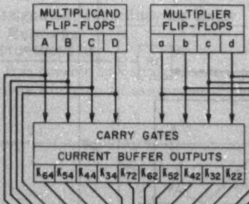

Fig. 17. Static multiplier block diagram

Appendix I. Conventions and Design Procedures

Conventions

1. The literal adjacent to the diode denotes the variable associated with the implicit current source impressed across the diode. When the state of the input represented by the literal is 1, the current source points up. Conversely, when the state of the input is zero, the current source points down.

2. The transmission is 1 when the direction of current flow through the load is down; conversely, a zero is obtained when the current through the load is directed up.

Dual Method

Basic Single-Stage Gates

1. Series-connected diodes pointing up, in the column adjacent to the literals which identify the current sources, represent the elements of an add gate.

2. Series-connected diodes pointing down, in the column adjacent to the literals which identify the current sources, represent the elements of a multiply gate.

Multistage Gates

1. Series-connected diodes pointing up represent the elements of add gates. The current input to each diode is either the output of a previous stage or the output of a primary current source.

2. Series-connected diodes pointing down represent the elements of multiply gates. The current input to each diode is either the output of a previous stage or the output of a primary current source.

Lattice Method

Basic Gates

1. The transmission of the basic lattice network is represented by the selection function, $T=AB+A'C$.

2. In accordance with the conventions of Fig. 7(B), the transmission is equal to the product of the central literal and the lower literal added to the product of the complement of the central literal and the upper literal.

Multistage Gates

1. The transmission of the general lattice network is represented by the selection function $T=T_aT_b+T_a'T_c$.

2. The current inputs are either the output of a previous stage or the output of a primary current source.

Assignment of Carry Variables in Iterative Networks

E. J. McCLUSKEY, JR.
NONMEMBER AIEE

BOTH SEQUENTIAL circuits (Fig. 1) and iterative circuits (Figs. 2 and 3) are usually designed by first forming a stable table (flow table) describing the desired circuit performance.[1–3] In this table the various combinations of signals on the feedback or carry leads (corresponding to the internal states of the circuits) are represented by decimal numbers. It is necessary to assign specific combinations of binary signals to these (decimal) states before the actual circuit design can be carried out. This corresponds to the transition from a state table, such as Table I—A to an output table, such as Table I—B. For a given table, different assignments will usually lead to different circuits which can vary significantly in cost. The problem of minimizing the cost of the equipment can be even more important for iterative circuits since each "cell" occurs many times in the final circuit. The number of different assignments is so large that it is not feasible to try all different assignments for circuits having more than two internal variables.[4] This particular problem of discovering assignments which correspond to economical circuits is still unsolved.

For certain types of iterative or sequential circuits there are restrictions on the assignments since certain assignments lead to circuits which are either not physically realizable or which do not perform according to the original state table. For example, an asynchronous sequential circuit must have an assignment in which either no more than one feedback loop is unstable at one time, or, if several loops are unstable simultaneously, the final stable state reached must be independent of the order in which the feedback loops change their conditions.[1,2]

In an iterative network constructed of contacts it is not true that any assignments will lead to a physically realizable network. For example, the function $Y_1 = y_1 y_2$ cannot be realized by a contact network. The symbols y_1 and y_2 represent inputs to a typical cell and will be called *input-carry variables* since they correspond to signals on the "carry" leads between cells. The symbol Y_1 represents an output from a typical cell and will be called an *output-carry variable*. The circuit inputs will be denoted by x or x_1, x_2 ..., and the circuit outputs by Z, or Z_1 Z_2, ... A specific combination of signals on the input-carry leads will be called an *input-carry state*, denoted by s_j; and a specific combination of signals on the output carry leads will be called an *output-carry state* and denoted by S_j.

The reason that $Y_1 = y_1 y_2$ cannot be realized by a contact network is that y_1 and y_2 represent signals on two separate leads; with the use of contacts only it is impossible to produce a signal on a third lead which is present only when signals are present on both the y_1 and y_2 leads. For similar reasons, it is impossible to realize a function such as $Y_1 = xy_1y_2$. The other type of function which cannot be realized is one which contains the complement of an input-carry variable: $Y_1 = x(y_1 + y_2')$. This is because it is impossible, with contacts only, to produce a signal on one lead whenever a signal is not present on another lead. In general, the following rule applies:

> Any function which contains the product of two or more y_i's or contains any y_i', cannot be realized in an iterative contact network.

A carry assignment for an iterative contact network must result in output and output-carry functions which satisfy this requirement.

It is possible to have a set of output-carry functions which satisfy the conditions required for a contact network realization and which are still not physically realizable. For example, the typical cell of Fig. 4 is derived from the output

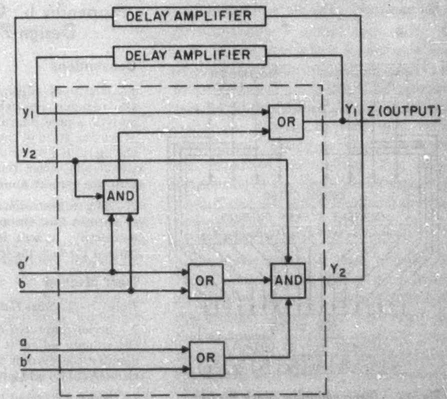

Fig. 1. Sequential circuit which has an output only if A<B:

$A = a_n 2^n + a_{n-1} 2^{n-1} + \ldots a_1 2^1 + a_0 2^0$
$B = b_n 2^n + b_{n-1} 2^{n-1} + \ldots b_1 2^1 + b_0 2^0$

Paper 60-1211, recommended by the AIEE Computing Devices Committee and approved by the AIEE Technical Operations Department for presentation at the AIEE Fall General Meeting, Chicago, Ill., October 9–14, 1960. Manuscript submitted May 27, 1960; made available for printing August 5, 1960.

$$X_1=2^0x_{10}+2^1x_{11}+2^2x_{12}+2^3x_{13} \quad Z=X_1+X_2$$
$$X_2=2^0x_{20}+2^1x_{21}+2^2x_{22}+2^3x_{23}$$

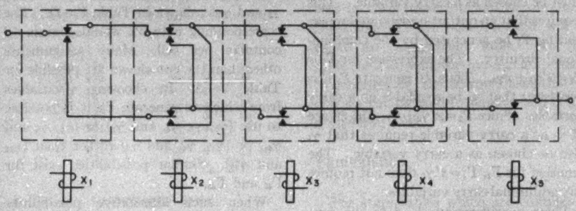

Fig. 3. Relay iterative network, closed when an odd number of relays are operated

table of Table II—B. Since this typical cell contains a "sneak path" ($x'y_1$) in Y_3, a network constructed from it will not function properly. The sneak path cannot be avoided (with the use of contacts only) and a different assignment of carry variables must be used in order to obtain a correct network.

Assignment Procedure for Relay Networks

It is possible by a straightforward procedure to obtain an assignment of carry variables appropriate for a contact network. The resulting assignment will specify output-carry and output functions which do not contain complements or products of input-carry variables. The assignment procedure itself does not guarantee the absence of sneak paths but it is possible to rule out such situations, by a simple modification of the basic procedure.

To facilitate the discussion, the following notation will be used:

γ_i=a variable equal to one only when the input-carry state is i.

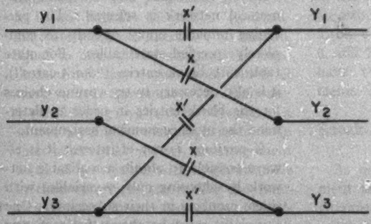

Fig. 4. Typical cell of iterative contact network with a sneak path

Table I. Tables for Fig. 1

A—Flow Table

Initial state		ab 00	01	11	10	z (output)
$A=B$	1	1	3	1	2	0
$A>B$	2	2	2	2	2	0
$A<B$	3	3	3	3	3	1

B—Output Table

Initial state y_1y_2	ab 00	01	11	10	z (output)
01	01	10	01	00	0
00	00	00	00	00	0
10	10	10	10	10	1
	Y_1Y_2				

$Y_1=y_1+y_2a'b;\ Y_2=y_2(a+b')(a'+b);\ z=Y_1$

γ_{ijk}=a variable equal to one only when the input-carry state is i or k or j, etc.

Γ_i=a variable equal to one only when the output-carry state is i, etc.

Thus, specifying $y_1=\gamma_2$, $Y_1=\Gamma_2$, $y_2=\gamma_{13}$, $Y_2=\Gamma_{13}$, $y_3=\gamma_{235}$ and $Y_3=\Gamma_{235}$ is equivalent to the following table:

s_k S_k	y_1 Y_1	y_2 Y_2	y_3 Y_3
1	0	1	0
2	1	0	1
3	0	1	1
4	0	0	0
5	0	0	1

If two γ-variables are added, the resulting sum variable has for its subscript all numbers which appear in the subscripts of either (or both) of the γ-variables which were added. Thus, $\gamma_{12}+\gamma_{35}=\gamma_{1235}$, $\gamma_{12}+\gamma_{23}=\gamma_{123}$. This is true since the sum of a variable which equals one only for row i (γ_i) and a variable which equals one for row j (γ_j) is a variable which equals one for both row i and row j (γ_{ij}), etc.

In terms of the γ-variables, the assignment of carry variables consists of selecting a set of γ-variables to be used as the carry variables. In the actual iterative network, signals which correspond to the selected γ-variables will be present on the carry leads. In general, signals corresponding to other γ-variables will be produced by the combinational circuitry.

In a contact network there is a restriction on the signals produced by the combinational circuitry: they can correspond only

to γ-variables which can be obtained by adding together some of the γ-variables used as carry variables.

This is true since it is impossible to complement or multiply carry variables in a contact network. For example, if the assignment $y_1=\gamma_2$, $y_2=\gamma_{13}$, and $y_3=\gamma_{235}$ is used, a contact network would generate signals corresponding to $\gamma_{123}=\gamma_2+\gamma_{13}$, and $\gamma_{1235}=\gamma_{13}+\gamma_{235}$, but not to γ_3 or γ_4 or γ_{23}, etc. The following discussion will apply only to iterative contact networks.

It is possible, without assigning carry variables, to write an expression for the outputs (Z_i) in terms of γ-variables. For Table III—A: $Z_1=\gamma_5$ and $Z_2=\gamma_{123}$; and for Table III—B: $Z_1=x\gamma_4$ and $Z_2=x'\gamma_{123}+x\gamma_{12}=\gamma_{12}+x'\gamma_3$. A set of γ-variables to be used as carry variables must be chosen so that the following obtains:

> All γ-variables which appear in the expressions for the outputs (Z_i) are either carry variables or are equal to sums of carry variables.

This is necessary since it is possible to generate only signals which correspond to carry variables or to sums of carry variables. In Table III—A, $Z_1=\gamma_5$, so that γ_5 must be chosen as one of the carry variables, since γ_5 can never be obtained as the sum of other γ-variables. Since $Z_2=\gamma_{123}$ in Table III-A, it is possible to use γ_{123} as one of the carry variables; but it is also possible to use γ_1 and γ_{23}, γ_2 and γ_{13}, γ_3 and γ_{12}, γ_{13} and γ_{23}, etc. Any set of γ-variables the sum of which is equal to γ_{123} will satisfy the requirements imposed by the fact that $Z_2=\gamma_{123}$.

In general, if any γ-variable with a single number in its subscript occurs in an output (Z_i) function for a state table, this γ-variable must be chosen as a carry variable. The occurrence in an output function of a γ-variable with more than one number in its subscript allows several choices of carry variables.

Once the carry variables required to generate the outputs have been determined, it is possible to express the corresponding output carry variables as functions of γ-variables, and from these expressions to determine which additional carry variables are necessary, etc. For example, in Table IV, $Z=\gamma_3$ so that γ_3 must be chosen as a carry variable. This requires that an output-carry signal representing Γ_3 be generated by the combinational circuitry. The expression for Γ_3 is $\Gamma_3=x'\gamma_3+x\gamma_2$. Thus, to generate Γ_3 it is necessary that γ_2 be available as a carry variable. Since $\Gamma_2=x'\gamma_2+x\gamma_1$, the choice of γ_2 as a carry variable requires that γ_1 also be chosen as a carry variable. The function for Γ_1, $\Gamma_1=x'\gamma_1$ does not require any additional carry variables.

These considerations lead to the conclusion that the choice of γ_3, γ_2, and γ_1 as carry variables is an appropriate assignment for Table IV. Moreover, this is the only possible assignment since no alternative possibilities occurred in the process of selecting the carry variables. A typical cell for the final network is shown in Fig. 5.

For the state table of Table V—A several different assignments are possible and the amount of equipment in the final network varies for different assignments. For this table, $Z=\gamma_{56}$ so that either γ_{56} or γ_5 and γ_6 must be chosen as carry variables. The carry-variable assignment which results from choosing γ_{56} is shown in Table V—C. The method for obtaining the functions for Γ_{56}, Γ_{12}, Γ_{45} and Γ_{23} is illustrated in Table V—B.

$\Gamma_6=x'\gamma_1+x\gamma_4$
$\Gamma_5=x'\gamma_2+x\gamma_5$
$\Gamma_1=x'\gamma_4+x\gamma_1$
$\Gamma_4=x'\gamma_3+x\gamma_6$
$\Gamma_2=x'\gamma_5+x\gamma_2$
$\Gamma_3=x'\gamma_6+x\gamma_3$

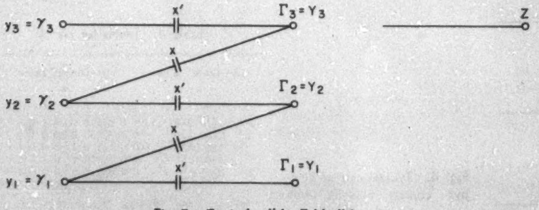

Fig. 5. Typical cell for Table IV

This assignment leads to a network in which there are eight contacts per cell. The assignment which results from using γ_5 and γ_6 is shown in Table V—D. The corresponding network would contain 12 contacts per cell. Many assignments other than the two shown are possible for Table V—A. In choosing γ-variables from which to generate Γ_{56} it is possible to use (γ_1, γ_2, γ_4, and γ_5) or (γ_1, γ_2 and γ_{45}) or (γ_{12}, γ_4, and γ_5) rather than (γ_{12} and γ_{45}). Similar possibilities exist for Γ_{45} and Γ_{23}.

When such alternative possibilities occur for choosing γ-variables, a suitable assignment (except possibly for sneak paths) for an iterative contact network will result from each of the different possibilities. Thus the procedure just described always results in a suitable assignment.

There is no technique known for determining which of several possible choices of γ-variables will result in the most economical network. If economy is important, it is necessary to carry out the procedure several times until all the various alternatives have been considered. For each assignment, the amount of equipment required in the corresponding network is determined and the most economical network is selected. The preceding remarks apply directly to completely specified state tables. For state table with blank entries ("don't-cares"), it is also necessary to try various choices for the blank entries in order to determine the most economical assignment.

If economy is not of interest it is always possible to obtain a realizable network by choosing only γ-variables with single numbers in their subscripts. One γ-variable must be chosen for each row

of the state table, although for some tables one of these γ-variables may prove to be not actually necessary. (A terminal state for which there are no outputs equal to one can be assigned the combination of carry variables for which all carry variables are equal to 0). Since any γ-variable (e.g., γ_{13}) can be obtained as a sum of γ-variables with single numbers in their subscripts ($\gamma_1+\gamma_3$), an assignment using all γ-variables with single numbers in their subscripts can realize the functions required for any state table. This is the so-called one-hot coding.

Inverse State Tables

The procedure just described is simplified by the use of an inverse state table. In the standard state table the output-carry states from the entries in the table. In the inverse state table, the input-carry states are the entries, and the rows correspond to output-carry states. The inverse state table corresponding to Table IV is shown in Table VI. The entry in the ($x=1$) column and ($S_j=2$) row is 1, which means that when the input is $x=1$ and the output-carry state is 2, the input-carry state must have been $s_j=1$. The entry for $x=1$, $S_j=4$ is 3,4, which means that the input-carry state could have been either 3 or 4 when the output-carry state is 4 and the input is $x=1$.

The output and output-carry functions of γ-variables can be written directly from the table. Thus $\Gamma_1=x'\gamma_1$, $\Gamma_2=x'\gamma_2+x\gamma_1$, $\Gamma_3=x'\gamma_3+x\gamma_2$, $\Gamma_4=x'\gamma_4+x\gamma_{34}$, $Z=\gamma_3$. By combining two or more rows, the Γ-functions for Γ's with several numbers in their subscripts can be obtained. See Table VII—B. Such a table will be called an "assignment table." In this table the Z-row shows that γ_{56} can be used to generate Z; the 56-row shows that γ_{12} and γ_{45} can be used to generate Γ_{56} ($\Gamma_{56}=x'\gamma_{12}+x\gamma_{45}$), etc.

Equivalence

For state tables which are completely specified (containing no don't-cares), it is unnecessary to test for equivalent states with this procedure for assigning carry variables. Equivalent states will automatically be assigned the same combination of carry variables if γ-variable having the maximum number of subscripts are chosen wherever possible.

This statement can be proved by the following technique: it can be shown that γ-variables required to directly generate the outputs (call these γ^1) correspond to the sets of states which are indistinguishable by an experiment of length one.[5] The γ-variables required to generate the Γ^1 (which correspond to the γ^1) correspond to the sets of states indistinguishable by an experiment of length two, etc. In Table VIII, states 1 and 2, 3 and 4, 5 and 6, and 7 and 8 are equivalent since they have the same carry-variable assignments.

Sneak Paths

As mentioned previously, the assignment procedure just discussed does not guarantee that there will be no sneak paths in the resulting network. However, it is possible to determine their existence directly from the assignment table. Those discussed here involve only a single cell. Sneak paths involving several cells are possible, but occur rarely and must be checked by inspection of the network.

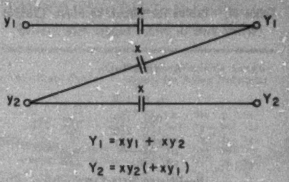

Fig. 6. Basic sneak path situation

The basic sneak-path situation is shown in Fig. 6. For this cell the desired functions are $Y_1=xy_1+xy_2$ and $Y_2=xy_2$. When the cell is designed, Y_2 is equal to xy_1+xy_2 instead of xy_2 because of a sneak path from y_1 to Y_1 to y_2 to Y_2. This sneak path cannot be eliminated without resorting to devices other than contacts, e.g., diodes. The specified functions require that when $x=1$, lead Y_1 is connected to lead y_2, and lead Y_2 is also connected to lead y_2. Thus, when $x=1$ leads, Y_1 and Y_2 must be connected to one another since they are both connected to the common lead y_2. From this it follows that when $x=1$, Y_1 and Y_2 must have the same signals and therefore that Y_1 $(x=1)$ $=Y_2$ $(x=1)$. This proves that it is impossible to design a contact network to have the specified Y_1 and Y_2 functions.

In general, the following rule applies:

> Whenever there is a term such as xy_i which appears in both of two output carry functions, any term such as xy_j which appears in only one of the functions will appear in both of the functions actually realized by a contact network.

For example, the functions for Table II—B are $Y_1=x'y_1+x'y_3$, $Y_2=xy_1$, $Y_3=x'$

y_2+xy_2. Since $x'y_2$ appears in both Y_1 and Y_2, $x'y_1$, which appears in only Y_1, will appear in Y_2 and Y_1 in the actual network. This is precisely the sneak path pointed out previously. The term xy_2, which appears in Y_2 but not in Y_1, is not involved since it contains an x rather than an x'.

The rule just stated in terms of functions can also be applied directly to the assignment table:

> If in any column of an assignment table, two rows have any entries in common, then any entry which appears in either row must appear in both rows.

In the assignment table of Table IX—B, the entry 34 appears in both the first and third rows of the 0 column. Therefore the actual network will correspond to an assignment table in which the 14 entry also appeared in both the first and third rows. This agrees with the preceding discussion in which $\gamma_{14}=y_1$, $\gamma_2=y_2$, and $\gamma_{34}=y_3$, and the sneak path was $x'y_1=x'\gamma_{14}$ in $Y_3=\Gamma_{34}$. For this particular table and assignment it is not possible to avoid the sneak path. However, for some tables and assignments it is possible to remove sneak paths by adding one or more extra contacts in the cell.

Table X shows a state table and an assignment, $Y_2=\gamma_2$, $y_1=\gamma_{12}$, for which the resulting cell contains a sneak path. The functions $Y_1=y_1+x$, and $Y_2=y_2+xy_1$ can be written as $Y_1=x(1+y_1)+x'y_1$ and $Y_2=x(y_2+y_1)+x'y_2$. For this table $\gamma_{012}=1$, since the network is always in one of its three states. Since they both contain the term xy_1, the resulting network will produce a sneak path of x in Y_2 and of xy_2 in Y_1. The x term in Y_2 cannot be

y_1	y_2	x 0	1	Z
0	0	01	10	0
1	1	10	01	1
1	0	00	11	0
0	1	11	00	1
		Y_1Y_2		

C—Functions

$$Y_1=x'y_2+xy_2'$$
$$Y_2=x'y_1'+xy_1$$
$$Z=Y_2$$

allowed. By setting $Y_1=x+x'y_1=x(1)+x'(y_1)$ and $Y_2=y_2+xy_1=x(y_1+y_2)+-x'(y_2)$, the common term xy_1 is removed and the sneak path destroyed.

The possibility arises that there may be some state tables which cannot be realized by a contact network because none of the possible carry-variable assignments correspond to networks which can be realized without unallowed sneak paths. This possibility can be immediately discarded since, for any state table a one-hot assignment will correspond to a realizable contact network. (For some state tables, this is the only realizable assignment; see the discussion of Table IV.) The fact that a one-hot assignment produces functions which contain no products or complements of carry-variables has been discussed. It is thus only necessary to demonstrate that a one-hot assignment never introduces sneak paths.

For a one-hot assignment, the assignment table is identical with the inverse state table. In the inverse state table each number appears only once in each column since any input-carry state can lead to only one output-carry state for each input combination. Since each number appears only once in a column, it is impossible for two rows to contain the same number in any column. Thus there can be no sneak paths since the criterion for a sneak-path is that two rows of the assignment table have a common entry in some one column.

Varying Assignments

In the preceding discussion of carry-variable assignments it has been assumed that the assignment of carry variables to states was constant throughout the network. This is necessary in sequential circuits, but for iterative circuits it need not be so, and it may be possible to obtain a more desirable network by varying the correspondence between states and carry variables. In particular, it may be possible to reduce the complexity of the cells and sometimes also to reduce the required number of carry leads. Of course, the network will no longer consist of a chain of identical cells; only every other cell or every third cell, etc., may be identical. This sacrifice of complete uniformity may be worth while if a sufficient saving is realized in the complexity of the individual cells.

4	4	4	0

The most economical iterative network (in number of gates per cell) for the state table shown in Table XI—A is one in which two carry-variable assignments alternate throughout the network. Since this table contains four carry states, there are three "different" assignments to two carry variables.[4] These assignments are shown in Table XI—B, where the variables v_1v_2 are used for one assignment, w_1w_2 for another, and y_1y_2 for the third. The functions which result from these assignments are shown in Table XII—A, B, and C.

The functions of Table XII—D, E, and F result when one pair of variables (e.g., y_1y_2) are used as input-carry variables and another pair of variables (e.g., V_1V_2), are used as output-carry variables. Table XIII illustrates the derivation of the functions of Table XII—D, and Table XIV lists the equipment required by networks for the functions of Table XII. Clearly, the most economical network is obtained by using w_1w_2 and v_1v_2 as carry variables. The network which results from this choice of carry variables is represented in Fig. 7.

Table XV shows a state table for which it is possible to reduce the number of carry leads from two to one by using different carry leads for different cells. The corresponding network is shown in Fig. 8. In this network there is only one carry lead between cells, but this carry lead sometimes represents y_1 and sometimes y_2. This is possible because for this particular state table and assignment $Y_2(=Z)$ is not a function of y_2, and Y_1 is not a function of y_1. Thus, a cell requires only y_1 or y_2 as an input carry. This is not true for other carry-variable assignments. For example, if the assignment $y_1=\gamma_{34}$, $y_2=\gamma_{24}$ is chosen the functions are:

$Z=Y_2,\ Y_1=y_1'$

$Y_2=x'(y_1y_2+y_1'y_2')+x(y_1y_2'+y_1'y_2)$

These functions require two carry leads per cell and would have more complicated cell circuitry than that shown in Fig. 8.

It is also possible to design relay networks for which the carry-variable assignment varies within the network. However, the same problems of realizability which were discussed in connection with networks having constant carry-variable assignments arise. It is not always possible to construct a network in which two assignments alternate even if each of the assignments corresponds to a realizable network with a constant carry-variable assignment. For example, there are six carry-variable assignments for Table XVI which correspond to physically realizable carry functions. It is not possible to construct a cell of relay contacts which has the assignment 1 for its input carries and assignment 2 for its output carries.

Fig. 9(A) is a diagram which shows which cells with different input-carry variable and output-carry variable assignments are realizable. An arrow from mode i to node j indicates that it is possible to construct a cell with assignment i for the input carries and assignment j for the output carries, and the absence of an arrow indicates that such a cell is impossible. This diagram shows that it is not possible to construct a relay network in which any pair of assignments alternate. In this case, it is possible only to construct a network in which the carry-variable assignment changes from one assignment to another (e.g., from point 6 to point 1) and then remains constant throughout the remainder of the network.

State tables do exist for which relay networks are possible in which two (or more) carry-variable assignments alternate. An example of such a state table is shown in Table XVII. Fig. 9(B) is a diagram which shows for Table XVII which cells are possible with different input-carry and output-carry assignments.

There is no method known for determining directly from the state table whether it is advantageous to vary the correspondence between carry variables and states within a network. It is necessary to derive the appropriate carry functions (as in Table XII) in order to assess the advantages of such a scheme for a given state table.

Summary

The problem of assigning combinations of carry variables to the network states has been discussed and procedures for obtaining assignments corresponding to physically realizable contact networks have been presented, with the possibility of varying assignments within the network also considered.

Universal Modulus

Matrix Logic VI

E. J. SCHUBERT
ASSOCIATE MEMBER AIEE

Synopsis: This paper continues the series based on the use of matrices in the design of switching networks. To avoid redundancy within the series, all previous papers on matrix logic are considered as prerequisite, in particular, references 1 and 2. This paper establishes a general classification scheme for logical functions, as follows: 1. General symmetric functions, which are the sum of ordinary symmetric functions. 2. Trivial and redundant functions. 3. Universal functions, which are capable of performing any logical functions by appropriate iterations.

THE LOGICAL or Boolean functions of binary variables may be classified in various categories. The purpose of the classification is to determine those logical functions which are independently capable of serving as the only building blocks in any logical network. The mechanization of these logical functions may be designated as "universal modulus."

It is no easy task to present topics of applied logic in a form that will appeal equally to electrical engineers and mathematicians. Terminologies and viewpoints differ to such an extent that two completely independent approaches must be taken. Therefore, for the electrical engineer, the paper proper emphasizes the engineering aspects in rather descriptive form using design rules for hardware. For the mathematician, Appendix II contains an excerpt of extended set theory to support the statements in the body of the paper.

General Symmetric Functions

All possible symmetric functions can be obtained through the logical summation of distinct elementary functions, which are called "ordinary symmetric." By definition, "a symmetric function ${}_pO_k$ is ordinary if it is operative for any combination of p inputs taken k at a time."[2] A typical ordinary symmetric function is the "half-adder" or "exclusive OR" circuit, which is a circuit of two input variables, operative if only one of the two inputs is present. It is designated ${}_2O_1$.

For p variables, there are $p+1$ ordinary functions ${}_pO_k$, for example:

$k=0$ inputs being present

${}_pO_0$: $\left\|\begin{matrix}p\\0\end{matrix}\right\|=1$ minterm involved

(NOR gate).

$k=1$ inputs being present

${}_pO_1$; $\left\|\begin{matrix}p\\1\end{matrix}\right\|=p$ minterms involved

.

.

.

$k=p$ inputs being present

${}_pO_p$; $\left\|\begin{matrix}p\\p\end{matrix}\right\|=1$ minterm involved

(AND gate).

Thus, any of the symmetric functions is the logical sum of some ordinary symmetric functions:

Table I. Classification of 2-Variable Functions

$$Y=H_0X_1'X_2'+H_1X_1X_2'+H_2X_1'X_2+H_3X_1X_2=\underset{i}{U}H_i\cdot N_i=(h)\cdot(n)$$

Conventional	Operator (h)	Symmetric (s)	Redundant r=	Universal	Circuit
$Y_0=0$	(0000)	$(\underline{0}00)$	1, 2		OFF
$Y_1=X_1'X_2'$	(1000)	$(\underline{1}00)$		X	NOR
$Y_2=X_1X_2'$	(0100)			X	
$Y_3=X_2$	(1100)		1		
$Y_4=X_1'X_2$	(0010)			X	
$Y_5=X_1'$	(1010)		1		
$Y_6=X_2'X_1+X_2X_1'$	(0110)	$(\underline{0}10)$			HALF ADDER
$Y_7=X_1'+X_2$	(1110)	$(\underline{1}10)$		X	SHEFFER
$Y_{10}=X_1X_2$	(0001)	$(\underline{0}01)$			AND
$Y_{11}=X_1X_2+X_1'X_2'$	(1001)	$(\underline{1}01)$			EQUALITY
$Y_{12}=X_1$	(0101)		1		
$Y_{13}=X_1+X_2'$	(1101)			X	
$Y_{14}=X_2$	(0011)		1		
$Y_{15}=X_2+X_1'$	(1011)			X	
$Y_{16}=X_1+X_2$	(0111)	$(\underline{0}11)$			OR
$Y_{17}=1$	(1111)	$(\underline{1}11)$	1, 2		ON

Table II. Number of Redundant Functions ${}_pQ_r$ and Probability of Redundancy P(p)

	${}_pQ_r$					
$r=$	1	2	3	4	5	$P(p)$
$p=1$	2	.	.	.		0.5
2	6	2	.	.		0.375
3	38	8	2	.		0.149
4	918	46	10	2		0.014
5	325, 382	2,292	112	12	2	$<10^{-6}$

$$Y=\bigcup_{k=0}^{p}{}_pS_k\cdot{}_pO_k \qquad (1)$$

In equation 1, the composite symmetric function Y is said to be the logical sum U (union) of the dot products (logical product) of all $p+1$ possible ordinary switching functions ${}_pO_k$ with an associated coefficient ${}_pS_k$. The latter is binary and may be expressed by a row matrix (s). As an example, the ordinary switching function of three out of four inputs is shown.

$$ABCD'+ABC'D+AB'CD+A'BCD$$
$$={}_4O_3\left\|\begin{matrix}4\\3\end{matrix}\right\|=4 \text{ minterms involved.}$$

$(s)=(\underline{0}0010)$; ${}_4S_3=1$; all other coefficients are zero.

The matrix coefficient ${}_4S_0$ corresponding to $k=0$ is underlined to define the location of column 0 in the matrix.

A function being true for at least k inputs is a threshold function. Its complement is the "inverse" threshold function and is illustrated as follows:

$${}_4O_3+{}_4O_4=ABCD'+ABC'D+AB'CD+A'BCD+ABCD.$$

$(s)=(\underline{0}0011)$ the threshold function.
$(s)'=(\underline{1}1100)$ the inverse threshold function.

From this it can be seen that the matrix (s) describes any symmetric function in a more efficient way than does the conventional function matrix.[2]

Equation 1 lends itself to the computation of the total number of symmetric switching functions for any number of p variables. Matrix (s) is a binary word comprising $p+1$ bits. Accordingly there can be only 2^{p+1} different numbers or matrices of (s) or different symmetric functions. The relative number of symmetric functions decreases rapidly when there are an increasing number of the p input variables.

Redundant and Trivial Functions

All possible switching functions of p variables include some which do not depend on all p variables. The latter are "redundant" if expressed in canonical form (the sum of minterms) with respect to p variables. By definition, a function eventually becomes "trivial" if only one significant variable remains, or the function is constant, 0 or 1. For a nontrivial function, at least two variables must remain.

The term ${}_pO_r$ is the number of switching functions of p variables wherein r variables are redundant. In Table I, a separate column is provided for the feature of redundancy. The value 1 or 2 corresponds to the number of redundant r variables. If $r=1$, then 6 of the 16 functions depending on two variables are redundant. For $r=2$, the two functions Y_0 and Y_{17} are redundant and constant. Actual computation of the number of redundant switching functions is treated in Appendix I. In Table II, the results indicate that the probability $P(p)$ of a function to be redundant decreases rapidly with increasing number of p variables. In the case of four variables, approximately 1 out of 50 functions exhibits redundancy. Around this minority centers the major effort of reduction or minimization techniques.

Universal Functions

Any logical function is a logical operator, because it performs an operation on the inputs. Diode logic comprising the AND gate and the OR buffer, requires an inverter to build up any logical function. In this concept, there are three operators involved: AND, OR, and NOT.

For some time, certain "primitive" functions have been known, capable of performing any logic.[3] It is suggested, however, that because of their outstanding capabilities the term "universal" be adapted for such functions. To qualify as universal, a function must have at least two inputs and be capable of inverting for at least one input. These are necessary but not sufficient conditions as far as symmetric functions are concerned. The additional criterion for symmetric functions can be stated with reference to the matrix (s), in which the entries 2 indicate irrelevant, i.e., "don't care" coefficients which might be either 0 or 1.

$$(s)=(\underline{1}222\ldots2220) \qquad (2)$$

For $p=2$, the following symmetric functions will satisfy these conditions:

$(s)=(\underline{1}00)$ NOR gate
$(s)=(\underline{1}10)$ SHEFFER'S STROKE

It will be noted that there are no other symmetric functions of two variables which are simultaneously universal.

From equation 2, the number of symmetric universal functions becomes immediate because, in this matrix, the p-1 binary coefficients can be permuted in 2^{p-1} ways. The first and last coefficients are constant, 1, and 0 respectively.

The number of asymmetric functions a_6 which are universal can be predicted from the number of trivial and symmetric

Table III. Input Variables Versus Population of Classes

Class of Functions	Population	$p=2$	$p=3$	$p=4$
Total	$a_1=2^{2^p}$	16	256	65, 536
Symmetric	$a_2=2^{p+1}$	8	16	32
Trivial	$a_3=2(p+1)$	6	8	10
Redundant	$a_4={}_pQ_1$	6	38	918
Symmetric-universal	$a_5=2^{p-1}$	2	4	8
Asymmetric-universal	$a_6=a_1-a_2-a_3+2$	4	234	65, 496

functions. Two of the trivial functions are symmetric at the same time. Referring to the entries in Table III,

$$a_4 = a_1 - a_2 - a_3 + 2 \tag{3A}$$
$$= 2^{2^p} - 2^{p+1} - 2(p-1) \tag{3B}$$

In Table I the complete set of functions of two variables is listed using the function matrix (h) as reference.[2]

UNIVERSAL MODULUS

It appears highly desirable to restrict the different types of building blocks for efficient production, assembly, and maintenance of switching systems. The eventual choice will mostly be based upon the over-all reliability of the circuit performing the switching function, and upon economical considerations.

The mechanization of the universal function is called "universal modulus." According to basic theorems any logical network can be assembled with the use of a single type of universal modulus. Even if the universal modulus comprises only two inputs, a cascade of these moduli will accommodate any larger number of inputs. The technique for the logical design has been developed previously and is suitable for any type of logical operator.[1]

Symmetric universal moduli are preferred in the present trend to solid-state circuits. Transistor and magnetic logic utilize the NOR function extensively. Inverse threshold functions are possible for reliable operation, but somewhat controversial because of their extremely close tolerances for components.

One disadvantage of universal moduli is that conventional Boolean algebra cannot be modified to handle such operators efficiently. Therefore, the engineering effort becomes more pronounced and costly, particularly for custom-built systems where neither computer routines nor improvements by redesign are applicable.

UNIVERSAL PACKAGE

In some cases, a circuit can be developed for a modulus which provides more than one logical output. If at least one combination of the logical functions yields a universal function, a circuit can be considered a universal package, even if each of the logical functions is not universal by itself.

The advantage of the universal package over the simple universal modulus with only one function is that greater simplicity of the final network can be gained with less hardware. Typical for such a package is the combination of an AND gate and an inverter. Referring to Table I, each of the outputs correspond to Y_3 and Y_{10} respectively. Taking two of the three inputs, with appropriate connection of the remaining input to one output, yields three different universal functions Y_2, Y_4, and Y_7.

UNIVERSAL MODULI FOR SEQUENTIAL LOGIC

Combinational logic can be performed in passive networks, provided the signal sources feeding into the inputs have sufficient power. In sequential logic, active elements are essential to maintain or retrieve the information from the storage. A basic storage element and its associated logic are described by a transformation derived previously.[4] To set a storage cell, a trigger signal $\dot{Z}$ must be replaced by a continuous feedback signal Z.

Two cascaded universal moduli, with a feedback loop from the output of the second modulus into an input of the first, will exhibit the latching function of a flip-flop. In general, any closed loop containing an even number of active symmetric universal moduli will perform a latching or memory function.

$$Y = (Y')' \ldots \text{two inverters} \tag{4A}$$

$$Y = (((Y')')')' \ldots \text{four cascaded inverters} \tag{4B}$$

In a subsequent paper "Logical Design by Regression—Matrix Logic VII," a novel design routine will be discussed which is highly efficient and directly applicable for any arbitrary universal function.

Conclusions

A classification for logical functions and the determination of their numbers indicates the pronounced majority of asymmetric and universal functions.

Existing hardware lends itself to a preference for symmetric universal moduli. The difficulties encountered in the logical design using these moduli, are due to basic limitations of Boolean algebra.

Appendix I. Number of Redundant Functions

Definition: ${}_pQ_r$ is the number of redundant functions in which at least r of the p variables are irrelevant $0<r<p$.

1. ${}_pQ_p = 2$; if all p variables are irrelevant, then 0 and 1 are the only remaining functions.

2. If k variables are irrelevant, then the p variables may be taken p-k at a time. The number of combinations are:

$$\left\|\begin{matrix} p \\ p-k \end{matrix}\right\| = \left\|\begin{matrix} p \\ k \end{matrix}\right\|$$

3. Any set of p-k variables can form $2^{2^{p-k}} - {}_{p-k}Q_1$ distinct nonredundant functions, excluding those wherein at least one of the p-k variables is redundant.

All sets of redundant functions of p-k variables will intersect in a proper subset containing ${}_pQ_{k+1}$ redundant functions characterized by $k+1$ irrelevant variables.

The following relation is immediate:

$${}_pQ_k = {}_pQ_{k+1} + \left\|\begin{matrix} p \\ k \end{matrix}\right\| \left(2^{2^{p-k}} - {}_{p-k}Q_1\right)$$

Substituting $r=k+1$ yields the recursion formula:

$${}_pQ_{r-1} = {}_pQ_r + \left\|\begin{matrix} p \\ r-1 \end{matrix}\right\| \left(2^{2^{p-r+1}} - {}_{p-r+1}Q_1\right) \tag{5}$$

The initial steps for computing Table II are:

$${}_1Q_1 = 2$$

$${}_2Q_2 = 2$$

$${}_2Q_1 = 2 + \left\|\begin{matrix} 2 \\ 1 \end{matrix}\right\| (2^2 - 2) = 6$$

$${}_3Q_3 = 2$$

$${}_3Q_2 = {}_3Q_3 + \left\|\begin{matrix} 3 \\ 2 \end{matrix}\right\| (2^2 - {}_1Q_1)$$
$$= 2 + 3(4-2) = 8$$

$$2Q_1 = {}_3Q_2 + \left\|\begin{matrix} 3 \\ 1 \end{matrix}\right\| (2^{2^2} - {}_2Q_1)$$
$$= 8 + 3(16-6) = 38$$

Appendix II. Criteria of Universal Laws of Composition

The terminology in this derivation follows closely the text of Jacobson's lectures.[5]

Definition: A Boolean universal algebra is a lattice with 0 and 1 restricted to a single law of composition, which is complementing.

Theorem: A universal law of composition in a Boolean universal algebra is complementing and excludes functions related to symmetric difference.

Corollary: A universal law of composition is complementing and either nonassociative (asymmetric), or if associative (symmetric) then not related to symmetric difference. (Equivalence is the complement of symmetric difference and therefore excluded).

Proof:

1. A Boolean algebra is a lattice with 0 and 1 that is distributed and complemented.
2. All Boolean algebras are isomorphic.
3. Boolean algebra and Boolean ring with identity are equivalent.
4. The composition's symmetric difference, intersection ($\oplus$,.), and the lattice are a Boolean ring. Therefore, neither symmetric difference nor intersection by itself suffices as single law of composition in a Boolean universal algebra.

Symmetric difference is identical with binary addition modulo 2 as mechanized in half-adders, $A'B + AB'$. Its complement is the equivalence, $A'B' + AB$. Both are the symmetric functions as excluded by the theorem.

Teaching the Uses of Digital Computers at the Technical University of Denmark

OLE IMMANUEL FRANKSEN
STUDENT MEMBER AIEE

Synopsis: A method for teaching electrical engineering students the use of digital computers in solving electric machinery problems, especially with regard to iterative methods, is explained. By emphasizing the process of stating actual problems and formulating them in flow diagrams, more general principles are brought to light. The method is illustrated with an example of a power transformer winding design. The use of the international computer language Algol, is demonstrated and discussed.

A RESEARCH PROGRAM investigating the use of digital computers in the field of solving engineering and design problems was initiated in the spring of 1957 in the Electric Machinery Department (headed by the Dean of Electrical Engineering, Prof. L. Hyldgaard-Jensen) at the Technical University of Denmark. The main purpose was to study this area from an educational point of view and to try, if possible, to develop a general approach which could be taught to electrical engineering students.

As we were especially interested in the problems of the iterative type (e.g., design), it was decided to develop a program for designing power transformers on the Danish computer Dask, to gain the necessary experience. This program (approximately 12,000 computer instructions) was finished during the summer of 1959. Before the completion of the transformer program, the new international computer language, Algol, had advanced so far that its use was incorporated into the investigation.

Using a notation close to normal mathematical standards, Algol describes the computational processes to be done in certain arithmetical and nonarithmetical statements (in English), each statement given a single, precise meaning. When the computer receives the Algol instructions, it translates these into its own terms by means of a special program called a "compiler."[1]

We have found that it is not yet possible to teach general procedures by lectures, enabling the student to formulate logically the problems in a flow diagram, even though it is possible to state part of the techniques in general terms. For this reason (which, by the way, means that the student only "learns by doing") we have not prepared a special computer course, but have incorporated an introduction to the use of digital computers in the graduate course in electric machinery.

The purpose here is to describe how we present this subject to our students, and what experience we have gained in doing so.

Scope

To secure a master's degree in electrical engineering at the Technical University of Denmark (which does not offer a bachelor's degree) requires normally $5^1/_2$ years' study, the last half-year being spent on a thesis. The "Computer Introduction" is given at the beginning of the student's last year, after he has specialized in electric machinery and has become somewhat familiar with the problems.

From the day the student enters the University, he is encouraged to take an optional course in programing (until 1959 in the Dask machine code and since then in Algol). It should be emphasized that the Introduction is intended to give the student the ability to so formulate the problem that it can be programed for the computer by personnel who know nothing at all about the problem itself. We feel that it is very important to familiarize the student with programing methods, enabling him to see when it will be feasible for him to put his problem on a digital computer. In practice, the computer specialist usually is unable to formulate a specialized problem for the computer, so the engineer must know how to do this.

The Introduction is therefore directed not toward future computer specialists but to engineers who are interested in the general utility of digital computers from the point of view that they want to be able to use the computers not only as large-scale slide rules. This requires, of course, quite a lot of experience, part of which the student may obtain during the work on his thesis.

Some of the most difficult problems to formulate for the computer are those of design, which the engineer solves by an intuitive cut-and-try method. By taking examples with backgrounds familiar to the student, we show him how to formulate them for the computer, i.e., what data were originally available; how these data were prepared; and how one must forget the usual methods and look at the problem anew (cf., the problems of the pressboard spacers and the computation of the winding temperature in the example which will be treated later). After having presented each problem along these lines, we encourage the student to criticize the solution and to suggest improvements.

Another important purpose of the Introduction is to emphasize the need of documenting the solution of the problem. Lack of such documentation often leads to computer programs that are too expensive to keep up to date, or even useless, owing, for example, to changes in personnel.

A very good and clear way of documenting this information is to work out flow diagrams. By such means, especially with involved problems, one is also able to eliminate the logical errors which usually occur when the solution to a problem is attempted mentally.

Flow Diagraming

Theoretical Considerations

The two properties of the digital computer which principally determine the method of attack in putting a problem on it are:

Paper 60-1184, recommended by the AIEE Computing Devices Committee and approved by the AIEE Technical Operations Department for presentation at the AIEE Fall General Meeting, Chicago, Ill., October 9–14, 1960. Manuscript submitted June 6, 1960; made available for printing September 2, 1960.

Ole Immanuel Franksen is with Rensselaer Polytechnic Institute, Troy, N. Y., on leave of absence from the Technical University of Denmark.

1. Arithmetically, the computer can do only the four basic operations: addition, subtraction, multiplication, and division.
2. Logically, the computer can compare only two numbers at a time and continue the series of computations along one of two alternative ways, depending on the result of the comparison.

A flow diagram can be defined as a map over the routes the computer has to follow to carry through the desired computations. This definition implies that the flow diagram, independently of the special computer used, should give a pictorial representation of the problem, stating the exact sequence of operations on the data and how the alternatives fit together.

Depending on the type of problem to be solved, there are, of course, many ways to work out a flow diagram, although they all basically consist of a collection of lines, arrows, and boxes, the last-mentioned containing instructions about the things to be done.

Normally, it is beneficial to work out a series of flow diagrams ranging from the bird's-eye view ("rough" flow diagram) to the ready-to-code diagram, not only from the point of view of getting a better solution but also because such a series is one of the best ways of transferring the solution to other personnel.

If the problem to be solved involves a long series of straightforward calculations (which, for example, is the case in the computation of performance), it may be advisable to list these equations in an appendix to the flow diagram and mark on this "Eqs. *n* to *p*," etc. If, on the other hand, the algebraic sequences between the different alternatives are relatively short (as in the design example to be treated later), then it may be better to have all the information on the flow diagram.

No matter how it is constructed, it is of vital importance that the flow diagram be as easy as possible to understand. It has been found desirable in working out a flow diagram to state the following:

1. Terminology.
2. Loops.
3. Numerical conditions.
4. Order.
5. Examples.

An explanation of items 1 and 2 follows immediately, while items 3, 4, and 5 will be discussed in the section "Practical Considerations."

A great help in clarifying the flow diagram is a standardized system of symbols and ways of writing the instructions. For the latter we adopted the ALGOL notation (as illustrated in Fig. 4) and expanded it with a short explanation, sometimes also adding a unit. These instructions plus comments are put into boxes which are numbered for identification. To indicate in which order the boxes must be run through during the computation, they are connected with lines, each of which is supplied with an arrow where it runs into another box or into a junction for several lines.

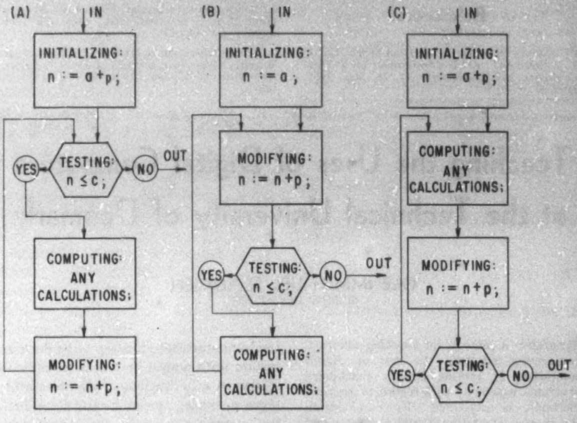

Fig. 1. Loops in computing

Because there is not as yet any international standard for the symbols, we do not insist on using a special set of symbols but explain to the student that it is normally sufficient to differentiate between four basic types of boxes, namely:

1. Input and output boxes.
2. Operation boxes.
3. Choice boxes.
4. Error boxes.

A particular flow diagram can contain more than one input and one output box, each of which has a function to define the entrance or exit with the name or a number, and at the same time it should list all the actual input or output parameters. It is advisable also to list the units of the parameters in order to prevent interconnection errors between several flow diagrams. The operation boxes describe the arithmetic computations which have to be done. The choice boxes are the only type with two exits, i.e., depending on a question which can be answered with YES or NO, they direct the computation along one of two alternative ways. The error boxes are used to indicate numbered stops which may be incorporated into the program.

Nearly always, one of the major factors in preparing a problem for solution on a digital computer is its limited memory space. Hence, it is necessary on the flow-diagraming level to consider where it is possible to use computation loops; by which is meant that parts of the computer program can be repeated with modifications. The savings in memory space and programing time thus obtained will always justify the longer machine time, and we shall therefore briefly treat the theory of loops in computing.

Referring to Fig. 1, it is always possible to divide a loop into four parts:

1. Initializing.
2. Testing.
3. Computing.
4. Modifying.

Interchange of the last three is freely possible. In practice, this interchange leads to only three different principles, as Fig. 1 implies, because the mutual order of parts 3 and 4 is unimportant for the function of the loop when they follow each other. It is hard to state a general rule to follow for the application of these three principles, which are so similar in theory but so different in practice. Which one to choose in a particular case depends not only on the computations which should be executed in the loop but also, for example, on outer loops.

Two questions must always be considered immediately after the construction of a loop:

1. Do the modification and the counter-constant work in the right way?
2. Is anything computed under the head-

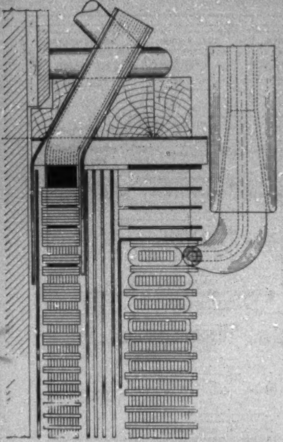

Fig. 2. Cross section of a pair of transformer windings

ing "Computation" which could just as well be computed outside the loop?

Considering question 1, it is always a good idea to see what would happen if the loop were to be executed only once. In an affirmative case, question 2 obviously involves a waste of machine time.

PRACTICAL CONSIDERATIONS

Numerical analysis is taught during the student's second year at the University, as a part of the applied mathematics course. Therefore, in the Introduction, we briefly consider only three different numerical relations, which, experience has shown, always amaze the student. These three sets of relations concern:

1. The floating decimal point.
2. The limited length of the accumulator.
3. The numerical accuracy of the original data.

All calculations coded in a programing language such as ALGOL are automatically performed with a floating decimal point. A repetitive type of problem in design is the determination of engineering standard values when these vary in discrete, often nonequidistant steps. We therefore try to tell the student (in ALGOL notation) what to do when the calculation gives as a result a nonstandard value, which has to be rounded off in a special way to a standard value. We also discuss the problem of rounding off and calculating with integers which have to be odd, even, or divisible by some other integer (i.e., the example in Fig. 4 where the ALGOL function "entier" is used for this purpose in the complex around box no. 38).

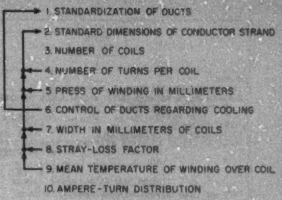
To illustrate the type of problems introduced by the limited length of the accumulator in the computer, some examples are given. It is shown:

1. How to arrange the order of a computation to avoid taking the difference between numbers of nearly equal size.
2. That there might be a difference between dividing with a number or multiplying by its reciprocal.
3. That sometimes a better result might be obtained by using Horner's diagram (also called the method of "nesting"), when values of a power series are being calculated, instead of using the built-in ALGOL "exponentation brackets."
4. How important it might be to have the different test values provided with tolerances; the problem of arranging the order of the tests, which is incidentally one of the major questions in design problems, is unfortunately a matter of experience.

Owing to the great numerical capabilities of the digital computer, one is often inclined to demand a number of digits after the decimal point, which is completely unrealistic from a physical point of view. The student is therefore urged to analyze carefully the original data and the problem from this aspect.

As just one error might be sufficient to ruin a whole program, it is obvious that good order and accuracy are of vital importance. Experience has shown that the number of errors grows with some power of the length of the program; this is why a good tactician always tries to subdivide his program into smaller procedures of limited length. As a rule of thumb, we advise the student to work out each of his flow diagrams on a single sheet of paper; this determines the maximum length of the individual procedures. Another aspect of this subdivision is that it helps the student to recognize repetitive problems and to work them out as routine (library) procedures. Good order also implies planning of input forms, output forms, and synonymous names for the parameters and an up-to-date and accurate correction of errors in the flow diagrams.

It is stressed that no problem can be regarded as finished before numerical test examples are worked out in such a way that every route in the flow diagrams can be run through and tested during the debugging process. However, owing to the iterations involved, the nature of a design problem is often such that it is impossible to work out a complete numerical example. In these cases, the student is advised to use the following techniques, which are very useful when the program is coded in ALGOL:



1. STANDARDIZATION OF DUCTS
2. STANDARD DIMENSIONS OF CONDUCTOR STRAND
3. NUMBER OF COILS
4. NUMBER OF TURNS PER COIL
5. PRESS OF WINDING IN MILLIMETERS
6. CONTROL OF DUCTS REGARDING COOLING
7. WIDTH IN MILLIMETERS OF COILS
8. STRAY-LOSS FACTOR
9. MEAN TEMPERATURE OF WINDING OVER COIL
10. AMPERE-TURN DISTRIBUTION

Fig. 3. Rough flow diagram of high-voltage disk coil winding

1. Divide the program into procedures, each of which can be easily supplied with numerical test examples for debugging.
2. Work out test examples for each of these procedures.
3. Prepare input parameters for the program as a whole.

The reason for this procedure is the sequential feature of ALGOL, which makes it rather easy to construct a tracing program which (during the tracing) will print out the output parameters of a procedure every time its exit is passed. Such a feature was planned to be incorporated in the ALGOL compiler for DASK.

As a check on the soundness of a flow diagram, it will often be wise to work out at least one of the numerical test examples with numbers which have a reasonable size from a physical point of view.

Example

Illustrating the foregoing ideas and viewpoints, the manner in which we present one of our examples to the student will be described. The problem is how to work out a flow diagram (Fig. 4) for the computation of the dimensions of a high-voltage disk-coil transformer winding, corresponding to the axial-radial cross section in Fig. 2.

The program should fulfill the following conditions: For a given set of insulation data (such as conductor insulation thickness, ducts between coils, and height of the winding), and for a given set of electrical data (such as number of turns, locations of taps, and current density), it should determine the axial and radial dimensions of a disk-coil winding, while taking account of economic and technical considerations (such as a maximum number of six special coils nearest each yoke, winding pressure, and allowable coil width tolerances), as well as considerations regarding losses (such as stray-load losses) and winding temperatures below certain limits.

It should be possible to design the

winding with reinforced coils (as well as without), the number of which (four is maximum) has been specified as input. To be able to use the same program for different types of transformers, it should furthermore be possible to carry out the design with, as well as without, mid-winding taps. The winding should be symmetrical about the mid-point, and two or more parallel circuits per transformer leg should be excluded. With tapping, to avoid circulating currents, the previous condition would mean that only a maximum of two parallel conductor strands could be used. Finally, regarding the design of the low-voltage winding, it was decided to end this program by calculating the ampere-turns along the winding.

The possible conductor dimensions for a given current and a given current density will describe a hyperbolic curve which will cut across the area of permissible conductor dimensions (as indicated at box 14 in Fig. 4). Introduction of parallel conductor strands implies a displacement of this hyperbola down toward the origin.

It was decided to base the process of iteration on a search of this curve from the right end, i.e., the iteration starts with the least possible number of coils and determines for every set of standard conductor dimensions (which are within certain tolerances of the hyperbola) if it is possible to design a winding which fulfills the above-mentioned conditions. If this is not the case, then the computations have to start over again with a new set of standard conductor dimensions; if it is the case, then the iteration process is stopped, and we have the optimum solution under the given conditions.

The problem was then analyzed from the point of view of setting up the different tests and their mutual order. Among other things, it was discovered (contrary to the common manual practice) that it was practical to calculate the mean temperature over oil of the winding at this point, even if the winding diameter and the dimensions of the rest of the transformer were unknown.

This analysis, combined with the aforementioned idea, led to the rough flow diagram of Fig. 3, where the different feedbacks to the hyperbolic curve (item 2) are shown from the tests 4, 5, and 7 through 9. In accordance with this, it was then possible to work out the complete and detailed solution (which is given in the flow diagram of Fig. 4).

From a practical point of view, this job was executed in the following way: the search of the hyperbola, the standardization of the ducts, the calculation of the stray-loss factor, and the calculation of the mean temperature over oil of the winding were all worked out as independent library procedures. This implies that future use for other purposes was taken into consideration when these procedures were constructed. With the rough flow diagram followed as closely as possible, the rest of the program was subdivided into these procedures: box numbers A6 through A13, 14 through 23, 24 through 41, 42 through 59, 60 through 76, 77 through 91, and 92 through 113. When all these steps were completed, they were joined together to make up the final flow diagram.

To illustrate the detailed "digging" in working out the different procedures, we shall shortly discuss how item 1 of Fig. 3 became box numbers 2 through 13 of Fig. 4.

The pressboard spacers are manufactured in standard thicknesses of 2, 3, and 4 millimeters (mm). To build up the ducts between the coils, standard pressboard spacers, fulfilling the following conditions, should be used.

1. To avoid waste of time in manufacturing the windings, the use of pressboard spacers of different thicknesses shall be avoided.
2. Accomplishment of item 1 must not be achieved at the expense of the copper space factor in an axial direction.

The problem was solved by constructing a procedure with two entries. Entrance through entry 1 determined for a given minimum value of the distance between the normal coils the nearest standard distance (i.e., composed of identical standard pressboard spacers) equal to or greater than the minimum distance. In case of a choice between different standard pressboard spacers, the type which gives the least possible number of spacers will be chosen. All other ducts as, for example, tap ducts, are determined by entrance through entry 2 with the given minimum value and the standard pressboard spacer found above, where the nearest standard distance (i.e., a distance composed of the given standard pressboard spacer) is found equal to or greater than the minimum distance.

The ducts thus determined are tested with regard to cooling on an empirical basis in box 61 of Fig. 4, where a feedback in negative cases leads back to the abovementioned calculation of the distance between the normal coils in box 7.

Use of Algol

From the point of view of the user, we are completely convinced of ALGOL's suitability in programing engineering problems. Besides all the probabilities of this language which are already directly or indirectly indicated in this paper, we should also like to point out that ALGOL is easily readable, a very important feature which we have tried to demonstrate by coding a part of the transformer winding program in the Appendix.

It is realized, of course, that the use of a symbolic programing language costs more in running time and memory space, compared with a machine language, but this extra expense seems justified, because many problems never would be put on the computer if only the machine code were used. In addition, the problem of debugging has certainly been reduced with ALGOL.

Conclusions

Experience with thesis work in this area and with laboratory reports in adjacent areas seems to indicate that this short Introduction to computers exerts a good influence on the student's working habits.

Furthermore, the principles behind the Introduction seem to arouse the student's interest for design problems in electric machinery, especially from an optimization point of view.

Instead of choosing an electric machinery design problem as we have done, problems of the same type, requiring iterative procedures, may be selected, in accord with the particular interests of the students.

Appendix. Algol-Coded Winding Program

The following are selected sections of the high-voltage disk-coil transformer winding program coded in ALGOL, given here to demonstrate the readability of, and the use of library routines in, the international computer language described in the paper.

Main Program

Block numbers 87 through 99 of Fig. 4.

```
87: hs1 := h1+e×d1;
88: skin effect (acu1, p1, h1, hs1, b1, f)
        =: (Rj11, q1);
89: if (q1 > 0.08);
    go to B14;
90: disk temp (B1, hs1, p1, m1, Rj11,
        q1, If1, d1, t) =: (ty1);
91: if (ty1>tm);
    go to B14;
92: n := 0;
    j := −1;
93: n := n+1;
94: j := j+1;
95: if (Nen≤0);
    go to 97;
```

```
96:  if (n<6);
     go to 93;
97:  ne := j-ns/2;
98:  if (ne>0);
     go to 100;
99:  ne := 0;
```

Calculation of D-C Resistance and Stray-Loss Factor

```
     procedure skin effect (acun, pn, hn,
     hsn, bn, f) =: (Rjn1, qn);

     comment acun is the area in square
     mm and hn and bn the height and
     width in mm of the bare conductor,
     while hsn is the height in mm of
     the insulated conductor.  pn is the
     number of conductors in parallel
     and f the frequency.
       Rjn1 is the d-c resistance in ohms
     per meter length of the conductor
     and qn the stray-loss factor, both at
     the reference temperature 75 degrees
     centigrade.  v is the reduced height
     of the conductor at the same tempera-
     ture.
       Reference: L. Hyldgaard-Jensen:
     Transformatoren, Appendix I, Copen-
     hagen 1954;

     begin skin effect:
      Rjnl := 2.17₁₀-2/acun;
     a(X) := X×(exp (2×X)-exp
             (-2×X)+2×sin (2×
             X))/(exp (2×X)+exp
             (-2×X)-2×cos (2×X));
     b(Y) := 2×Y×(exp (Y)-exp
             (-Y)-2×sin (Y))/(exp
             (Y)+exp (-Y)+2×cos
             (Y));
       cs := 95.5₁₀-3×sqrt(f×hn/(50×
             hsn));
        v := bn×cs;
       qn := -1+a(v)+(pn↑2↓-1)×
             b(v)/3;
     return end skin effect;
```

Temperature of Winding Over Oil

```
     procedure layer temp (Bn, hsn, pn,
     T2, Rjn1, qn, Ifn, t) =: (tyn),
     disk temp (Bn, hsn, pn, mn, Rjn1,
     qn, Ifn, t) =: (tyn);
     comment The mean temperature tyn
     over oil of the winding is computed
     by Gotter's method (G. Gotter:
     Erwarmung und Kuhlung elektrischen
     Maschinen, Springer Verlag 1954, pp.
     198-204) by considering a 1-meter-
     long section of a thread in a layer-
     winding respectively of a coil in a
     disk-coil winding, where Bn is the
     width and hsn the height of the
     section, while dn is the conductor
     insulation thickness, all three in mm.
       pn is the number of conductors
     parallel in radial direction.  T2 is
     the number of threads, if the winding
     is of the layer-type, while mn is the
     number of turns per coil, if the
     winding is of the disk-coil type.
       Rjn1 is the d-c resistance in ohms
     per meter length of the conductor
     and qn the stray-loss factor.  Ifn is
     the current in amperes per phase,
     and t is the maximum temperature of
     the winding in degrees centigrade.
     The covered area has been put to
     0.30 in the computation of Afn;
     begin layer temp:
     mn := 1;
     I := Ifn/T2;
     go to 75;
     begin disk temp:
     I := Ifn;
 75: if (t≤75);
     begin a0 := 70.724; a1 := 17.165;
       a₂ := -3.2939; a3 := 0.27769;
     go to RD end;
105: if (t ≤ 105);
     begin a0 := 79.570; a1 := 22.725;
       a2 := -3.9282; a3 := 0.31699;
     go to RD end;
     stop;
 RD: RD(X) := ((a3×X+a2)×X+a1)
       ×X+a0;
     comment RD(X) is the heat con-
     vection factor in radial direction as
     a function of the loss in watts per
     square meter surface area of the
     section (Gotter: Abb. 94);
         b0 := 1.0022; b1 := -2.4544₁₀
         -2; b2 := 3.4928₁₀-4; b3 :=
         -2.3164₁₀-6; b4 := 5.8695₁₀
         -9;
 AD: AD(Y) := (((b4×Y+b3)×Y+b2)
       ×Y+bl)×Y+b0;
     comment AD(Y) is the heat con-
     vection factor in axial direction
     divided by the heat convection factor
     in radial direction as a function of
     the width Bn of the section (Gotter:
     Abb. 95);
     Afn  := 1.4₁₀-3×(Bn+hsn);
     W    := mn×Rjn1×(1+qn)×
             I↑2↓/pn;
     w    := W/Afn;
     myr  := RD(w);
     f    := AD(Bn);
     mym  := myr×(1+f×Bn/hsn)/
             (1+Bn/hsn);
     if (dn≤1);
     begin tyn := w/mym;
     return end layer and disk temp;
     tyn  := w×(2.75₁₀-3×(dn-1)+
             1/mym;
     return end layer and disc temp;
```

Proposed Symbology for Digital Systems

AIEE COMMITTEE REPORT

THE URGENT NEED for a reference on suggested algebraic and graphical symbols for the design and maintenance requirements of digital systems prompted the preparation of this report. It is also intended to serve as a reference for the symbology used in tutorial lectures sponsored by the AIEE Subcommittee for Logic and Switching Circuit Theory of the Computing Devices Committee. Included are algebraic symbols for representing variables and connectives used in logical expressions; graphical symbols for manually prepared logical diagrams; and printed graphical symbols for logical diagrams prepared by high-speed printers.

It is fully appreciated that this report reflects the opinon of engineers engaged in computer production or service and that it may be subject to numerous comments. It is the hope of the ad hoc group who prepared the report that, in response to AIEE policy of inviting written comment, it will provoke discussion and thus serve as a direct contribution to the formulation of engineering standards by other authorized organizations.

In preparing the report the philosophy of U. S. Government agencies and the U. S. Air Force in particular as the largest users, has been taken into consideration. Much of the material is based on the findings of a study by the Air Force,[1] and on related military standards, for example, reference 2.

Paper 60-1224, recommended by the AIEE Computing Devices Committee and approved by the AIEE Technical Operations Department for presentation at the AIEE Fall General Meeting, Chicago, Ill., October 9–14, 1960. Manuscript submitted June 3, 1960; made available for printing September 23, 1960.

The members of the Ad Hoc Working Group of the Logic and Switching Circuit Theory Subcommittee of the AIEE Computing Devices Committee are T. H. Mott, Jr., *chairman*; T. C. Bartee, D. Drusdow, R. J. Preiss, E. J. Schubert, W. J. Smith, and T. W. Sze.

Table I. Symbols for Logical Operations

Operation	Symbol	Example
OR	$+$	$A+B$ (A OR B)
AND	$\cdot$	$A \cdot B$ (A AND B)
NOT	$'$	A' (NOT A)
EQUIVALENCE	$=$	$A+A=A$

Ground Rules for Choice of Symbols

Three major divisions are proposed as follows, in which the choice of symbols is based on the following rules:

1. *Algebraic Symbols:* Algebraic symbols shall designate the relations of logical variables in binary notation for combinational and sequential logic. Appropriate indexing for canonical forms (minterms and maxterms), general logical expressions, and time-dependent expressions is tentatively provided. All symbols are restricted to those types which are available on conventional typewriters and printers' keyboards.
2. *Graphical Symbols:* Drafting symbols are suggested for manually prepared logical diagrams with provision for complete terminal, signal, and functional identification. The shape of the symbols is restricted to those formed by combinations of horizontal and vertical lines, and circles.
3. *Printed Graphical Symbols:* Printed graphical symbols are equivalent to the drafting symbols in the next section but are prepared by programed printing devices. The shape of the symbols is dictated by the restriction to the minimum number of additional characters.

Algebraic Symbols for Logic Equations

The proposed algebraic symbols, used to designate relations between logical variables, and restricted to those available on conventional typewriters and printers' keyboards, are divided into four categories: logical variables, logical operations, logical expressions, and time-dependent expressions.

Logical Variables

As in conventional algebra, the logical variables are represented by letter symbols with or without subscripts. Capital or lower-case letters may be used, e.g., A, B, C, a, b, c, etc. However, when both logical and algebraic variables are present in a text, it is recommended that the capital letters be assigned to the logical variables and the lower-case letters to the algebraic variables. For example:

(Logical variables)		(Algebraic variables)
$T=A+B$	when	$b^2-4ac \geq 0$
$T=A \cdot B$	when	$b^2-4ac<0$

Associated with logical variables are the values which they take on. In binary logic, these values are represented by 1 and 0 (truth and falsity, active and inactive, etc). The Greek letter ϕ should be used if the designer "doesn't care" whether the value of a variable is 1 or 0.

Logical Operations

When a logical operation word appears in a text, it should be spelled out in full with capital letters, e. g., A AND B.

For expressing the following logical operations in symbolic form, it is proposed that the symbols listed in Table I be used.

$A+B$ is called the sum of A and B; $A \cdot B$, the product of A and B; and A', the negation of A.

Other operations, such as OR-NOT (NOR), AND-NOT, and EXCLUSIVE OR, are considered as derived operations, and will use the combinations of symbols listed in Table I.

Logical Expressions

General form. General logical expressions are built up from logical operations, logical variables, parentheses, and brackets. Where parentheses and brackets are omitted in an expression, the hierarchy of operations is assumed to be: $'$, $\cdot$, $+$, $=$.

Logical functions are associated with logical expressions as follows: Suppose A, B, C, D, . . . are the variables appearing in a logical expression; then, the expression specifies the value of the function for the arguments A, B, C, D, ... For instance, suppose $A \cdot B' + C \cdot D$ is a logical expression; then, for the different values of the arguments A, B, C, and D, the values $f(A, B, C, D)$ of the corresponding function f are calculated from the expression $A \cdot B' + C \cdot D$.

Canonical form. Associated with any given logical function are many different logical expressions. Assume the arguments of the function expressed by a fixed assignment of variables; then, two of the logical expressions associated with each function are defined as canonical. The "sum of products" canonical form is the sum of certain products called minterms. These are products in which all of the assigned variables appear exactly once, negated or unnegated. The dual canonical form is defined analogously as a "product of sums."

Positional notation. The minterms of a function correspond in obvious fashion to those value assignments of the arguments which give the function the value 1 (or truth). Hence, instead of expressing the function in canonical form as a sum of products it is sometimes convenient to represent it in terms of a set of (0, 1) n-tuples (where n is the number of arguments of the function). Analogously, introducing a third symbol,—(dash) or 2 or x, to indicate that the corresponding argument (variable) is not present in the product, enables one to represent products in general logical expressions as (0, 1,—) n-tuples.

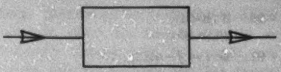

Fig. 1. Illustrating use of arrowheads for direction of signal flow; not to be placed immediately adjacent to any graphical symbol, input, or output

For instance, the 3-argument function expressed by $A' \cdot B' \cdot C' + B \cdot C$ has a canonical form $A' \cdot B' \cdot C' + A \cdot B \cdot C + A' \cdot B \cdot C$. Hence the function may be denoted by the set of triples 000, −11, or alternately by the set 000, 111, 011.

Time-Dependent Expressions

It is proposed that superscripts be reserved to denote values of time variables. For example, $f^{t+1}(A, B, C) = (A \cdot B + C)^t$ or $= A^t \cdot B^t + C^t$.

Graphical Symbols for Logic Diagrams

This section contains a system of drafting symbols proposed for digital circuits. Each symbol represents a "binary logical function," and is a graphical representation of an electrical function. The list presents basic logic symbols in their simplest form, and is consistent with other accepted standards and conventions. The system of symbols is fundamental in nature and therefore has growth potential. The basic symbols were selected with two objectives in mind:

1. Specific (geometrical) shape.
2. "Logical" associations to functional circuits.

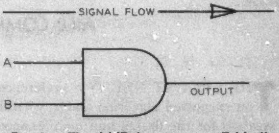

Fig. 2. The AND function; see Table II

Table II. The AND Function of Fig. 2

Input		Output
A	B	$X=A \cdot B$
0	0	0
0	1	0
1	0	0
1	1	1

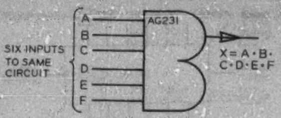

Fig. 3. Multiple input AND gate

All graphical symbols contained in this section are drawn to the same scale, and rectangular symbols are in specific aspect ratio.

State of Signal and Direction of Signal Flow

A signal may assume either the "active or true" state (1) or the "inactive or false" state (0). The electric signal levels (high or low) for the true or false state must be specified explicity for the individual circuit diagrams.

1. The direction of signal flow shall be indicated by arrowheads superimposed on the line channel path in all cases where direction of flow is not obvious.
2. When the direction of signal flow is obvious from the associated logic, the arrowheads may be omitted.
3. Arrowheads shall not be placed immediately adjacent to any graphical symbol, input or output; see Fig. 1.

Basic Logic Symbol Reference States

In this report all basic logic symbols shall be considered to operate for the input signals being true (1), high level. The true (1) high-level state of the input signals activates the logic element in the manner indicated by the specific symbol. This convention shall be followed regardless of the actual mode of operation of the physical devices used to implement the logic. Small circles adjacent to the symbols shall indicate inversion of the signal, i.e., low level.

The presence of a small circle at the input of the logic element indicates that it will be activated by the (0) low-level signal. Absence of the small circle at the input indicates that (1) high-level is the activating signal. Accordingly, a small circle at the output indicates that the function is the inverse of the normal symbol function.

Table III. The OR Function of Fig. 4

Input A	Input B	Output X = A + B
0	0	0
0	1	1
1	0	1
1	1	1

Graphical Symbol Shape and Size Considerations

The size and shape of each graphical symbol in this report are determined by the following requirements:

Each symbol must be instantly recognizable in a complex diagram by virtue of a distinctively different geometric shape dictated by its different peripheral configuration.

Each symbol must be evacuous, thus permitting 0.140-inch high-internal letter tagging to identify the following:

1. Logic reference designation; two alphabetical symbols and three digits.
2. Six-digit number which locates circuit by cabinet number, rack, row, and nest.
3. Four-digit number identifying circuit schematic.

Basic Logic Symbols

AND *Gates—Function*

The AND gate is a circuit or device performing the logical AND function (i.e., the Boolean operation of intersection), if and only if all the inputs are in the 1 state; see Fig. 2 and Table II.

Note that:

1. AND gates are indicated by a horizontally elongated letter D, with data flowing from the straight base line to the curved side.
2. The input lines contact the vertical base line at a perpendicular angle.
3. The output line departs from the midpoint of the curved side.
4. Two or more input lines may be shown.
5. Fig. 3 illustrates an application where many input lines are required.
6. The output equals 1 (logical 1) if and only if all the inputs are 1; see Table II.

OR *Gates—Function*

The OR gate is a circuit or device whose output is energized when one or more of the inputs is in its prescribed state. An OR circuit performs the function of the logical OR, which is, in Boolean algebra the operation of union; see Fig. 4 and Table III.

Note that:

1. OR circuits are indicated by an arrowhead type of symbol with data flowing from the curved portion to the point.

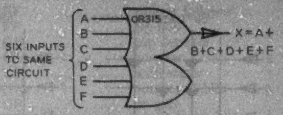

Fig. 5. Multiple input or gate

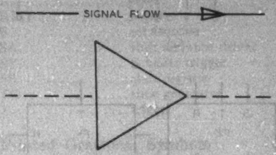

Fig. 6. Amplifier symbol

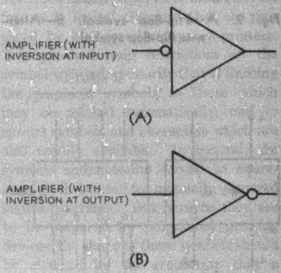

AMPLIFIER (WITH INVERSION AT INPUT)
(A)
AMPLIFIER (WITH INVERSION AT OUTPUT)
(B)

Fig. 7. Amplifier. A—With inversion at input. B—With inversion at output

2. The input lines contact the symbol's curved portion.
3. The output line departs from the point of the symbol.
4. Two or more inputs may be shown.
5. Fig. 5 illustrates an application where many input lines are required.

Amplifier—Function

The amplifier is a device whose output is some function of a single input. Generally the output is an improved version of one or more of the essential features of the input (such as level, signal swing, or rise time). The symbol is shown in Fig. 6.

Note that:

1. The amplifier is shown as an equilateral triangle, pointed in the direction of signal-data flow; see Figs. 6 and 7.
2. The exact function of the device may be indicated by markings within the triangle.
3. Function markings and abbreviations (other than those included within this symbolic system) shall be identified by notation for each drawing.

Examples are shown in Figs. 7(A) and 7(B).

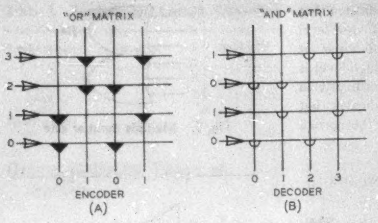

Fig. 8 (left). OR and AND matrices. Symbols for logical network with elements connected at some of its intersections of input-output leads

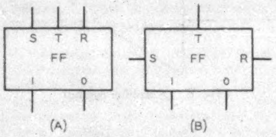

Fig. 9. A—Flip-flop symbol. B—Alternate flip-flop symbol

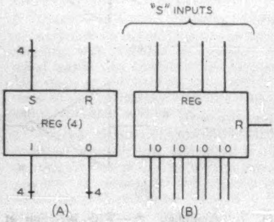

Fig. 10. A—Binary register symbol. B—Alternate binary register symbol

AND/OR *Matrices–Function*

AND/OR matrices are any logical network whose configuration is a rectangular array of intersections of its input-output leads, with elements connected at some of these intersections. The symbols are shown in Fig. 8.

Note that inputs and outputs may be oriented as is convenient.

Storage Circuits—Function

A storage device is able to retain a signal. Conventional storage elements are: flip-flops (single-bit storage), binary registers (*N*-bit storage); and shift registers (a binary register with internal shift provision).

Example 1—Flip-Flop: The flip-flop, Figs. 9(A) and (B), is a bistable circuit capable of storing a single bit of information. It has three possible inputs; set, reset, and trigger; with two possible outputs, 1 and 0.

The two outputs are always of opposite polarity. A 1 is stored in the flip-flop when the 1 output is at the 1 level and the 0 output is at the 0 level. A zero is stored in the flip-fiop when the above condition is reversed.

The flip-flop assumes the 1 state (1 output at conventional 1 level) when an effective signal appears at the S input. It assumes the 0 state when an effective signal appears at the R input. It reverses its state when an effective signal appears at the T input.

Note that:

1. Symbols for trigger circuits are indicated by rectangles which have an aspect ratio of 0.8 to 1.4.
2. The trigger input contacts the center of one broad side, and may be identified by the letter T.
3. The set and reset inputs must be identified by letters S and R respectively:
   S input shall be in proximity to the 1.
   R input shall be in proximity to the 0.
4. The 1 and 0 output lines contact the broad side which is not contacted by an input.

Example 2—Binary Register: This device is a group of flip-flops used in parallel to constitute a single register (as to store four bits of a character).

Note that:

1. The number of bits or individual flip-flops in the register is indicated within parentheses following the abbreviation REG.
2. Fig. 10(A) shows four S inputs grouped on one multiple input line and four each 1 and 0 grouped output lines.
3. In some applications, individual input and output lines are shown as in Fig. 10(B).
4. The aspect ratio of the symbol shall be 1 to 2.5 or greater.

Example 3—Shift Register: This device is a group of flip-flops with provisions to displace or shift the content of the register one stage at a time to the right or left by means of the "shift" inputs.

Note that:

1. The location of shift input at the left corner of the symbol indicates that the shift is from left to right.
2. If the shift is from right to left, the shift input is located at the right corner of the symbol.
3. The aspect ratio shall be to 1 to 2.5 or greater as required.

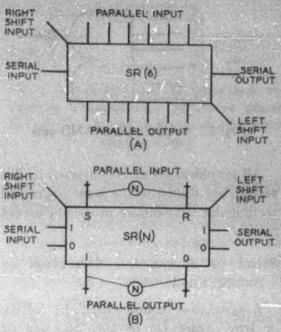

Fig. 11. A—Shift register symbol. B—Alternate shift register symbol

Fig. 12 (left). Inversion symbol

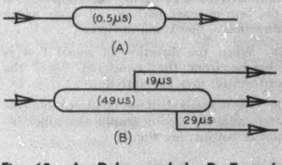

Fig. 13. A—Delay symbol. B—Tapped-delay symbol

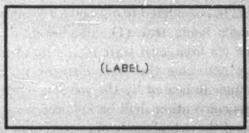

Fig. 14. General logic element symbol

4. The choice of either the symbol in Fig. 11(A) or that in 11(B) is dependent on diagram arrangement of associated symbology.

INVERSION

A small circle represents inversion. It is placed adjacent to the inputs or outputs of symbols, as required, to realize the positive internal reference (fiducial) state of the symbol; see the section "Basic Logic Symbol Reference States." The symbol is shown in Fig. 12.

Delay

Delay is expressed by any passive device which effects a time delay of the signal. The symbol is shown in Fig. 13.

Note that:

1. Delay time indicated within parentheses; see Fig. 13(A).

2. Fig. 13(B) illustrates a tapped delay line.

3. Aspect ratio generally 5 to 11.

GENERAL LOGIC ELEMENT—FUNCTION

An attempt to assign a logical symbol to the many digital operations and junctions designed into digital devices would cause this system of symbols to become unmanageable and would defy the average person's memory for correct application. Accordingly, a "general logic symbol" with inscribed notations serves as an excellent catchall for any function not classified herein. The symbol is shown in Fig. 14.

Note that:

1. The symbol shall be adequately labeled to describe completely the function performed.

2. The aspect ratio is 1.1 to 2.2.

MAGNETIC HEADS—FUNCTION

Magnetic heads are electromagnetic devices used for magnetizing (recording), detecting (reading), or demagnetizing (erasing) a magnetic surface. The graphic symbols are shown in Fig. 15.

Note that:

1. Orientation of magnetic heads may be in any direction, as convenient.

2. Inscribed capital letters identify functional use of each magnetic head as shown.

Fig. 16 (left). Magnetic drum graphic symbol

MAGNETIC DRUMS—FUNCTION

A rotating cylinder on which information may be stored as magnetically polarized areas, usually along several parallel tracks around the periphery. The graphic symbols are shown in Fig. 16.

Note that:

1. Each track of a magnetic drum, Fig. 16 (or similar recording device), is indicated by a single line terminating in an open arrowhead indicating direction or travel.

2. The angular position of each head is indicated in degrees, or delay time, near the head.

3. The position of all heads are related to the recording head W unless otherwise noted.

EXPANDED LIST OF BASIC LOGIC SYMBOLS

Employing the logic symbols developed so far, Fig. 17 represents an expansion of the system to demonstrate its growth potential.

ABBREVIATIONS

Nondistinctive logic symbols shall be tagged with mnemonic abbreviations (in alphabetical order) to describe the function performed. In the list below the function follows the abbreviation:

AG	AND gate
CT (*N*)	binary counter (*N* bits)
RG (*N*)	register (*N*) stage
BO	blocking oscillator
CF	cathode follower
CD	current driver
DL	delay
EF	emitter follower
FF	flip-flop
GD	gap detector
IV	inverter
LS	level setter
(N)	number of bits
OR	OR gate
OS	one shot
PA	pulse amplifier
PG	pulse generator
R	reset
REG	register
S	set
SA	shift advance driver
ST	Schmitt trigger
SR	shift register
TG	time generator

Printed Graphical Symbols

The graphical symbols and notation described in this paper have been selected for use in logical diagrams that are prepared by high-speed computer printers. This places certain restrictions on the symbology used: primarily that of limiting the graphical symbols to those which may be printed automatically, and to special symbols and characters which are also readily available. In general, the symbols and notation should be equivalent to those used for manually prepared logical diagrams. But because they are to be prepared by programed printing devices, the shape of these symbols should be dictated by the restriction that a minimum number of additional characters need to be added to the most commonly used mechanical or electronic printing devices.

Fig. 17 (right). Expansion of logic symbol system to demonstrate its growth potential

This restriction, then, rules out the use of the shapes of the symbols on the diagrams as a possible means for identifying their functions. Also, since machine-produced records are usually used for more than one purpose, the difference between the pure logic and the other information, such as implementation or placement information, must be clearly kept separate.

With these two aims in mind, the proposed philosophy offered is recommended for solicited AIEE papers:

FLOW OF INFORMATION

At least one major direction of flow of information must be maintained on a logic diagram. If no arrows are shown, information is to be read from left to right, top to bottom.

ALPHABETIC AND NUMERIC INFORMATION

The burden of distinguishing a letter from a number shall always be placed on the letter. Three instances are cited with recommendations: The letter O and the number 0 should be clearly distinguishable on a printed diagram. Similarly, the capital letter I and the number 1, and the letter Z and the number 2 should be clearly distinguishable. It is recommended that the letter O be slashed: Ø; the capital letter I have bars at top and base; and the letter Z appear with a bar through it: Ƶ.

SIGNAL NAME AND FUNCTION NAME

It is recommended that a distinction be maintained between signal line name and logical function name, or logical implementation name. A signal line name in its most abstract form is a variable. A logical function name in its most abstract form is a connective.

A variable, or signal line name, has two basic properties: a name and a state. It may represent a compound logical statement, a factor, or it may represent a grouping of signal lines that have gone through an abstract type of connective. Note that a variable cannot change name or state unless it passes through a connective.

The state may be indicated by a sign (+, −), a number (1, 0) or a special character (*s*, ◊, ~) as part of a signal line name. A position convention may be used to indicate the state of a connective, but it is preferred that, even then, the special character be also used.

A connective is the name given to the relationship between the output of a logical function and its inputs. A connective therefore acts on one or more variables to change their name or state, or both. A connective may exist in three forms: It may be an algebraic connective; it may be a physical implementation of an algebraic, or a group of algebraic connectives; or it may be an abstract, or undefined connective. The difference between these three types must be clearly discernible on the diagram.

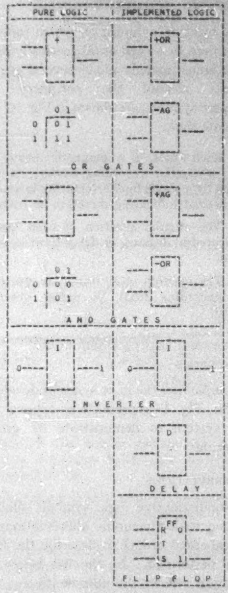

Fig. 18. Machine-produced block diagrams

LOGIC AND CIRCUIT INFORMATION

To distinguish between implemented logic and abstract logic, it is recommended that logical symbols be used as logical connectives, and that letters or combinations of letters be used for implemented logic symbols. The appearance of both types of symbols on one diagram should not lead to confusion. A concerted effort should be made, however, to guarantee that the same letter or combination of letters does not stand for different types of circuits.

It is recommended that a clearly defined symbol should exist between line names, connective names, and other information on the diagram. If a symbol is not used, then a clearly defined convention may be substituted so that the grouping belonging to the name or to the connective be clearly distinguishable. Thus, for instance, a machine-produced block diagram would contain all the information pertaining to the circuit within the outlines of the block. Lines drawn entering and leaving the block are clearly recognizable as input and output information lines for that block.

EXAMPLES OF GRAPHICAL AND ALGEBRAIC SYMBOLS

The types of the graphical symbols used are limited to rectangles by the fact that these symbols are to be automatically printed. Therefore it is necessary to indicate the function yielded by a given block by indicating the function within the rectangle. Fig. 18 illustrates the recommended block diagrams for AND gate, OR gate, FLIP-FLOP, DELAY, and INVERTER.

The symbols shown in Fig. 18 are printed on an automatic printer. Space is left within each rectangle in the implemented logic block so that part number, location in the computer, voltage levels, and other details may also be printed inside the rectangle. The designation for external pins is placed outside the rectangle.

Two types of symbols are shown: 1. Pure logic symbols, for use in diagrams, when only the logic of the machine is to be printed. 2. Implemented logic symbols for diagrams in connection with the construction and maintenance of the machine. For this reason, both positive and negative AND and OR gates are shown in the implemented logic section of the figure. (A negative AND gate corresponds physically to a positive OR gate, and a negative OR gate corresponds physically to a positive AND gate.)

Also, NOR is used to designate an OR gate with an inverted output; and NAG an AND gate with an inverted output. This distinction is necessary because the small circles used to indicate signal inversion recommended in the previous section cannot be printed by most automatic printers.

Following is an example of the recommended use of algebraic symbols:

T=A+−B. (C·−(D+E)+F) corresponds to:

$$T=A+B'.\ (C.\ \ (D+E)'\ \ +F)$$

T11*3=A *1+−B13*2. (C12 .−(G1 +G2) +C10) corresponds to:

$$T_{11}{}^{3}=A^{1}+B'_{12}{}^{2}.(C_{12}.(G_1+G_2)'+C_{10})$$

Note that:

1. The use of the prime after a variable or parenthesis is replaced by the use of the minus sign before the variable or parenthesis, to indicate negation.
2. Subscripts are written immediately after a variable, while superscripts are preceded by an asterisk.

Discussion

Ralph J. Preiss (International Business Machines Corporation, Poughkeepsie, N. Y.): First, I would suggest that the following definition of a symbol be inserted at the start of the section "Graphical Symbols for Logic Diagrams":

> A symbol is considered as the aggregate of all its parts. It consists of an evacuous shape and an alphanumeric code inside this shape. This alphanumeric code may be used in conjunction with its respective shape, or with the general logic element shape, at the discretion of the user, and consequently is alone capable of fulfilling the requirements and intentions of the standard.

Without this definition, the section "Printed Graphical Symbols" is inconsistent.

Second, I should like to submit a revised list of alphanumeric codes for the abbreviations in the section "Abbreviations," as follows:

A.....and
AM...amplifier
BO....blocking oscillator
C......converter
CT....counter
E.....extender
EF....emitter follower
FF....flip-flop
G.....gate
GD...gap detector
I.....inverter
L.....level setter
O.....or
OE...exclusive or
OS...oscillator (time generator)
PG...pulse generator
RG...register
SR.....shift register
SS.....single shot (one shot)
TD....time delay

Third, all the illustrations representing the symbols should include their alphanumeric codes in accordance with the first two suggestions.

J. F. Kalbach (Burroughs Corporation, Pasadena, Calif.): The symbols proposed in this paper might have been useful to the company with which I am affiliated had they been available when needed. However, in the absence of national and internal company standards, sets of logic symbols have been generated and used by each major engineering activity. Because each activity deals with different types of logic and different digital applications, there are differences between the standards of several engineering divisions within our company.

The symbols used by our particular engineering division are different from the proposed standards. Perhaps we are prejudiced by familiarity, but in comparison with our own, the proposed symbols appear awkward and too large. Drawing space requirements, using the proposed template would greatly exceed the requirements using our own. Perhaps this could be overcome by changing the dimensions of the proposed template. Engineers who are familiar with our own symbology are reluctant to use another.

However, the above considerations become academic to any group which is converting to machine-produced logic block diagrams. We have embarked on such a program and have encountered practically no objections from those who use the rectangular diagrams produced by machine. A program for generating logic block diagrams with variable size and position was described in a paper by Carroll Slemaker in 1960. The logical symbols are all rectangular and are of varying size and position on the page. They have no dots or arrowheads to identify function. The sole identification consists of symbols printed within the rectangular blocks.

In view of the predicted general adoption of machine-printed logic diagrams throughout the industry, we feel that standardization is needed in sets of symbols to be used for identifying rectangular blocks.

G. L. Hollander (Hughes Aircraft Company, Fullerton, Calif.): The ad hoc group should be congratulated on their pioneering action of proposing standard symbology and providing a forum for comments from diverse groups to speed the time of a universally acceptable standard. The selection of specific graphical and algebraic symbols may be controversial, but in time everyone will benefit from the adoption of standards that are unambiguous, consistent, and easily distinguishable in poor drawings and when greatly reduced. However, to be universal, a standard should provide for all present and future approaches to logical design.

The two prevalent approaches to logical design differ by the primary reliance on drawings (pictorial symbology) or equations (notational symbology). Historically the pictorial or the notational approach was favored by the "Eastern" and "Western" factions respectively; automated design procedures also depend on the notational approach.

The proposed symbology is incompatible with the notational approach. The letter symbols for the gating structures do not distinguish between the basic and the inverted functions, such as OR and NOR. Reference to the drawing is essential to differentiate the two. Since, during the last few years, the NOR function has been widely adopted, the standard should provide for a basic literal NOR and NAND designator.

One should also question whether the "basic" operations, described in the section "Logical Operations," are really fundamental or merely historical. If, e.g., the NOR and NAND circuitry become the standard building blocks, designers may gradually consider the negated functions to be basic. Limiting the basic functions in the specifications may freeze an antiquated system into logical design.

It is hoped that these comments will help the ad hoc group establish a more universal standard.

The Analog Solution of Some Functional Analysis Problems

K. K. GRAUPE
NONMEMBER AIEE

THIS PAPER presents several methods of setting up an analog computer to solve a system of coupled equations for several unknown functions; these methods extend Clymer's "implicit synthesis" technique.[1] The system can also contain derivatives of the unknown functions, but in that case only one independent variable is considered. The system of equations need not be linear. Only the existence of certain derivatives of the given functions is assumed.

The principal method, here called the least-squares method, is mentioned in an abstract,[2] but was evidently applied only to linear systems. No practicable description of that method was found. A simpler variation, here called the least-magnitude method, seems to be new.

When only one equation connects all given and unknown functions, the least-squares method and the least-magnitude method can be generalized to a method which gives more freedom in the computer setup. This method is described as problem 1 in the next section.

Another new method, here called the

Paper 60-1230, recommended by the AIEE Computing Devices Committee and approved by the AIEE Technical Operations Department for presentation at the AIEE Fall General Meeting, Chicago, Ill., October 9–14, 1960. Manuscript submitted June 7, 1960; made available for printing August 9, 1960.

K. K. Graupe is with the Boeing Airplane Company, Seattle, Wash.

determinant method, could serve as an independent check on other methods.

For the special case, a linear system of equations with constant coefficients, the matrix of which is positive definite, there is a very simple method of solving the problem.[3] But such conditions are seldom fulfilled.

Proofs are given which assume that ideal operational amplifiers are available for the convergence of the new methods. The success of the computing procedures is illustrated by several examples. Many applications of these computing procedures are described by Clymer.[1]

The Different Computing Methods

The computing methods will be described in several steps progressing from simple to more complex problems.

PROBLEM 1

One algebraic or transcendental equation for k unknown constant parameters x_ν is given ($\nu=1, 2, \dots k$)

$$f(t, x_1, \dots x_k)=0 \tag{1}$$

The computer is to solve for all parameters x_ν. If equation 1 were valid only for a certain instant of time t, then the solution would have k-1 degrees of freedom. But equation 1 is valid for a period of time and the computer exploits this fact; it takes a certain time to obtain the solution.

Now, f may depend on t by way of several given functions $g_1(t)$, $g_2(t)$, ... $g_m(t)$ and some may be derivatives of other $g_\mu(t)$. What kind of functions these are is not important immediately. Therefore the dependence of f on all the $g_\mu(t)$ is summarized in equation 1 by $f(t, \dots)$.

One of the parameters x_ν may be a function of time. Then the problem is defined as above and the circuit will work, if the speed of the computer is as high, as will be expressed later by condition 4.

SOLUTION OF PROBLEM 1

The computing system of Fig. 1 will produce a set of functions $X_\nu(t)$ which converge to one solution x_ν of equation 1. The functions $P_\nu(t)$ appearing in Fig. 1 are arbitrary, but positive, functions of time. In special problems one will dispose of the functions $P_\nu(t)$ so as to simplify the computer as much as possible. G_ν is the gain of the pertinent integrator ($G_\nu>0$). The symbol ϵ, which will be referred to as the error of the computer, is defined by

$$\epsilon=f(t, X_1, X_2, X_3, \dots X_k)$$

The following proof that $X_\nu(t)$ converges to one solution x_ν of equation 1 will make clear the operating principle of the circuit.

Differentiating the function $f(t, X_1, X_2, \dots X_k)$, one obtains

$$\frac{d\epsilon}{dt}=\frac{\partial\epsilon}{\partial t}+\sum_{\nu=1}^{k}\frac{\partial\epsilon}{\partial X_\nu}\dot{X}_\nu$$

and from Fig. 1

$$\dot{X}_\nu=-G_\nu P_\nu\left(\operatorname{sign}\frac{\partial\epsilon}{\partial X_\nu}\right)\epsilon \tag{2}$$

(The symbol sign y means $y/|y|$, i.e., $+1$ or -1 depending on the sign of y.) Hence

$$\frac{d\epsilon}{dt}=\frac{\partial\epsilon}{\partial t}-\epsilon\sum_{\nu=1}^{k}G_\nu P_\nu\left|\frac{\partial\epsilon}{\partial X_\nu}\right| \tag{3}$$

If one requires all functions $P_\nu(t)$ to be so large that

$$\left|\frac{\partial\epsilon}{\epsilon\partial t}\right|<\sum_{\nu=1}^{k}G_\nu P_\nu\left|\frac{\partial\epsilon}{\partial X_\nu}\right| \text{ when } |\epsilon|>|\epsilon_{\min}| \tag{4}$$

then

$$-\frac{d\epsilon}{\epsilon dt}>0 \quad \text{for} \quad |\epsilon|>|\epsilon_{\min}| \tag{5}$$

Obviously condition 4 cannot hold for $|\epsilon|<|\epsilon_{\min}|$, except for special functions $f(t, \dots)$, because of the denominator ϵ in the left side of the condition.

The inequality 5 expresses that ϵ will monotonically go to the "final" error $\epsilon_{\min}$. Afterward, ϵ will fluctuate between about $\pm|\epsilon_{\min}|$. Only in this practical sense is the output X_ν of the computer "converging" to the solution x_ν of equation 1.

Condition 4 requires that $\partial\epsilon/\partial t$ be bound. The computer will fail near poles of $\partial\epsilon/\partial t$. The other occasion where condition 4 cannot be fulfilled takes place around such instants t' where all $\partial\epsilon/\partial X_\nu$ vanish simultaneously. These instants are unique; otherwise equation 1 could not be solved for x_ν. Since X_ν is put out by an integrator, $X_\nu(t)$ will be a continuous function.

The term $\partial\epsilon/\epsilon\partial t$ is of the order of the main frequency in the $g_\mu(t)$'s. If the right side of condition 4 were a constant, its reciprocal could be called the time constant of the computer. Therefore condition 4 can be interpreted to mean that the time constant of the computer should be shorter than the main period in the given functions.

If, for instance, x_1 is an unknown function of time and $x_2, x_3, \dots x_k$ are unknown constants, it is advantageous to choose $G_2\approx G_3\approx \dots \approx G_k<<G_1$ in such ratio that all multiplier outputs in Fig. 1 have about the same signal level.

To use all multipliers to their full accuracy and for the best suppression of noise and disturbances, integrator gains should be made as low as possible provid-

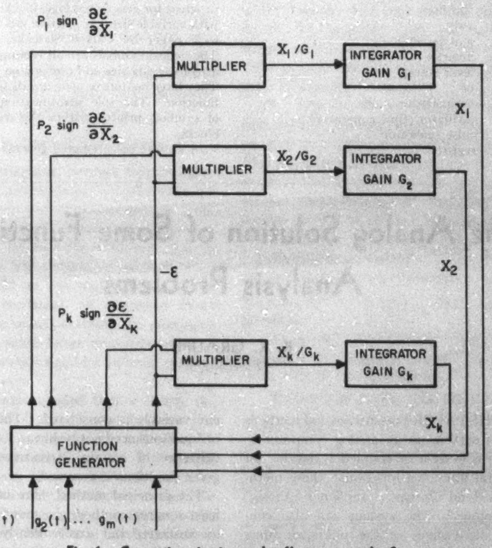

Fig. 1. Computing circuit to solve $f(t, x_1, \dots, x_k)=0$

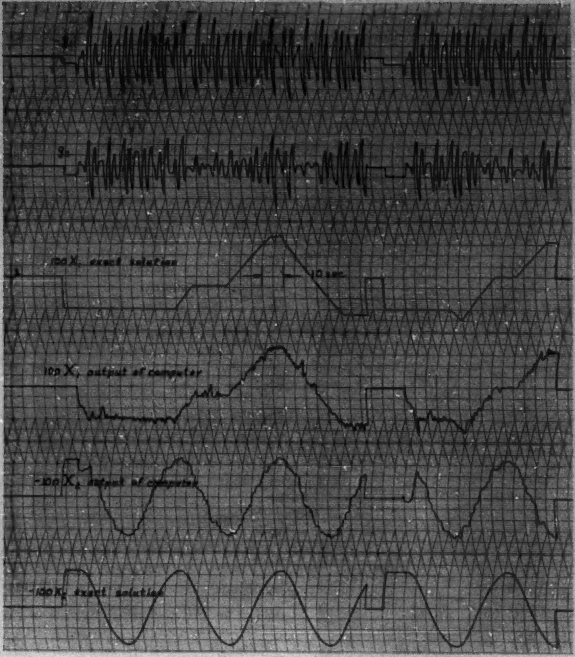

Fig. 2. Solution of $x_1\dot{g}_1+x_2g_1+g_2=0$, $G_1=G_2=1/\text{sec}$, $P_1=P_2=1{,}000$

ing that the multipliers do not overload. To increase the computer speed, and thereby the accuracy of the result, one should increase all P_ν, as long as the computer remains stable. According to condition 4 this procedure will decrease the final error $|e_{\min}|$.

In problem 1 the unknown quantities x_ν were assumed to be constant. In practical problems several parameters may vary slowly with time; then equation 1 does not determine the parameters sharply. Such a problem causes an additional loss of accuracy which cannot be avoided even with the fastest computer using the most accurate components. The following example represents such an ill-determined problem.

AN EXAMPLE OF PROBLEM 1

Fig. 2 is a record of the functions X_1 and X_2 which a computing circuit has put out as solutions of the equation

$$x_1\dot{g}_1+x_2g_1+g_2=0$$

The comparison of X_ν with the exact solutions x_ν demonstrates the accuracy obtained. Two computer runs are reproduced in Fig. 2. From the start of both runs one can read how long it takes for the computer to overcome wrong initial conditions: approximately 6 sec (seconds) or 2 cycles of the average frequency contained in the given functions g_1 and g_2.

This long response time of the computer is characteristic of the kind of problem. If the problem were well defined as, for instance, the one given in Fig. 3, one would obtain a much shorter response time.

PROBLEM 2

A more complex problem is to solve k coupled equations

$$f_\mu(t, x_1, x_2, \ldots x_k)=0 \qquad (6)$$

($\mu=1, 2, \ldots k$) for k unknown parameters or functions of time.

In general, two basically different methods are available to solve problem 2: the first will be called the method of least squares; the second, the determinant method. The first method is mentioned in an abstract by Brown,[2] but it was evidently applied only to linear systems. No description of the method was found. But because for more complex problems the least-squares method needs fewer components than the determinant method, the first method is proposed to solve this problem and the second as an independent check or for use in special problems.

LEAST-SQUARES-METHOD SOLUTION OF PROBLEM 2

It is convenient to abbreviate $e_\mu=f_\mu(t, X_1, X_2, \ldots X_k)$ and $e_{\mu\nu}=\partial e_\mu/\partial X_\nu$. The convergence of the computer output $X_\nu(t)$ to the exact solution $x_\nu(t)$ is obtained by setting

$$\dot{X}_\nu=-G\sum_{\mu=1}^{k} Q_\mu e_\mu e_{\mu\nu} \, (Q_\mu=\text{constant}>0) \qquad (7)$$

G is an integrator gain, chosen as small as possible for best filtering. Q_μ are high gains chosen to produce high speed and accuracy in the computer.

The right side of equation 7 may be considered as the νth component of the negative gradient of

$$\sum_{\mu=1}^{k} Q_\mu e_\mu^2$$

in the space of X_ν. Thus the point $(X_1, \ldots, X_k)$ is following a curve of steepest descent on the surface

$$\sum_{\mu=1}^{k} Q_\mu e_\mu^2$$

until it reaches a minimum.

The least-squares method can also solve problem 1. Then the computing method given for problem 1 includes the least-squares method, since equation 7 results from equation 2 when $P_\nu=Q_1|\partial e/\partial X_\nu|$ and when all G_ν are made equal.

Fig. 3 shows the solution of

$$x_1x_2-g_1(t)=0$$

$$2x_1+3x_2-g_2(t)=0$$

by the least-squares method. From the given functions $g_1(t)$ and $g_2(t)$, the computing circuit finds a solution X_1 and X_2. When the sign of $(3x_2-2x_1)$ changes, the computer can branch off to the other possible solution. In the example shown the computer just does that.

By applying a step change to x_1 or x_2 the response time of the computer was found to be about 0.1 second.

LEAST-MAGNITUDE-METHOD SOLUTION OF PROBLEM 2

The least-magnitude method is closely related to the least-squares method. By setting

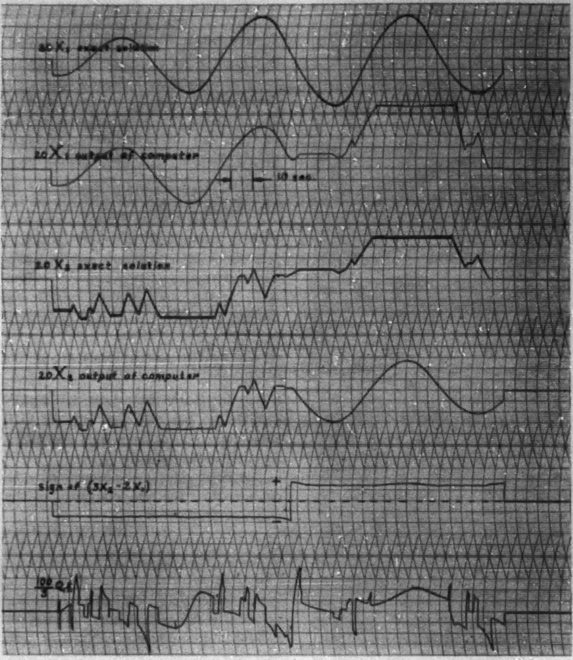

Fig. 3. Solution of $x_1x_2-g_1(t)=0$ $2x_1+3x_2-g_2(t)=0$, $G=1/\text{sec}$, $Q_1=200$, $Q_2=100$

$$\dot{X}_\nu=-G\sum_{\lambda=1}^{k} Q_\lambda\epsilon_{\lambda\nu}\text{ sign }\epsilon_\lambda \tag{8}$$

the point $(X_1, \ldots, X_k)$ will follow a curve of steepest descent on the surface

$$\sum_{\lambda=1}^{k} Q_\lambda|\epsilon_\lambda|$$

until it reaches a minimum. This is simpler than the least-squares method. Instead of k^2 multipliers which are necessary to compute $\dot{X}_\nu$ according to equation 7, only k^2 switches are needed to compute $\dot{X}_\nu$ according to equation 8.

The computing method given for problem 1 includes also the least-magnitude method when both methods are applied to problem 1.

When the set of equations 6 consists of m equations with k unknown parameters and when $m>K$, the problem is overdetermined. By extending the sums in equations 7 and 8 over μ from 1 to m, and by proportioning the Q_μ "justly," all available data can adequately contribute to the solution. Such simple participation of redundant data is not possible in the determinant method which is described in the following.

DETERMINANT-METHOD SOLUTION OF PROBLEM 2

Set

$$\dot{X}_\nu=-G\text{ sign }D\sum_{\lambda=1}^{k} P_\lambda(t)\epsilon_\lambda D_{\lambda\nu} \tag{9}$$

where $P_\lambda(t)$ are arbitrary positive functions of time, G is an integrator gain, chosen as low as possible for best filtering; $P_\lambda(t)$ are high gains chosen to obtain high speed and accuracy of the computer

$$D=\begin{Vmatrix} \epsilon_{11} & \ldots & \epsilon_{1k} \\ \cdot & & \cdot \\ \epsilon_{k1} & & \epsilon_{kk} \end{Vmatrix} \tag{10}$$

and $D_{\mu\nu}$ is defined by

$$D=\sum_{\nu=1}^{k} \epsilon_{\mu\nu}D_{\mu\nu}\text{ (for each }\mu=1, \ldots, k) \tag{11}$$

After integration $\dot{X}_\nu$ is fed back to the function generator. Instead of the sum

$$\sum_{\mu=1}^{k} Q_\mu\epsilon_\mu^2$$

each individual ϵ_μ^2 is minimized as shown in the following proof of convergence:

$$\frac{d\epsilon_\mu}{dt}=\frac{\partial\epsilon_\mu}{\partial t}+\sum_{\nu=1}^{k} \epsilon_{\mu\nu}\dot{X}_\nu$$

$$=\frac{\partial\epsilon_\mu}{\partial t}-G\text{ sign }D\sum_{\lambda=1}^{k}\sum_{\nu=1}^{k} \epsilon_{\mu\nu}D_{\lambda\nu}P_\lambda\epsilon_\lambda$$

According to a theorem on the development of determinants

$$\sum_{\nu=1}^{k} \epsilon_{\mu\nu}D_{\lambda\nu}=\frac{D}{0}\text{ when }\frac{\mu=\lambda}{\mu\neq\lambda}$$

which means that

$$\frac{d\epsilon_\mu}{dt}=\frac{\partial\epsilon_\mu}{\partial t}-GP_\mu|D|\epsilon_\mu \tag{12}$$

If one requires each $P_\mu(t)$ to be so large that

$$\left|\frac{1}{\epsilon_\mu}\frac{\partial\epsilon_\mu}{\partial t}\right|<GP_\mu|D|$$

when

$$|\epsilon_\mu|>|\epsilon_{\min}| \tag{13}$$

then

$$-\frac{1}{\epsilon_\mu}\frac{d\epsilon_\mu}{dt}>0$$

for

$$|\epsilon|>|\epsilon_{\min}|$$

and also

$$-2\epsilon_\mu\frac{d\epsilon_\mu}{dt}=-\frac{d}{dt}(\epsilon_\mu)^2>0 \tag{14}$$

But ϵ_μ^2 can decrease only until it reaches zero. So the determinant method minimizes each ϵ_μ^2 individually. It appears that minimizing each ϵ_μ^2 individually is a safer and more direct way to obtain a solution of equation 6 than minimizing only the one expression

$$\sum_{\mu=1}^{k} Q_\mu\epsilon_\mu^2$$

To save multipliers it is advantageous to set

$$P_\lambda\epsilon_\lambda=\text{constant} \tag{15}$$

where the constant has the same sign as ϵ_λ.

PROBLEM 3

Two equations

$$f_1(t, x_1, x_2, x_3)=0$$
$$f_2(t, x_1, x_2, x_3)=0 \tag{16}$$

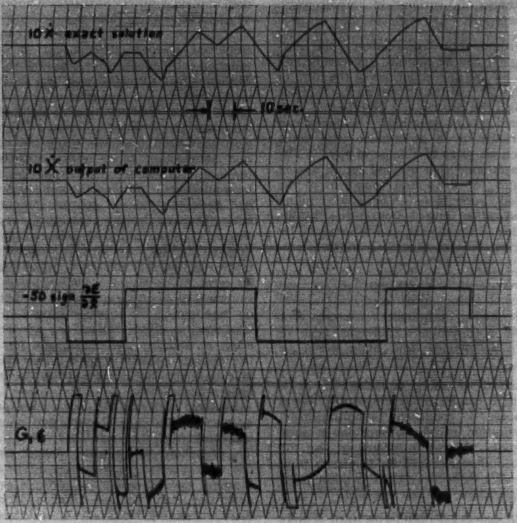

Fig. 4. Solution of $100\,g(t)-0.1x\dot{x}\sin 0.07t+10\dot{x}\cos 0.07t=0$, $G=1/6$ sec, $P=200$

are to be solved for three unknown constants or "slowly" varying parameters x_v. The determinant method of solving this problem rests on equalizing

$$\dot{X}_v=GE_vS \tag{17}$$

where

$$E_1=A_2(\epsilon_1\epsilon_{23}-\epsilon_2\epsilon_{13})+A_3(\epsilon_2\epsilon_{12}-\epsilon_1\epsilon_{22})$$

$$E_2=A_3(\epsilon_1\epsilon_{21}-\epsilon_2\epsilon_{11})+A_1(\epsilon_2\epsilon_{13}-\epsilon_1\epsilon_{23})$$

$$E_3=A_1(\epsilon_1\epsilon_{22}-\epsilon_2\epsilon_{12})+A_2(\epsilon_2\epsilon_{11}-\epsilon_1\epsilon_{21}) \tag{18}$$

$$S=A_1(\epsilon_{12}\epsilon_{23}-\epsilon_{13}\epsilon_{22})+A_2(\epsilon_{13}\epsilon_{21}-\epsilon_{11}\epsilon_{23})+A_3(\epsilon_{11}\epsilon_{22}-\epsilon_{12}\epsilon_{21}) \tag{19}$$

A_v ($v=1, 2, 3$) are three arbitrary functions of time, G is the integrator gain. In contrast the least-magnitude method would require

$$-\dot{X}_v=GQ_1\epsilon_{1v}\text{ sign }\epsilon_1+GQ_2\epsilon_{2v}\text{ sign }\epsilon_2 \tag{8A}$$

Thus for problem 3 the least-squares and the least-magnitude methods are much simpler and generally should be preferred.

The presentation given here is designed for analog computers but is applicable also to digital computers. The latter use will become mandatory when higher accuracy is required.

The procedures described do not change when given and unknown functions depend on more than one independent variable. In this case one can solve the equations by letting one variable run and keeping all others constant.

If the unknown functions appear together with their derivatives, the same methods are applicable. One must then find at first only the highest derivative of each unknown function.

The application of the methods described to differential equations eliminates the need to isolate the highest derivative, which may not always be possible in closed form. Two examples for this kind of problem are solved as shown in in Figs. 4 and 5.

Conclusions

1. Among the four demonstrated computation methods the least-magnitude method should be preferred in general because of its relative simplicity. If only one equation is given, the method given for problem 1 allows more freedom of design, and is therefore simpler and preferable.
2. Nonlinear problems can be solved. However, it may be necessary to feed additional information into the computer which selects, of several possible solutions, the one desired.
3. Two computation methods, the least-squares and the least-magnitude methods, can digest and weigh redundant data, thereby improving the accuracy of the computer. Without using especially quick computer components, a response time of 0.1 sec was obtained. Thus the computing methods shown in this report should be able to find "momentary" quantities continuously while a process is running. It is estimated that the use of redundant data also will decrease the response time of the computer.
4. These methods can solve ordinary differential equations, in which case it is not necessary to isolate the highest derivative.

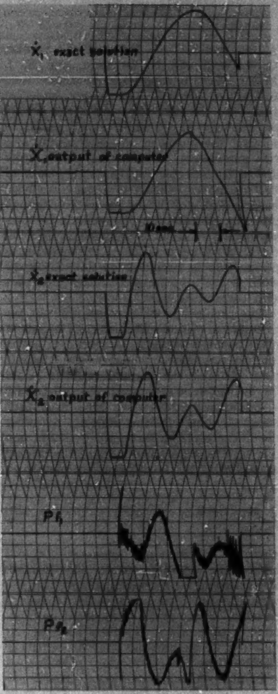

Fig. 5. Solution of $0=g_1(t)+\dot{x}_1\cos 0.06t-0.001x_1\dot{x}_2\sin 0.06t+0.1x_1$, $0=g_2(t)+{}_2\cos 0.06t+0.001x_1\dot{x}_1\sin 0.06t-0.1x_2$ by the determinant method. $G=0.2$/sec, $P_1=P_2=600$

Discussion

A. B. Clymer, T. F. Potts, W. C. Franke, C. R. Walli, G. N. Ornstein, and **B. J. Miller** (North American Aviation, Inc., Columbus, Ohio): The paper deserves study by all concerned with the design or analysis of dynamic experiments, in solving the problem of determining system parameters. Publication of this paper makes it desirable to report the work of the discussers which has been carried on independently of that of the author, though pursuing parallel developments. In presenting its relation to the general problem, together with extensions of the methods, a perspective is provided on Mr. Graupe's work and a step forward in an important area recognized.

One problem form is determining the parameters of systems characterized by one or more ordinary differential equations, given forcing function and dependent variable time histories. A general problem could be couched in mathematical terms, but only a simple case is discussed here, extensions being obvious. In the author's notation, the linear problem discussed is determination of n of k parameters x_ν of the system characterized by the differential equation:

$$\sum_{\nu=1}^{k} x_\nu g_\nu(t)=0 \tag{20}$$

where $n \leq k$, given all functions $g_\nu(t)$ and $k-n$ of the k parameters x_ν. One or more of $g_\nu(t)$ could be forcing functions and the remainder time derivatives of the dependent variable. Some or all of x_ν could be functions of time or g_ν. There is a duality in equation 20 permitting $x_\nu(t)$ to be either unknown coefficients, forcing functions, or some of both, and $g_\nu(t)$ to be accordingly known functions or constants. This class of problems denoted by equation 20 includes the general case of being given incomplete information concerning forcing functions, some information describing the system, and complete system response information, and one is to determine the missing information. An example would be determination of gust and buffet information and some aerodynamic parameters from flight test data.

At any time t, equation 20 is a condition on n unknowns. If the functions $g_\nu(t)$ are given throughout a time interval or at more than n instants, the n unknowns, if constants, are overdetermined. It is the large amount of redundant given information often available which characterizes the problem mathematically and underlies the existence of many distinct approaches.

A convenient procedure is to distinguish open-loop from closed-loop methods. Open-loop methods involve direct calculation of n coefficients from at least n independent conditions of equation 20. Closed-loop involves continuous or intermittent iterative procedures employing some error quantity, as in a servo. Open-loop methods are explicit; closed-loop, implicit.

To appreciate the richness of the field of open-loop methods, each given function can be visualized as $g_\nu(t, \omega)$, a surface plotted against time t, and frequency ω. The input data to the n conditions can be visualized as points or loci obtained by sampling or scanning the surfaces in various ways, such as:

1. Without regarding frequency, the functions $g_\nu(t)$ can be sampled repeatedly and stored for use in n equations of the form of equation 20. If the unknowns $x_\nu(t)$ are not constant, the process can be repeated with staggered sets of equations. Sampling can be periodic or in accordance with some criterion on rates of change of $g_\nu(t)$. The discussers tried this method on an analog computer for $n=3$ and found it to be reasonably successful. A periodic sampling interval Δt is limited from below by ill-condition of the matrix, and from above by resolution considerations for variable coefficients.

2. Short-term averages can be used as samples to reduce error from noise of frequencies higher than those of interest. For variable coefficients, a different type of error is introduced, and little would be gained.

3. Instead of using equation 20 at n instants, it can be differentiated $n-1$ times to obtain n conditions simultaneously. Differentiation introduces error due to noise for rapidly varying functions, or else the matrix is ill-conditioned for slowly varying functions. Either way there is a low practical upper limit on the value of n.

4. The curves $g_\nu(t)$ can be sampled at more than n times, and classical methods of regression analysis, multiple correlation analysis, least squares, etc., applied to obtain n conditions incorporating all of the sampled data. For variable coefficients x_ν, dynamic least squares[1] can be used.

5. It might be possible to sample the functions $g_\nu(t, \omega)$ along the frequency dimension to obtain n or more simultaneous conditions.

Closed-loop methods may be classified according to the error quantity employed. Implicit synthesis[1] uses an error ϵ_1 in the synthesized dependent variable, as do Meissinger,[3] and Margolis and Leondes.[4] Mr. Graupe and the discussers have shown the use of an error ϵ_2 in satisfying equation 20 by tentative values X_ν for the unknowns. Each method utilizes an error ϵ_i in some scheme such as "steepest descent"[5] down an even function of ϵ_i to drive the unknowns toward correct values.

Methods using error ϵ_1 in the dependent variable perforce use also a mathematical system model to synthesize continuously a tentative dependent variable. Margolis and Leondes call this model a "learning model," since in a sense it learns the proper values for coefficients. No explicit learning model is in the methods using error ϵ_2, though the whole circuit could be learning coefficients. The learning concept serves as a bridge to current activity in human learning simulation with digital computer programs, automata, etc.[6]

For one unknown coefficient, methods using dependent variable error ϵ_1 degenerate to implicit synthesis. Interestingly, both the author's and the discussers' investigations used implicit synthesis initially, but led finally to use of error ϵ_2 rather than ϵ_1. Independently of Clymer,[1] others in unpublished work have used implicit synthesis to generate a forcing function. Coincidentally the author and others have used implicit synthesis as their first approach when faced with nuclear reactor problems.

Meissinger, and Margolis and Leondes, employed steepest descent on an even function of dependent variable error ϵ_1. Mathematical formulation of the gradient used involves the concept of parameter sensitivity or perturbation"[7,8] as used in optimization studies.[3] Mr. Graupe's steepest descent methods using the equation satisfaction error ϵ_2 are apparently the first with significant generality to have been published. Earlier, the same principle had been used in fire control computers, analog sine and cosine generating circuits, and other specialized and isolated applications to continuously apportion corrections to two or more quantities contributing to an error. The author's methods may be summarized as continuous steepest descent on functions of the equation error ϵ_2. His least-squares method uses the square of error ϵ_2, and his least-magnitude method the absolute value of error ϵ_2. It is creditable that the chosen demonstration problems are nonlinear.

In these methods the function of error ϵ_2, when plotted against unknowns x_ν, may be visualized as a trough-like hypersurface. The trough rotates in some manner about the answer point as functions $g_\nu(t)$ vary. Steepest descent sends the process point down the side of the instantaneous trough. With adequate gains G_ν, the error decreases to $\epsilon_{\min}$. The process point's velocity component toward the answer point is small; eventually the answer point vicinity is reached. Independently, the discussers observed a 5-second convergence time constant for four unknowns in a linear third-order system.

Convergence rate of steepest descent can be increased by using sampled and held troughs. Various sampling criteria can be used, but periodic sampling is no better than continuous methods. It is conceivable that better performance could be obtained by accumulating products ϵg_ν algebraically for a time Δt to obtain a net correction vector directed at the answer point instead of along the gradient, repeating the cycle periodically or according to some error criterion. Running weighted averages of products ϵg_ν would permit a continuous solution.

Related methods can be derived by considering the equation error ϵ_2 as a sum of terms proportional to functions $g_\nu(t)$, each having a characteristic "signature." Appearance of the signature of a particular $g_\nu(t)$ in the error indicates that the tentative corresponding X_ν is too high. The coefficient could be decreased at a rate proportional to the amount of $g_\nu(t)$ in the error, estimated as some function of ϵg_ν. Other methods could employ both errors (ϵ_1 and ϵ_2) simultaneously or alternately to obtain the best features of both approaches. A blend of Meissinger and Graupe would be steepest descent on the sum of squares (or absolute values) of ϵ_1 and ϵ_2. New methods or variants could be conceived by substituting the concepts of linear programing,[3] steep descent,[5] or dynamic programing,[5] e.g., for steepest descent.

Considering again the class of problems described in conjunction with equation 20, the art of solution seems to deserve the name "analysis of dynamic experiments," to stand alongside the classical art of analysis of statistical experiments. The two arts, united by stochastic process theory or future mathematical developments in spectrostatistics, together with the art of experiment design, constitute a general field that could be termed "design and analysis of experiments." It would be desirable to extend the problem domain to include determination of partial differential equations, integral equations, etc., for systems having distributed parameters.

A sufficient number of distinct methods and formulations have been described to illustrate that the general problem of system parameter determination offers a wealth of research opportunities. Hopefully, readers will be stimulated to seek a unified mathematical description, help evaluate methods, and indicate those more flexible, convenient, rapid, and accurate.

Study areas to be addressed would be restrictions on forcing functions, optimization of forcing functions, methods development from stochastic process theory, restrictions on number and magnitude of linear system parameters to be determined, limitations on applications to nonlinear systems (e.g., time delays), limitations imposed by computer bandwidth, desirable specifications for computers and tape recorders, special problems associated with systems of equations, evaluation of best mathematical areas of application of each method, optimization of doctrine for dynamic experiments to take maximum advantage of method capability, and selection of highest priority areas of application. Mr. Graupe's opinions on some of these questions would be valuable guides to further research.

Kurt K. Graupe: I appreciate the comments of Mr. Clymer and his associates. Their discussion raises questions which I feel cannot be answered immediately. I am aware that the article itself leaves many questions open; e.g., the argument that the steepest descent down a surface must lead to a minimum on the surface is true only for stationary surfaces. On deforming and moving surfaces an additional condition must be fulfilled for the computer output to approach the minimum. This condition will be a mathematical formulation of the idea that the speed of the computer must be greater than the speed of deformation and translation of the error surfaces. Only the fact that examples have been tried which obtained "good" solutions (as good as actual computer components are) gave me the justification to publish this paper.

Quantitative Study of Low-Frequency Hysteresis Loops of Polarized Polycrystalline Barium Titanate

FERROELECTRICS belong to that group of dielectrics which are said to be nonlinear, but a nonlinear dielectric is not necessarily ferroelectric. The statement that a dielectric is nonlinear requires rather careful consideration.[1] If the temperature of a ferroelectric ceramic and also the external pressure on it are maintained constant, and if an electric field is applied which is below the saturation level, then the electric displacement D, or equivalently the polarization P, depends not only on the magnitude of the applied field but also on the past history and state of strain of the material. Linear dielectrics are characterized by the unique function $D(\omega)=\epsilon(\omega)E(\omega)$, which does not hold true for nonlinear dielectrics. This implies that when one is dealing with a nonlinear dielectric: (1) frequencies appear in $P(t)$, or in $D(t)$, which are not present in $E(t)$; and/or (2) if $E_1(t)$ produces $D_1(t)$ and E_2 produces $D_2(t)$, then $A_1E_1(t)+A_2E_2(t)$ does not produce $A_1D_1(t)+A_2D_2(t)$.

The nonlinearity of ferroelectrics is best exhibited, perhaps, by the P versus E hysteresis loops which characterize such materials. Much qualitative and descriptive information concerning these loops is to be found in the literature concerning ferroelectrics. For example, Heywang and co-workers studied the effect of grain size in the ceramic on the shape of hysteresis loops of unpolarized barium titanate ($BaTiO_3$).[2,3] They found that small grain size causes the domain configuration to be more markedly fixed and less responsive to field strength if time is taken into consideration. On long field-free storage of unpolarized polycrystalline samples, a domain configuration having a minimum of free energy results.

With modern facilities moderately accurate quantitative data can be deduced from oscillograms of hysteresis loops. It is the purpose of this paper to present, interpret, and discuss certain quantitative results obtained through the study of the hysteresis loops of polarized $BaTiO_3$ ceramics. Papers now in preparation will deal with the loops of unpolarized ceramics and with specific anomalies inherent in these loops.

Theory

It is of interest to study theoretically the maximum average directed polarization obtainable in a polycrystalline ferroelectric ceramic the domains of which have all possible orientations prior to polarization by an external field. The general case will be considered first.

Imagine a hemisphere of polarized ceramic of radius R and volume V as shown in Fig. 1. Assume that $\mathbf{P}$, the dipole moment per unit volume, is always

Paper 60-1285, recommended by the AIEE Basic Sciences Committee and approved by the AIEE Technical Operations Department for presentation at the AIEE Fall General Meeting, Chicago, Ill., October 9–14, 1960. Manuscript submitted April 8, 1960; made available for printing September 20, 1960.

G. W. MARKS and D. A. HANNA are with the U. S. Navy Electronics Laboratory, San Diego, Calif.

The authors take the opportunity to thank Dr. R. N. Goss and his staff, of the Numerical Analysis Section, for carrying out the computations with the aid of electronic computers; Mrs. Marian Hicks who drafted the figures; Dr. R. D. Redin for helpful suggestions during the course of the work; and the Solar Manufacturing Company of Los Angeles, Calif., who kindly supplied the samples for investigation.

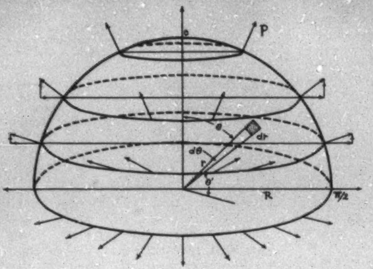

Fig. 1. A theoretical hemisphere of polarized ceramic $BaTiO_3$ of radius R and volume V

oriented in the radial direction, and that it has a constant magnitude and no components $\mathbf{P}_y$ directed opposite to the direction of the original polarizing field. We want to find the average $\bar{P}_y$ for this hemisphere.

Given, then, an element of volume dv in the hemisphere, if r is the radial distance of this element from the center of the hemisphere and θ is the angle this radius makes with a vertical plane

$$dv=(2\pi r\cos\theta)rdrd\theta \tag{1}$$

The vertical component P_y of the polarization vector is

$$\mathbf{P}_y=\mathbf{P}\cos\theta \tag{2}$$

Therefore the average value of $\bar{\mathbf{P}}_y$ for the hemisphere is given by

$$\bar{P}_y=\frac{\int_0^{\pi/2}\int_0^R P\cos\theta(2\pi r\sin\theta)rd\theta dr}{2/3\pi R^3}=P/2 \tag{3}$$

This result states that if the polarization vector is assumed to be constant in magnitude, then the average polarization normal to the basal plane of the hemisphere is equal to half this constant value.

Actually the magnitude of the vector P varies with direction and can be expected to have such a gaussian distribution that the maximum occurs in the direction of the original polarizing field. This distribution will depend on the degree of polarization, grain size, aging, etc. Suppose that P varies with direction in this manner:

$$P=P_Me^{-B\theta^2} \tag{4}$$

where P_M is the maximum dipole moment per unit volume and β is a constant. By way of illustration let $\beta=1$. Then equation 3 becomes

$$\bar{P}_y=\frac{3P_M}{R^3}\int_0^{\pi/2}\int_0^R e^{-\theta^2}\sin\theta \cos\theta d\theta r^2dr \tag{5}$$

$$=P_M\int_0^{\pi/2}e^{-\theta^2}\sin\theta\cos\theta d\theta \tag{6}$$

This integral was evaluated by plotting the integrand over the range from 0 to $\pi/2$ and determining the area. The result is $\bar{P}_y=0.26\,P_M$. The constant β determines the spread of the exponential curve, and so $\bar{P}_y$ can be properly evaluated only when β is estimated from experimental observations.

In tetragonal $BaTiO_3$ we must take into account the fact that any one of the three orthogonal crystallographic axes can become the polar axis. This means that the direction of polarization is limited to an angle of less than 90 degrees after the application of a d-c field of sufficient magnitude to orient the polar axes of all domains. The polar directions of the domains tend to take that crystallographic axis as polar axis which most nearly approximates the applied field direction.

The axial ratio for tetragonal $BaTiO_3$ is 1 to 1.01. Hence the angle between a diagonal of a unit cell and the polar axis is 54.5 degrees. This is the maximum angle that the polar axis of a domain in ceramic $BaTiO_3$ can make with the field direction providing that the polarizing field was of sufficient magnitude. We must now modify equation 3. It is seen that

$$\bar{P}_y=\frac{\int_0^{\theta^0}\int_0^R 2\pi Pr^2\sin\theta\cos\theta drd\theta}{\int_0^{\theta_0}\int_0^R 2\pi r^2\sin\theta d\theta} \tag{3A}$$

where $\theta_0=54.5$ degrees:

$$\bar{P}_y=0.79P$$

Thus the maximum possible value of the average field-directed spontaneous polarization is nearly 0.8 of that for a single domain crystal. However, it is always less than this because of incomplete orientation, relaxation, and aging after removal of the field.

Experimental Considerations

Disks of technical grade $BaTiO_3$ and $BaTiO_3$ with additives which had been manufactured under identical conditions for experimental work by a gas-firing process, machined to a diameter of one inch and a thickness of 100 mils, and provided with fired-on-silver electrodes, were polarized at approximately 45 volts per mil in hot silicone oil for about 30 minutes. Prior to use, these disks were aged at 80 C (degrees centigrade) for 24 hours and were then shelf-aged for a year. Compositions and average densities are given in Table I. Hereafter, identification of disks under investigation will be made by reference to (a), (b), (c), and (d) of this table. The calculated porosity of the (a) ceramics was 8.3%.

For the display of hysteresis loops the previously described circuit, utilizing capacitance voltage dividers, was employed at a frequency of 60 cps (cycles per second).[4] The output of this circuit was connected to the vertical and horizontal sweeps of a Hewlett Packard model *130A* oscilloscope. The rms values of these voltages were measured for calibration purposes with vacuum-tube voltmeters. Oscillograms were recorded by means of a Dumont oscillograph-record camera, type *297*, employing the Polaroid-Land photographic process. Enlargements of the oscillograms of about four diameters were made on glossy photographic paper. Transparent co-ordinate paper was then mounted over these enlargements and the necessary data read off. Finally, these data were converted to the desired units.

Samples for investigation were lightly clamped between two copper plates 1/4 inch thick, which served as high-voltage electrodes and aided in the rapid transmission of heat away from the sample. The unit was immersed in silicon transformer oil contained in a brass beaker. The latter was then placed in a constant temperature oil bath maintained at 25 C.

Polarized $BaTiO_3$ ceramics rise in temperature on the application of alternating fields of high strength because of the losses occurring and the low heat conductivity. In time, this temperature rise

results in depolarization of the sample. The copper electrodes used tend to minimize the effect. Further to ensure accurate results, readings were made and oscillograms were taken rapidly, usually in less than 15 seconds. By following this procedure only moderate warming of the samples was observed. Coupling coefficients of the samples were determined from admittance data before and after each experiment; representative results are contained in Table I. Essentially no change was observed. Thus, results were not altered by changes in the state of polarization during an experiment.

Meter readings of voltages applied to the horizontal and vertical plates of the oscilloscope were assumed to be rms values. This is not strictly correct, particularly for voltages referring to polarization or current as the distortion of the waveform is then greater. These distortions will be discussed later. The over-all accuracy of the results deduced from oscillograms was estimated to be ±10%.

Hysteresis Loops

Hysteresis loops at saturation showing the actual variation of polarization with field strength as deduced from the corresponding oscillograms for the four different compositions are presented in Fig. 2. The loop for ceramic (d) is shaped much like that for a single domain crystal of $BaTiO_3$. With increase in concentration of additive the remanent polarization P_r decreases somewhat and the coercive field strength E_c increases, as shown in Table II.

An anomalous loop or jog sometimes appears in the linear portion of a saturated P(or D) versus E loop for a polarized ceramic, i.e., when the direction of the field is in the direction of polarization but is declining in magnitude. Such a loop is observed in the oscillograms of Fig. 3(A). It first makes its appearance at a field strength of about 7 kv/cm (kv per centimeter). However, on the addition of lead titanate ($PbTiO_3$) this voltage becomes higher; for ceramic (d) it was above 16 kv/cm. With increase in maximum field strength applied to any given ceramic the position of this loop of the P versus E diagram moves out to higher voltages.

In an effort to find the source of this anomaly the operation of the display circuit was checked by replacing the ceramic with a high-voltage mica capacitor having a low dissipation factor. The oscillogram then observed was a straight line with positive slope when the vertical gain of the oscilloscope was zero. Voltage output to both the horizontal and vertical deflection plates of the oscilloscope was found to vary sinusoidally with time. Moderate changes in circuit constants other than the constant of the ceramic did not remove this loop. It must be concluded that this behavior is an inherent characteristic of the ceramic in conjunction with the described circuit.

As may be expected, when the barium titanate capacitor is in the circuit, the voltage output to the oscilloscope plates is not a fundamental sine wave. Examples are given in Figs. 3(A) through (D) for the described polarized ceramics. These figures show the variation of field strength and of polarization with fractional time as deduced from the corresponding oscillograms. The deviation from a pure sine wave is much greater for the polarization-versus-time curves. The anomalous loop occurring in the hysteresis loop now appears as the humps a and a'. The appearance of the hump in the field-versus-time curve as the field declines is equivalent to charging a condenser through a resistance when the declining field reaches a certain value, then adding the curve showing the variation of field strengths versus time on the condenser to the sine wave of the field applied to the ceramic. Perhaps a sudden switching of domains occurs in the ceramic with release of charge. The oscillograms for ceramics (a), (b), and (c) more nearly resemble each other than they do those for ceramic (d). For the latter the humps a and a' are less marked, and the polarization is about one-tenth that for the sample without additives.

It was of interest to make a Fourier analysis of these curves; this can be done readily by the use of electronic computers. Consider the equation

$$f_m(t/T)=\frac{A_0}{2}+\sum_{n=1}^{N} A_n \cos\left(\frac{2\pi mn}{M}\right)+\sum_{n=1}^{N} B_n \sin\left(\frac{2\pi mn}{M}\right) \qquad (7)$$

where

$$A_0=\frac{1}{M}\sum_{m=1}^{M} y_m$$

$$A_n=\frac{2}{M}\sum_{m=1}^{M} y_m \cos\left(\frac{2\pi mn}{M}\right)$$

and

$$B_n=\frac{2}{M}\sum_{m=1}^{M} y_m \sin\left(\frac{2\pi mn}{M}\right)$$

$A_0/2$ is the d-c component, and y_m refers to the magnitude of the polarization or of the field strength, as the case may be, at the fractional time t/T, where T is the period. For this work 100 ($=M$) equally spaced readings were taken from each respective curve in the range $t/T=0$ to 1. Thus $m=1, 2, 3, \ldots 100$ ($=M$) and $n=1, 2, 3, \ldots 50$ ($=N=M/2$). Partial

C—4% $PbTiO_3$. D—12% $PbTiO_3$+8% $CaTiO_3$; pure sine waves (dashed curves) introduced for comparison

results of the computations are presented in Table III. A_n and B_n are the Fourier coefficients. If u is the column number and v is the row number in this table, then the coefficient number $n = u + (v-1)5$.

An examination of Table III shows that in all cases the d-c component was quite small. The variation of the field strength with time is largely represented by those frequencies having coefficients in the first row, whereas the variation of the polarization is primarily represented by frequencies having coefficients in the first and second rows.

Energy Loss

The area enclosed by a ferroelectric hysteresis loop represents energy loss per cycle. This loss depends upon the chemical composition and domain structure of the material, and on the temperature, pressure, and frequency of the applied field. In a polarized ferroelectric ceramic the loss occurs almost entirely when the direction of the applied field is opposite to the direction in which the ceramic was polarized.

In Fig. 4 are shown plots of energy loss in calories per gram per cycle versus maximum field strength in kv/cm for the polarized ceramics previously discussed. These losses were calculated from calibration data and planimeter measurements of the area of the loops on enlarged oscillograms. It is observed from the figure that at low maximum field strengths the losses are negligible and that there is a field strength E_0, above which the losses rise rapidly. Above E_0 it was found that the empirical expression

$$l = a(E_m - E_0)^2 \tag{8}$$

satisfactorily represents the experimental results. In this equation l is the loss in calories per gram per cycle, E_m is the maximum field strength and a and E_0 are constants. E_0 increases with increase in added percentage of $PbTiO_3$. Deviation from the empirical curve occurs when saturation sets in, for thereafter the polarization varies linearly with field strength as for an ordinary dielectric. Constants E_0 and a for different compositions are given in Table IV. Since energy storage in an ordinary linear dielectric varies as E^2, perhaps it is to be expected that the losses in a ferroelectric also would vary as E^2.

Differential Permittivity

The permittivity of $BaTiO_3$ varies considerably with electrical field strength, temperature, and mechanical stress. Among the properties with which we should be concerned in our discussion of hysteresis loops is the differential permittivity ϵ_d. This is given by the relation $\epsilon_d = 1 + 4\pi\eta_d$; $\eta_d = (\partial P/\partial E)$ is defined as the differential susceptibility at any point on the virgin curve or on the hysteresis loop for a ferroelectric single crystal, a polarized or an unpolarized ferroelectric ceramic.[6] The η_d is written in partial form because it is dependent on temperature, frequency, field strength, mechanical strain, chemical composition, and the previous history of the ferroelectric material. In this work the virgin curve was not recorded. Only the differential permittivity determined from the loop for polarized ceramics will be discussed. The η_d is high for $BaTiO_3$, so that within the limits of experimental error $\epsilon_d = 4\pi(\partial P/\partial E)$.

Studies were made of the variation of differential permittivity with field strength at increasing maximum field strengths for

ceramics (a), (c), and (d). Differential permittivities were determined by measuring the angle of slope at points on a given hysteresis loop, then making the necessary calculations based on the calibration of the oscillogram; for results see Figs. 5 through 7. Inserts of the corresponding oscillograms are enclosed with each graph. In all cases the direction of rising positive field and the direction of polarization are the same in the first quadrant of the oscillogram. Differential permittivities are always positive in sign.

These curves are representative rather than absolute for, in general, no two ceramics which are identical in size and composition yield precisely the same oscillograms. The degree of polarization, represented by the coupling coefficient, is seldom exactly the same for two samples from the same lot. In some cases duplicate studies were made, but marked variations were not observed. However, the results given are not mean determinations but are, in each case, those for a single disk.

Some interesting deductions can be made from an examination of these curves which show the rate of change of polarization with field strength. Even at relatively low maximum field strengths the deviation from the linearity which characterizes ordinary low-loss dielectrics is more apparent than is indicated by the original oscillograms; see curve *A* in Figs. 5 through 7. Linearity, of course, often occurs when the direction of the field is in the direction of polarization. Although this portion of some of the oscillograms is not strictly linear, it has been so interpreted largely because of the inherent limitations in obtaining data from oscillograms; see the inserted oscillograms of Figs. 5 through 7.

All these curves are similar in shape. Choose any representative curve (e.g., *E*, Fig. 5) and consider the differential permittivity corresponding to maximum negative field strength. As the field declines negatively the differential permittivity rises to a peak *a* where $(\partial\epsilon_d/\partial E)=0$. It is found that with increase in the maximum applied field this peak rises in magnitude rather slowly as saturation sets in. An S-shaped curve is the result, as shown in Fig. 8. With increase in maximum applied field the position of this peak moves closer to the axis of ordinates; see Table V. After peak *a* has been reached, the differential permittivity declines rapidly and nearly linearly to the constant value ϵ_{d1} which describes

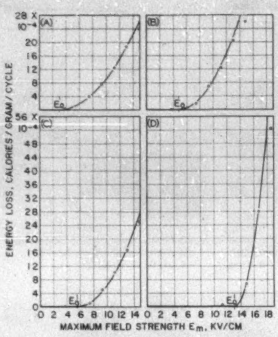

Fig. 4. Dependence of energy loss in calories/gram/cycle on maximum field strength in kv/cm for $BaTiO_3$ ceramics. Additives are A—None. B—2% $PbTiO_3$. C—4% $PbTiO_3$. D—12% $PbTiO_3$+8% $CaTiO_3$. Experimental data indicated by plotted points. Curves represent equation $l=a\ (E_m-E_0)^2$

the polarized ceramic. For well-polarized samples ϵ_{d1} commences at or very near zero field and then remains essentially constant to maximum positive field strength. On decrease of positive field ϵ_{d1} remains about the same until reversal of field occurs, whereafter there is sometimes a decline to a small minimum at low negative field strength, e.g., see curve *D*, Fig. 5(A). The differential permittivity then rises with increase in the negative field, and at higher field strengths reaches a maximum value (peak *b*) before it commences to decline to the tip of the loop. It finally returns to the original value and the cycle is repeated. Also at peak *b* and minimum *c*, $(\partial\epsilon_d/\partial E)=0$. The characteristic differential permittivity ϵ_{d1} rises a little in magnitude with increase in maximum applied field; see Table V.

It is observed in all these graphs that there is a point where the portion of the curve for rising negative field strength intersects that for declining negative field strength. This corresponds to opposite points on the hysteresis loop where the slopes are the same. The differential permittivity at this point of intersection will be designed as ϵ_{d2}. With increase in maximum negative field ϵ_{d2} increases; see Table V.

Normal Permittivity

The normal or over-all permittivity ϵ_n is defined as $\epsilon_n=1+4\pi\eta$ where $\eta=P/E$. In this expression *P* is the polarization observed at any point on a hysteresis loop for a stated field strength *E*. Normal

D	18.56	0.7	−12.4	1.6

permittivities for saturated loops were determined from data representing the curves of Fig. 2. Results for the four different compositions are plotted in Fig. 9.

Let us examine these curves. They are much the same for ceramics (a), (b), and (c). Except at field strengths in the range −1 to +1 kv/cm, ϵ_n ranges from about $0.9^{7}6$ to $1.0^{7}5$. The linear portion of the hysteresis loop where saturation occurs yields, of course, a hyperbolic variation of normal permittivity with field strength. At negative field strengths two branches are obtained: branch *a* corresponding to the upper portion of the hysteresis loop *a* (Fig. 9) and branch *b* corresponding to the lower portion of the hysteresis loop *b*. Both branches approach an ϵ_n of 0 at very low field strengths. Curves *b* have a maximum which lies between values of ϵ_n of $1.0^{7}10$ to $1.0^{7}13$ at −4 to −6 kv/cm.

Current Density Versus Field Strength Diagrams

If the capacitor in series with the ferroelectric sample in the circuit for the display of hysteresis loops is replaced by a resistor, then the figure observed on the oscillograph screen is one in which the abscissa is proportional to the applied field and the ordinate proportional to the current in the ferroelectric.[6] Then, one can study the variation of current density *J* with field strength *E*. For this work the 7.2-μf (microfarad) capacitor of the display circuit was replaced with a 970-ohm noninductive resistor.

The (*J*, *E*) diagram for an ordinary linear dielectric, when a sinusoidal potential is applied, is an ellipse. If, during the cycle, nonlinear polarization changes occur in a dielectric, then changes in permittivity result with consequent changes in impedance so that the diagram is no longer such a curve. When the average permittivity falls to a minimum the current rises to a maximum. The diagram for an unpolarized ceramic is centrosymmetrical about the origin, but that for a polarized sample is not.[3]

Oscillograms were taken at increasing maximum potentials up to saturation for the described ceramic disks. Current density *J* in amp/cm² (amperes/cm²) versus field strength *E* in kv/cm were deduced therefrom. Representative data for a $BaTiO_3$ disk containing no additives are plotted in Fig. 10. It is seen that at a low maximum field strength of 0.745 kv/cm the resulting (*J*, *E*) diagram approximates the ellipse

$$\frac{E^2}{(0.745)^2}+\frac{J^2}{(0.40\times10^{-4})^2}=1 \qquad (9)$$

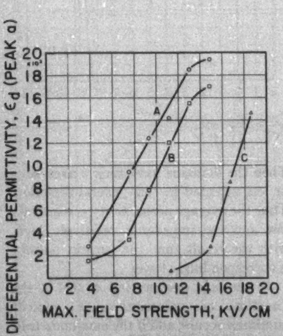

Fig. 8. Dependence of maximum differential permittivity (peak a) on field strength for $BaTiO_3$. Additives as follows: A—$BaTiO_3$, no additive. B—4% $PbTiO_3$. C—12% $PbTiO_3$ + 8% $CaTiO_3$

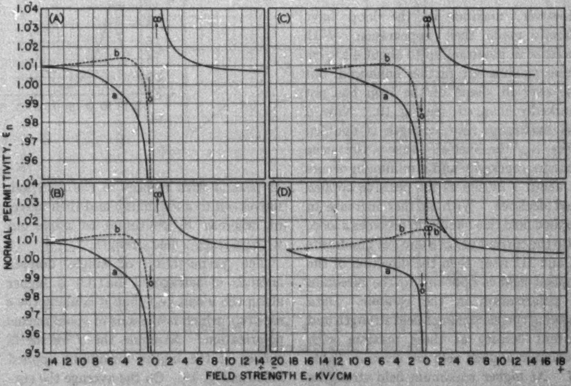

Fig. 9. Dependence of normal permittivity ϵ_n on field strength E in kv/cm. Additives as follows: A—$BaTiO_3$, no additive. B—2% $PbTiO_3$. C—4% $PbTiO_3$. D—12% $PbTiO_3$ + 8% $CaTiO_3$

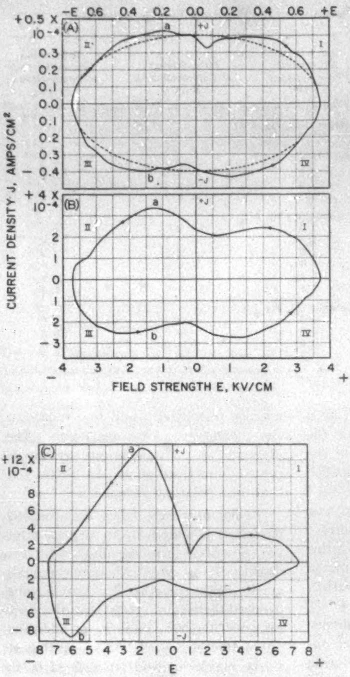

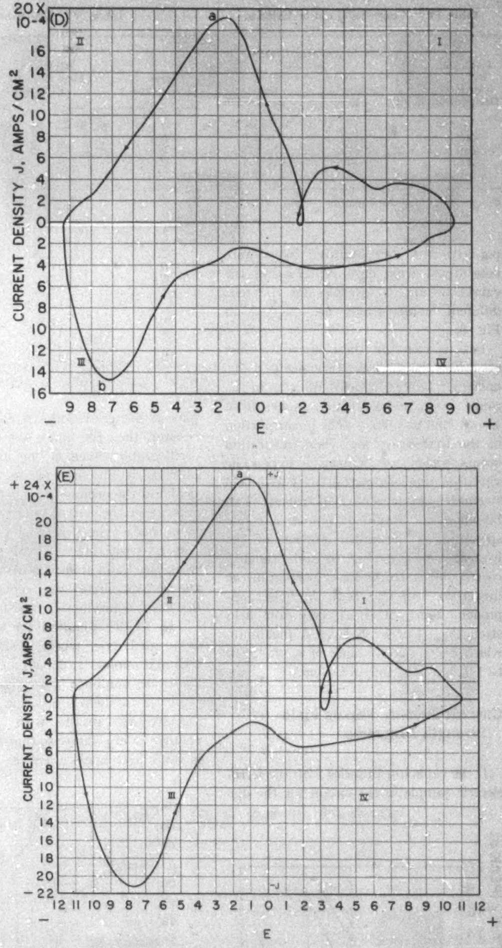

Fig. 10. Variation of current density J in amp/cm² with field strength E in kv/cm for increasing maximum field strength as follows: A—0.745. B—3.72. C—7.45. D—9.20. E—11.2

However, maxima in the loop have already made their appearance. With increase in potential up to about 4 kv/cm these maxima are further enhanced, but the over-all shape of the loop has not markedly changed; see Fig. 10. Now, if the maximum field strength is doubled (Fig. 10), the over-all shape of the curve changes markedly and a minimum occurs at about 1 kv/cm as the positive applied field declines. With further increase in applied field this minimum becomes a loop. Also the current peaks *a* and *b* in quadrants II and III rise; then the direction of the applied field is opposite to the direction of polarization in the ceramic. Data showing the variation of field strength and current density at these maxima with maximum applied field are given in Table VI. At higher maximum field strengths the current densities at these peaks, J_a and J_b respectively, change linearly with E_M. As seen by Table VI, the position of peak *a* with respect to the field axis moves out to a maximum and then moves in, whereas E_b continues to move out with increasing field strength.

The permittivity of single domain crystals of tetragonal $BaTiO_3$ is higher along the *a* axis (ϵ_a) than it is along the *c* axis (ϵ_c), which is the axis of spontaneous polarization.[7] Examine the *J* versus *E* curves at the higher maximum applied fields in Fig. 10. On the average the current density is lower when the direction of the field is in the direction of polarization of the ceramic (quadrants I and IV). Then the domains have their *c* axes more or less oriented in this general direction. Thus the average permittivity is relatively low and the impedance relatively high, with the result that the current density is correspondingly lower.

As the field declines but is still in the direction of polarization, a current minimum occurs, and if the maximum field strength has been sufficiently high this minimum results in the formation of a small anomalous loop as previously pointed out. The loop corresponds to the regions *a* and *a′* of the field-versus-time

Table VI. Variation of Current Density and Field Strength

Maximum Applied Field E_M, Kv/Cm	Peaks, Fig. 10

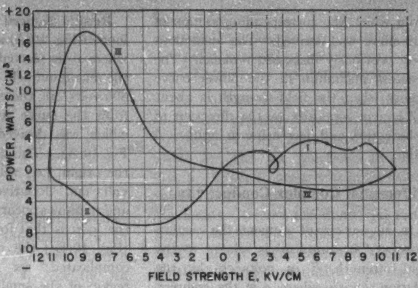
7.45	−1.75	13.2	−6.1	8.80
9.20	−1.60	19.1	−7.2	14.7
11.2	−1.10	24.5	−7.7	21.2

Fig. 11. Energy storage and return as derived from Fig. 10(E) for a polarized $BaTiO_3$ capacitor with no additives



and polarization-versus-time curves respectively of Figs. 3(A) through (C). The loop arises gradually with increase in field strength and first appears as a minimum in the curve. Only a point of inflection is observed in the field strength versus time curve. Although the applied field is declining, the resultant field of the ceramic falls and then rises again with time; see Fig. 3(A). In the course of the anomalous loop the current declines to zero then rises to a maximum in the opposite direction and again declines to zero, after which it continues to rise positively with declining field strength; see Fig. 10. The size and abscissas of this loop increase with increase in maximum field strength, which shows it to be time-dependent.

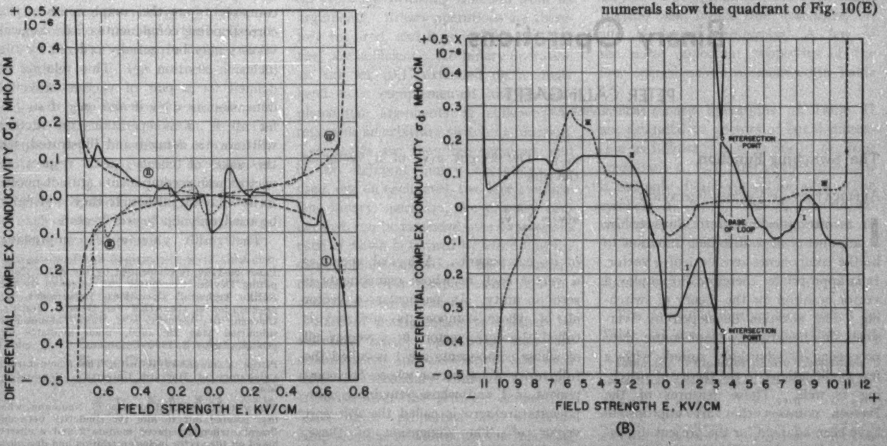
The explanation for the occurrence of this loop probably lies in the appearance of charge and its change with time and field strength at domain boundaries. At the contact surfaces of two arbitrarily oriented domains the limitations concerning the continuity of the normal components of electric displacement D_h are not met, so a surface charge must appear at the interface. Consider the relationship for the charge density between two media across which a current J_n is flowing:

$$\rho_s = J_n\left(\frac{\epsilon_1}{\sigma_1} - \frac{\epsilon_2}{\sigma_2}\right) \qquad (10)$$

where ϵ_1, ϵ_2 and σ_1, σ_2 are the permittivities and conductivities respectively of the two media.[8] The permittivity of ferroelectrics is not only anisotropic but also is dependent on field strength. If two domains are rather differently oriented with respect to the field, then ϵ_1 and ϵ_2 will differ with respect to this field and will change with it, however, often with a time lag and with growth and decline of the domains. The σ_1 and σ_2 would also vary somewhat with field strength, but this effect can be expected to be quite secondary to the permittivity change. This discussion refers, of course, to current through the media. The d-c component is small. However, the magnitude of the alternating current is dependent on the permittivities and accumulated charge.

When $\epsilon_1/\sigma_1 = \epsilon_2/\sigma_2$, the charge between the boundaries of the media drops to zero. When $\epsilon_1/\sigma_1 > \epsilon_2/\sigma_2$, then ρ_s/J_n is positive, whereas when $\epsilon_1/\sigma_1 < \epsilon_2/\sigma_2$, it is negative. Statistically the over-all charge density at the interfaces changes, with the result that there is a change in internal field and consequently in current density.

The rate of energy storage and return in watts per cubic cm versus field strength in kv/cm for a polarized $BaTiO_3$ capacitor (with no additives) under saturated conditions as derived from Fig. 10(E) is shown in Fig. 11. Roman numerals show the quadrant of Fig. 10(E)



(A) (B)

Fig. 12. Variation of differential complex permittivity in mhos/cm with field strength in kv/cm for $BaTiO_3$ disk. A—Dash-dot curve refers to ellipse of Fig. 10(A) from which it was derived; roman numerals refer to quadrant numbers of Fig. 10(A). B—Intersection point is that of loop in Fig. 10(E); roman numerals refer to quadrant numbers of Fig. 10(E)

from which the corresponding section of the curve was derived. The anomalous loop previously discussed remains. The greatest maximum in the power curve occurs when the field strength is about 8.7 kv/cm, opposite to the direction of polarization and decreasing in numerical value.

Differential Complex Conductivity

In an a-c circuit element the current density J in amp/cm^2 is related to the field strength E in volts/cm by the relation $J=\sigma E$, where σ is the complex conductivity in mhos/cm. Since a polarized $BaTiO_3$ ceramic condenser is a nonlinear circuit element, σ varies with E. The σ can be determined at any point on the J versus E loop. Because the dissipation factor of these condensers is quite small, the complex conductivity is largely imaginary.

The slope at any point on the J-versus-E loop is the rate of change of the current density with respect to the field at some particular value of the rising or declining field; thus $(dJ/dE)=\sigma_d$. The σ_d can be defined as the differential complex conductivity.

Results deduced from the low-voltage loop of Fig. 10(A) are shown in Fig. 12(A) where σ_d is plotted versus E. Although the maximum field strength was less than 800 volts/cm, there is a marked deviation from the curve for a linear condenser which was derived from the ellipse of Fig. 10(A). This deviation is largest near the origin, i.e., within a range of ±100 volts/cm. Relatively marked maxima and minima appear in this region. When the loop is that for a saturated ceramic [Fig. 10(E)] the derived curve is very complicated; see Fig. 12(B). In the region of the small anomalous loop the change of current with potential is extremely rapid.

For portions of the loop lying in quadrants II and IV of Fig. 10(E) σ_d varies only slightly from a constant value except in the neighborhood of the origin and, of course, at maximum field strengths. These results again are to be ascribed to change of domain configuration and redistribution and change of charge between domain walls with change in field. There is a time lag between field and response. The response, in part at least, is probably discontinuous and can be imagined to be a sort of Barkhausen effect as observed for single crystals of $BaTiO_3$ by de Bretteville.[9] The statistical mean of the discontinuities for the many domains appears as a continuous change.

Switching Function Canonical Forms Based on Commutative and Associative Binary Operations

PETER CALINGAERT
NONMEMBER AIEE

The Switching Function

Application of Vector Notation

It is often convenient to consider the arguments of a switching function to be the components zero or 1 of a vector. It is appropriate, therefore, to employ a vector notation for the theory of switching. The notation developed by Iverson[1] for the study of automatic data processing is admirably suited, with a few modifications, to the theory of switching as well. Those features of the Iverson notation that are appropriate have been adapted for the present discussion, and are set forth below.

The dimension $\nu(\mathbf{v})$ of a vector $\mathbf{v}$ is the number of its components $\mathbf{v}_0, \mathbf{v}_1, \ldots, \mathbf{v}_{\nu-1}$. The weight $\sigma(\mathbf{v})$ of a vector is the sum

$$\sigma(\mathbf{v})=\sum_{k=0}^{\nu-1} \mathbf{v}_k$$

of its components. A logical vector is a vector each of whose components is zero or unity. In particular, a vector all of whose components are zero is called the zero vector $\mathbf{0}$; a vector all of whose components are 1 is called the full vector $\boldsymbol{\epsilon}$; a vector whose kth component is 1 and whose remaining components are zero is called the kth unit vector $\boldsymbol{\epsilon}^k$. The dimension of these, as of all other vectors, will be stated specifically only if not clear from the context.

Each member of the set (0,1) is the complement of the other. The complement of a component $\mathbf{v}_k$ of a logical vector is denoted $\bar{\mathbf{v}}_k$. The complement $\bar{\mathbf{v}}$ of a logical vector $\mathbf{v}$ is the vector whose components are the complements of the corresponding components of $\mathbf{v}$. Logical vectors may be partially ordered by the inclusion relation $\geq$. This relation is defined for a pair of vectors of equal dimension as $\mathbf{u}\geq\mathbf{v}$ if and only if $\mathbf{u}_k\geq\mathbf{v}_k$ for all k. Two operations on vectors will now be defined and illustrated, for the sake of clarity, with respect to vectors whose components are not necessarily 0 or 1, although they will later be used only on logical vectors.

The result $\mathbf{y}=\mathbf{u}/\mathbf{v}$ of compressing

Paper 60-1199, recommended by the AIEE Computing Devices Committee and approved by the AIEE Technical Operations Department for presentation at the AIEE Fall General Meeting, Chicago, Ill., October 9–14, 1960. Manuscript submitted May 25, 1960; made available for printing August 3, 1960.

Peter Calingaert is with The Computation Laboratory of Harvard University, Cambridge, Mass.

The writer is indebted to Peter G. Neumann, who first pointed out to him the similarity between Pascal's triangle reduced modulo 2 and a chart[2] based on the vector inclusion relation and designed for the detection of monotonicity in switching functions. The advice of Kenneth E. Iverson, Warren L. Semon, and Martin Cohn is gratefully acknowledged.

Table I. Switching Functions of Two Arguments

j	$\mathbf{b}^j$	x_0	x_1	K: 0	1	2	3	4	5	6	7	8	9	10	11	12	13	14	15
0	00	0	0	0	1	0	1	0	1	0	1	0	1	0	1	0	1	0	1
1	01	0	1	0	0	1	1	0	0	1	1	0	0	1	1	0	0	1	1
2	10	1	0	0	0	0	0	1	1	1	1	0	0	0	0	1	1	1	1
3	11	1	1	0	0	0	0	0	0	0	0	1	1	1	1	1	1	1	1

the arbitrary vector $\mathbf{v}$ by the logical vector $\mathbf{u}$ of the same dimension is the vector obtained from $\mathbf{v}$ by suppressing $\mathbf{v}_k$ if and only if $\mathbf{u}_k=0$. It follows that $\nu(\mathbf{y})=\sigma(\mathbf{u})$. For example

$$\mathbf{v}=(S,T,A,R,K) \qquad \nu=5$$

$$\mathbf{u}=(0,1,1,1,0) \qquad \nu=5 \quad \sigma=3$$

$$\mathbf{y}=\mathbf{u}/\mathbf{v}=(T,A,R) \qquad \nu=3$$

The result $\mathbf{w}=\left|\mathbf{t},\mathbf{u},\mathbf{v}\right|$ of meshing the arbitrary vectors $\mathbf{t}$ and $\mathbf{v}$ on the logical vector $\mathbf{u}$ is defined implicitly as the unique vector $\mathbf{w}$ such that $\bar{\mathbf{u}}/\mathbf{w}=\mathbf{t}$ and $\mathbf{u}/\mathbf{w}=\mathbf{v}$. The component $\mathbf{w}_k$ is selected from $\mathbf{t}$ or $\mathbf{v}$ according as $\mathbf{u}_k$ is 0 or 1. The operation is defined only for $\nu(\mathbf{t})=\sigma(\bar{\mathbf{u}})$ and $\nu(\mathbf{v})=\sigma(\mathbf{u})$, and it follows that $\nu(\mathbf{w})=\nu(\mathbf{t})+\nu(\mathbf{v})=\sigma(\bar{\mathbf{u}})+\sigma(\mathbf{u})=\nu(\mathbf{u})$. For example

$$\mathbf{t}=(A,A,A) \qquad \nu=3$$

$$\mathbf{v}=(N,G,R,M) \qquad \nu=4$$

$$\mathbf{u}=(0,1,0,1,1,0,1) \qquad \nu=7 \quad \sigma=4$$

$$\mathbf{w}=\left|\mathbf{t},\mathbf{u},\mathbf{v}\right|=(A,N,A,G,R,A,M) \qquad \nu=7 \|$$

The vector $\mathbf{b}^j$ of dimension ν is the vector whose components are the coefficients of the ν-digit base 2 representation of the nonnegative integer j, taken in natural order, so that $\mathbf{b}_k{}^j$ is the coefficient of $2^{\nu-1-k}$. The vector is defined only for $\nu \geq \log_2(j+1)$. For example, if $\nu=6$, $\mathbf{b}^{26}=(0,1,1,0,1,0)$.

A switching function of n arguments may be defined as a function from the argument set of 2^n vectors $\mathbf{x}$ of n components $\mathbf{x}_0, \ldots, \mathbf{x}_{n-1}$ each 0 or 1, to the value set (0,1). A switching function is uniquely specified by listing its value $F(\mathbf{x})$ for each of the 2^n sets of values, or configurations, of its arguments. The jth configuration of the arguments $\mathbf{x}$ is that for which the argument $\mathbf{x}_k$ is assigned the value $\mathbf{b}_k{}^j$, i.e., $\mathbf{x}=\mathbf{b}^j$. If $\mathbf{f}_j$ is the value $F(\mathbf{b}^j)$ for the jth configuration, then the vector $\mathbf{f}$ of dimension 2^n uniquely specifies the function. The complement $\bar{F}(\mathbf{x})$ of the switching function $F(\mathbf{x})$ is the function specified by the vector $\bar{\mathbf{f}}$. For the jth configuration $\mathbf{x}=\mathbf{b}^j$, the functions $F(\mathbf{x})$ and $\bar{F}(\mathbf{x})$ assume the complementary values $\mathbf{f}_j$ and $\bar{\mathbf{f}}_j$ respectively.

Table II. Commutative and Associative Binary Operations

u	v	K=6 u Δ v	K=8 u ∧ v	K=9 u ∇ v	K=14 u ∨ v
0	0	0	0	1	0
0	1	1	0	0	1
1	0	1	0	0	1
1	1	0	1	1	1

The vectors $\mathbf{f}$ for each of the 16 switching functions of two arguments are listed in Table I. Each is identified by the characteristic number K defined by $\mathbf{f}=\mathbf{b}^K$.

THE CHOICE OF OPERATIONS

To investigate systematically the properties of switching functions it is important to have standard algebraic forms for their representation and manipulation. For maximum utility the representation must be simple and the manipulation easy.

Simplicity of representation is achieved by using algebraic operations requiring few arguments, and by limiting the number of levels over which the operations are iterated. Complementation, the only nontrivial unary operation on the set (0,1), is inadequate to construct an arbitrary switching function from its arguments. Binary operations are therefore required, and it is well known that they are sufficient. No binary operation on the set (0,1) extended on a single level over complemented and uncomplemented arguments is sufficient to represent an arbitrary switching function. Two levels are therefore required and if two different binary operations are used, one on each level, two levels suffice. One binary operation, the primary connective, can be extended over expressions each of which is formed by extending the other binary operation, the secondary connective, over complemented and uncomplemented arguments.

Ease of manipulation is attained by selecting binary operations that are commutative and associative, and such that the secondary connective is distributive over the primary connective. That these properties aid algebraic simplification is shown by the following example in the algebra of real numbers, in which multiplication is distributive over addition.

$$\begin{aligned} &[a(bc)]+[a(db)] \\ &\quad=[a(bc)]+[a(bd)] && \text{by commutativity} \\ &\quad=[(ab)c]+[(ab)d] && \text{by associativity} \\ &\quad=(ab)(c+d) && \text{by distributivity} \end{aligned}$$

The 16 binary operations on the set (0,1) are precisely the 16 switching functions of two arguments listed in Table I. The six functions for $K=0, 3, 5, 10, 12, 15$ are trivial in that their values depend on at most one of the arguments. Of the ten nontrivial functions, those for $K=2, 4, 11, 13$ are asymmetric in the arguments and therefore constitute noncommutative operations. Of the six functions remaining, the associative law does not hold for $K=1$ or for $K=7$. These two operations, the Lukasiewicz and Sheffer functions respectively, are precisely the only two binary operations either of which alone suffices to represent an arbitrary switching function in terms of its arguments. Although the resulting expressions use a single connective, they are extremely cumbersome.

There remain the four functions for $K=6, 8, 9, 14$. It is easily verified that each of the four is a commutative and associative binary operation. They will be denoted by the operation symbols introduced in Table II.

The operation Δ has been called *symmetric difference, sum modulo 2, exclusive or,* and *exclusive disjunction.* The operation ∧ has been called *Boolean product, logical product, and,* and *conjunction.* The operation ∇ has been called *logical equivalence,* and *if and only if.* The operation ∨ has been called *Boolean sum, logical sum, (inclusive) or,* and *(inclusive) disjunction.* A few of the more important properties of the four operations are summarized in Table III.

The binary operations of Table II are extended to vectors of equal dimension as follows. If ⊙ is one of the four operations Δ, ∧, ∇, and ∨, then $\mathbf{u}=\mathbf{v}\odot\mathbf{w}$ if and only if $\mathbf{u}_k=\mathbf{v}_k\odot\mathbf{w}_k$ for all k. The symbols Δ, ⋀, ∇, and ⋁ denote extended application of the operations Δ, ∧, ∇, and ∨ respectively.

CANONICAL FORMS

The four distributive laws stated in Table III are the only ones that hold

Table III. Properties of the Operations

$u \wedge u=u$	$u \vee u=u$	$u \,\Delta\, u=0$	$u \,\nabla\, u=1$
$u \wedge \bar{u}=0$	$u \vee \bar{u}=1$	$u \,\Delta\, \bar{u}=1$	$u \,\nabla\, \bar{u}=0$
$u \wedge 0=0$	$u \vee 0=u$	$u \,\Delta\, 0=u$	$u \,\nabla\, 0=\bar{u}$
$u \wedge 1=u$	$u \vee 1=1$	$u \,\Delta\, 1=\bar{u}$	$u \,\nabla\, 1=u$

$$u \wedge (v \vee w)=(u \wedge v) \vee (u \wedge w) \tag{1}$$

$$u \vee (v \wedge w)=(u \vee v) \wedge (u \vee w) \tag{2}$$

$$u \wedge (v \,\Delta\, w)=(u \wedge v) \,\Delta\, (u \wedge w) \tag{3}$$

$$u \vee (v \,\nabla\, w)=(u \vee v) \,\nabla\, (u \vee w) \tag{4}$$

Table IV. Coefficients, Products, and Sums for a Function of Three Arguments

j	$\mathbf{b}^j$	f	p	g	q	h	r	i	s
0	000	0	$\bar{\mathbf{x}}_0 \wedge \bar{\mathbf{x}}_1 \wedge \bar{\mathbf{x}}_2$	0	$\mathbf{x}_0 \vee \mathbf{x}_1 \vee \mathbf{x}_2$	0	1	0	0
1	001	1	$\bar{\mathbf{x}}_0 \wedge \bar{\mathbf{x}}_1 \wedge \mathbf{x}_2$	1	$\mathbf{x}_0 \vee \mathbf{x}_1 \vee \bar{\mathbf{x}}_2$	1	$\mathbf{x}_2$	0	$\bar{\mathbf{x}}_2$
2	010	1	$\bar{\mathbf{x}}_0 \wedge \mathbf{x}_1 \wedge \bar{\mathbf{x}}_2$	1	$\mathbf{x}_0 \vee \bar{\mathbf{x}}_1 \vee \mathbf{x}_2$	1	$\mathbf{x}_1$	0	$\bar{\mathbf{x}}_1$
3	011	0	$\bar{\mathbf{x}}_0 \wedge \mathbf{x}_1 \wedge \mathbf{x}_2$	0	$\mathbf{x}_0 \vee \bar{\mathbf{x}}_1 \vee \bar{\mathbf{x}}_2$	0	$\mathbf{x}_1 \wedge \mathbf{x}_2$	1	$\bar{\mathbf{x}}_1 \vee \bar{\mathbf{x}}_2$
4	100	1	$\mathbf{x}_0 \wedge \bar{\mathbf{x}}_1 \wedge \bar{\mathbf{x}}_2$	1	$\bar{\mathbf{x}}_0 \vee \mathbf{x}_1 \vee \mathbf{x}_2$	1	$\mathbf{x}_0$	0	$\bar{\mathbf{x}}_0$
5	101	0	$\mathbf{x}_0 \wedge \bar{\mathbf{x}}_1 \wedge \mathbf{x}_2$	0	$\bar{\mathbf{x}}_0 \vee \mathbf{x}_1 \vee \bar{\mathbf{x}}_2$	0	$\mathbf{x}_0 \wedge \mathbf{x}_2$	1	$\bar{\mathbf{x}}_0 \vee \bar{\mathbf{x}}_2$
6	110	0	$\mathbf{x}_0 \wedge \mathbf{x}_1 \wedge \bar{\mathbf{x}}_2$	0	$\bar{\mathbf{x}}_0 \vee \bar{\mathbf{x}}_1 \vee \mathbf{x}_2$	0	$\mathbf{x}_0 \wedge \mathbf{x}_1$	1	$\bar{\mathbf{x}}_0 \vee \bar{\mathbf{x}}_1$
7	111	1	$\mathbf{x}_0 \wedge \mathbf{x}_1 \wedge \mathbf{x}_2$	1	$\bar{\mathbf{x}}_0 \vee \bar{\mathbf{x}}_1 \vee \bar{\mathbf{x}}_2$	0	$\mathbf{x}_0 \wedge \mathbf{x}_1 \wedge \mathbf{x}_2$	1	$\bar{\mathbf{x}}_0 \vee \bar{\mathbf{x}}_1 \vee \bar{\mathbf{x}}_2$

among the four commutative and associative operations. The operations in each distributive law will be used as the connectives of a standard, or canonical, form of an arbitrary switching function $F(\mathbf{x})$ of n arguments.

$$u\wedge(v\vee w)=(u\wedge v)\vee(u\wedge w) \tag{1}$$

$$u\vee(v\wedge w)=(u\vee v)\wedge(u\vee w) \tag{2}$$

$$u\wedge(v\Delta w)=(u\wedge v)\Delta(u\wedge w) \tag{3}$$

$$u\vee(v\nabla w)=(u\vee v)\nabla(u\vee w) \tag{4}$$

Corresponding to equation 1 is a form with primary connective $\vee$ and secondary connective $\wedge$, defined by

$$\mathbf{p}_j=\bigwedge_{k=0}^{n-1}(\mathbf{x}_k \nabla \mathbf{b}_k{}^j)$$

$$F(\mathbf{x})=\bigvee_{j=0}^{2^n-1}(\mathbf{f}_j \wedge \mathbf{p}_j) \tag{5}$$

The products $\mathbf{p}_j$ have been called fundamental products, constituents of unity, and minterms. The canonical form, equation 5, has been called the sum of products canonical form and the disjunctive canonical form.

Corresponding to equation 2 is a form with primary connective $\wedge$ and secondary connective $\vee$, defined by

$$\mathbf{q}_j=\bigvee_{k=0}^{n-1}(\mathbf{x}_k \Delta \mathbf{b}_k{}^j)$$

$$F(\mathbf{x})=\bigwedge_{j=0}^{2^n-1}(\mathbf{g}_j \vee \mathbf{q}_j) \tag{6}$$

The sums $\mathbf{q}_j$ have been called fundamental sums, constituents of zero, and maxterms. The canonical form, equation 6, has been called the product of sums canonical form and the conjunctive canonical form.

Corresponding to equation 3 is a form with primary connective Δ and secondary connective $\wedge$, defined by

$$\mathbf{r}_j=\bigwedge_{k=0}^{n-1}(\mathbf{x}_k \vee \mathbf{b}_k{}^j)$$

$$F(\mathbf{x})=\mathop{\Delta}_{j=0}^{2^n-1}(\mathbf{h}_j \wedge \mathbf{r}_j) \tag{7}$$

The products $\mathbf{r}_j$ may be called reduced fundamental products, constituents of unity, or minterms. The canonical form, equation 7, may be called the delta canonical form or the exclusive disjunctive canonical form.

Corresponding to equation 4 is a form with primary connective ∇ and secondary connective $\vee$, defined by

$$\mathbf{s}_j=\bigvee_{k=0}^{n-1}(\bar{\mathbf{x}}_k \wedge \mathbf{b}_k{}^j)$$

$$F(\mathbf{x})=\mathop{\nabla}_{j=0}^{2^n-1}(\mathbf{i}_j \vee \mathbf{s}_j) \tag{8}$$

The sums $\mathbf{s}_j$ may be called reduced fundamental sums, constituents of zero, or maxterms. The canonical form, equation 8, is believed to be new and may be called the del canonical form or the equivalence canonical form.

The logical vectors **f**, **g**, **h**, and **i** are determined by the switching function $F(\mathbf{x})$. For example, let $F(\mathbf{x})$ be the function of three arguments, which assumes the value unity if and only if exactly one or exactly three of the arguments are unity. The coefficients **f**, **g**, **h**, and **i**, the products **p** and **r**, and the sums **q** and **s** are all listed for this function in Table IV.

The connective joining $\mathbf{x}_k$ and $\mathbf{b}_k{}^j$ in the definition of $\mathbf{p}_j$, $\mathbf{q}_j$, $\mathbf{r}_j$, or $\mathbf{s}_j$ serves only to help specify whether $\mathbf{x}_k$ is to be included or not, or complemented or not, in the product or sum being defined. Contrary to appearances, it does not constitute a third connective in any of the canonical forms, as may be verified by inspection of Table IV.

Writing out the canonical forms, equations 5 through 8, for the example yields, upon replacement of the sign $\wedge$ by juxtaposition and after some elementary algebraic simplification, the following four expressions:

$$F(\mathbf{x})=\bar{\mathbf{x}}_0\bar{\mathbf{x}}_1\mathbf{x}_2 \vee \bar{\mathbf{x}}_0\mathbf{x}_1\bar{\mathbf{x}}_2 \vee \mathbf{x}_0\bar{\mathbf{x}}_1\bar{\mathbf{x}}_2 \vee \mathbf{x}_0\mathbf{x}_1\mathbf{x}_2$$

$$F(\mathbf{x})=(\mathbf{x}_0 \vee \mathbf{x}_1 \vee \mathbf{x}_2)(\mathbf{x}_0 \vee \bar{\mathbf{x}}_1 \vee \bar{\mathbf{x}}_2)(\bar{\mathbf{x}}_0 \vee \mathbf{x}_1 \vee \bar{\mathbf{x}}_2)(\bar{\mathbf{x}}_0 \vee \bar{\mathbf{x}}_1 \vee \mathbf{x}_2)$$

$$F(\mathbf{x})=\mathbf{x}_2 \Delta \mathbf{x}_1 \Delta \mathbf{x}_0$$

$$F(\mathbf{x})=0 \nabla \bar{\mathbf{x}}_2 \nabla \bar{\mathbf{x}}_1 \nabla \bar{\mathbf{x}}_0$$

It is evident from the example that some canonical forms yield expressions more concise than others for a given function. Some may be better suited than others to describing switching circuits in a given technology. It is obviously necessary to have means of translating from one representation to another. For any particular translation, straightforward algebraic manipulation can be employed. For example, the disjunctive form can be translated to the delta form in three steps. The first is the replacement of $\vee$ by Δ, which leaves the function unchanged because the individual products are disjoint. The second is the replacement of $\bar{\mathbf{x}}_i$ by its equivalent $(\mathbf{x}_i \Delta 1)$. The third is the application of the properties listed in Table III, together with the commutativity and associativity of $\vee$ and Δ, to reduce the resulting expression to the form of equation 7. For the function of Table IV these steps yield

$$\begin{aligned}F(\mathbf{x})&=\bar{\mathbf{x}}_0\bar{\mathbf{x}}_1\mathbf{x}_2 \Delta \bar{\mathbf{x}}_0\mathbf{x}_1\bar{\mathbf{x}}_2 \Delta \mathbf{x}_0\bar{\mathbf{x}}_1\bar{\mathbf{x}}_2 \Delta \mathbf{x}_0\mathbf{x}_1\mathbf{x}_2\\&=(\mathbf{x}_0 \Delta 1)(\mathbf{x}_1 \Delta 1)\mathbf{x}_2 \Delta (\mathbf{x}_0 \Delta 1)\mathbf{x}_1(\mathbf{x}_2 \Delta 1)\\&\qquad \Delta \mathbf{x}_0(\mathbf{x}_1 \Delta 1)(\mathbf{x}_2 \Delta 1) \Delta \mathbf{x}_0\mathbf{x}_1\mathbf{x}_2\\&=\mathbf{x}_0\mathbf{x}_1\mathbf{x}_2 \Delta \mathbf{x}_0\mathbf{x}_2 \Delta \mathbf{x}_1\mathbf{x}_2 \Delta \mathbf{x}_2 \Delta \mathbf{x}_0\mathbf{x}_1\mathbf{x}_2\\&\qquad \Delta \mathbf{x}_0\mathbf{x}_1 \Delta \mathbf{x}_1\mathbf{x}_2 \Delta \mathbf{x}_1 \Delta \mathbf{x}_0\mathbf{x}_1\mathbf{x}_2 \Delta \mathbf{x}_0\mathbf{x}_1\\&\qquad \Delta \mathbf{x}_0\mathbf{x}_2 \Delta \mathbf{x}_0 \Delta \mathbf{x}_0\mathbf{x}_1\mathbf{x}_2\\&=\mathbf{x}_0 \Delta \mathbf{x}_1 \Delta \mathbf{x}_2\end{aligned}$$

Such tedious manipulation can be avoided by the use of the transformations that carry the coefficient vector of one representation into the coefficient vector of another. It will be shown, for example, that the translation just performed algebraically can be effected by the transformation

$$\left\|\begin{matrix}1&0&0&0&0&0&0&0\\1&1&0&0&0&0&0&0\\1&0&1&0&0&0&0&0\\1&1&1&1&0&0&0&0\\1&0&0&0&1&0&0&0\\1&1&0&0&1&1&0&0\\1&0&1&0&1&0&1&0\\1&1&1&1&1&1&1&1\end{matrix}\right\| \left\|\begin{matrix}0\\1\\1\\0\\1\\0\\0\\1\end{matrix}\right\| = \left\|\begin{matrix}0\\1\\1\\0\\1\\0\\0\\0\end{matrix}\right\|$$

which may be written as $\mathbf{h}=\mathbf{A}\mathbf{f}$, where $\mathbf{A}$ is the matrix shown and where matrix multiplication is performed using modulo 2 arithmetic. The desired transformations will all be determined explicitly with the aid of two further results. These are a theorem on the partial ordering of Boolean vectors, and a derivation of the delta canonical form by means of the partial difference operation.

Partial Ordering of Boolean Vectors

PARITY OF BINOMIAL COEFFICIENTS

It is assumed throughout this discussion that arguments of binomial coefficients are restricted to nonnegative integral values. Use will be made of two relations on binomial coefficients, stated here without proof.

$$\begin{bmatrix}x+y\\z\end{bmatrix}=\sum_{h=0}^{z}\begin{bmatrix}x\\z-h\end{bmatrix}\begin{bmatrix}y\\h\end{bmatrix} \tag{9}$$

$$\begin{bmatrix} y \\ x \end{bmatrix} = \sum_{h=0}^{i} \begin{bmatrix} i \\ h \end{bmatrix} \begin{bmatrix} y-i \\ x-h \end{bmatrix} \tag{10}$$

for $0 \leq i \leq y$.

The following lemmas concern the parity of binomial coefficients. It is assumed in each lemma that n is integral.

Lemma 1

$$\begin{bmatrix} 2^n \\ k \end{bmatrix} \equiv 1 \pmod 2 \longleftrightarrow k=0 \text{ or } k=2^n$$

Proof: Sufficiency for all k and necessity for $k=0$ and $k=2^n$ follow from the relations

$$\begin{bmatrix} 2^n \\ 0 \end{bmatrix} = 1 \text{ and } \begin{bmatrix} 2^n \\ 2^n \end{bmatrix} = 1$$

Since

$$\begin{bmatrix} 2^n \\ k \end{bmatrix} = 0$$

for $k > 2^n$, necessity need be further demonstrated only for $0<k<2^n$. The demonstration proceeds by induction on n. The proposition is trivially true for $n=0$ and, since

$$\begin{bmatrix} 2 \\ 1 \end{bmatrix} = 2$$

it is also true for $n=1$. Let it be true by hypothesis for $n-1$. In considering the coefficient

$$\begin{bmatrix} 2^n \\ k \end{bmatrix}$$

no generality is lost by assuming that $k \leq 2^{n-1}$, since

$$\begin{bmatrix} 2^n \\ k \end{bmatrix} = \begin{bmatrix} 2^n \\ 2^n-k \end{bmatrix}$$

By equation 9

$$\begin{bmatrix} 2^n \\ k \end{bmatrix} = \begin{bmatrix} 2^{n-1}+2^{n-1} \\ k \end{bmatrix} = \sum_{j=0}^{k} \begin{bmatrix} 2^{n-1} \\ k-j \end{bmatrix} \begin{bmatrix} 2^{n-1} \\ j \end{bmatrix}$$

If $k<2^{n-1}$, the factor

$$\begin{bmatrix} 2^{n-1} \\ k-j \end{bmatrix}$$

is even, by the inductive hypothesis, for $j \neq k$, and the factor

$$\begin{bmatrix} 2^{n-1} \\ j \end{bmatrix}$$

is likewise even for $j \neq 0$. Since $k \neq 0$, at least one factor of each term is even and so, therefore, is their sum. If $k=2^{n-1}$, the sum reduces to

$$\sum_{j=0}^{2^{n-1}} \begin{bmatrix} 2^{n-1} \\ 2^{n-1}-j \end{bmatrix} \begin{bmatrix} 2^{n-1} \\ j \end{bmatrix} = \sum_{j=0}^{2^{n-1}} \begin{bmatrix} 2^{n-1} \\ j \end{bmatrix}^2$$

Since the first and last terms of this sum are unity and by hypothesis all other terms are even, the sum is even.

Lemma 2

$$\left.\begin{matrix} a \leq b \\ a < 2^n \end{matrix}\right\} \rightarrow \begin{bmatrix} b+2^n \\ a \end{bmatrix} \equiv \begin{bmatrix} b \\ a \end{bmatrix} \pmod 2$$

Proof: By equation 9

$$\begin{bmatrix} b+2^n \\ a \end{bmatrix} = \sum_{k=0}^{a} \begin{bmatrix} b \\ a-k \end{bmatrix} \begin{bmatrix} 2^n \\ k \end{bmatrix}$$

Since, by lemma 1, the second factor

$$\begin{bmatrix} 2^n \\ k \end{bmatrix}$$

is odd if and only if $k=0$, the sum will be odd if and only if the first factor

$$\begin{bmatrix} b \\ a-0 \end{bmatrix}$$

is odd. The lemma follows immediately.

Lemma 3

$$\left.\begin{matrix} b < 2^n \\ a < 2^n \end{matrix}\right\} \rightarrow \begin{bmatrix} b+2^n \\ a+2^n \end{bmatrix} \equiv \begin{bmatrix} b \\ a \end{bmatrix} \pmod 2$$

Proof: By equation 10

$$\begin{bmatrix} b+2^n \\ a+2^n \end{bmatrix} = \sum_{k=0}^{2^n} \begin{bmatrix} 2^n \\ k \end{bmatrix} \begin{bmatrix} b \\ a+2^n-k \end{bmatrix}$$

Since, by lemma 1, the factor

$$\begin{bmatrix} 2^n \\ k \end{bmatrix}$$

is odd if and only if $k=0$ or $k=2^n$, only for these two values of k may there be an odd term in the sum. Hence

$$\begin{bmatrix} b+2^n \\ a+2^n \end{bmatrix} \equiv \begin{bmatrix} b \\ a+2^n \end{bmatrix} + \begin{bmatrix} b \\ a \end{bmatrix} \pmod 2$$

Since $a+2^n > b$

$$\begin{bmatrix} b \\ a+2^n \end{bmatrix} = 0$$

and the lemma follows immediately.

Partial Ordering and Parity

Let $\mathbf{b}^u$ and $\mathbf{b}^v$ be the logical vectors of dimension n whose components are the coefficients of the base 2 representations of the integers u and v, where $u<2^n$ and $v<2^n$. The main result relating the partial ordering of logical vectors to the parity of binomial coefficients is established in the following theorem:

Theorem 1

$$\mathbf{b}^v \geq \mathbf{b}^u \longleftrightarrow \begin{bmatrix} v \\ u \end{bmatrix} \equiv 1 \pmod 2$$

Proof: The theorem is easily verified for $n=1$, and the proof proceeds by induction on n. The equations

$$u = 2^{n-1}\mathbf{b}_0^u + u'$$

$$v = 2^{n-1}\mathbf{b}_0^v + v'$$

uniquely determine the integers u' and v' represented by the $n-1$ rightmost components of $\mathbf{b}^u$ and $\mathbf{b}^v$ respectively. The corresponding logical vectors of dimension $n-1$ are $\mathbf{b}^{u'}$ and $\mathbf{b}^{v'}$.

Case 1: If $\mathbf{b}_0^v \geq \mathbf{b}_0^u$ does not hold, then $\mathbf{b}^v \geq \mathbf{b}^u$ does not hold, and since $v<u$ in this case

$$\begin{bmatrix} v \\ u \end{bmatrix} = 0$$

and the theorem is verified.

Case 2: If $\mathbf{b}_0^v \geq \mathbf{b}_0^u$, then

$$\mathbf{b}^v \geq \mathbf{b}^u \longleftrightarrow \mathbf{b}^{v'} \geq \mathbf{b}^{u'} \tag{11}$$

Moreover,

$$\begin{bmatrix} v \\ u \end{bmatrix} = \begin{bmatrix} v'+2^{n-1}\mathbf{b}_0^v \\ u'+2^{n-1}\mathbf{b}_0^u \end{bmatrix} \equiv \begin{bmatrix} v' \\ u' \end{bmatrix} \pmod 2$$

identically for

$$\mathbf{b}_0^v = \mathbf{b}_0^u = 0$$

and by lemma 2 for

$$\mathbf{b}_0^v = 1,\ \mathbf{b}_0^u = 0$$

and by lemma 3 for

$$\mathbf{b}_0^v = \mathbf{b}_0^u = 1$$

Hence

$$\begin{bmatrix} v \\ u \end{bmatrix} \equiv 1 \pmod 2 \longleftrightarrow \begin{bmatrix} v' \\ u' \end{bmatrix} \equiv 1 \pmod 2 \tag{12}$$

But, by the inductive hypothesis,

$$\mathbf{b}^{v'} \geq \mathbf{b}^{u'} \longleftrightarrow \begin{bmatrix} v' \\ u' \end{bmatrix} \equiv 1 \pmod 2$$

Hence, from equations 11 and 12,

$$\mathbf{b}^v \geq \mathbf{b}^u \longleftrightarrow \begin{bmatrix} v \\ u \end{bmatrix} \equiv 1 \pmod 2$$

and the theorem is established.

An Alternative Proof

It has been called to the writer's attention that theorem 1 can be deduced from a theorem of Kummer.[3] Consider the prime radix p representations of the integers a and b:

$$a = \mathbf{a}_0 p^{n-1} + \ldots + \mathbf{a}_{n-1} p^0$$

$$b = \mathbf{b}_0 p^{n-1} + \ldots + \mathbf{b}_{n-1} p^0$$

The addition of a and b defines the sum $d=a+b$ and the logical vector $\mathbf{c}$ whose kth component $\mathbf{c}_k$ is the carry generated in the kth column. Kummer proved that the highest power p^N of p that divides

$$\begin{bmatrix} a+b \\ a \end{bmatrix}$$

is given by $N=\sigma(\mathbf{c})$.

Setting $a+b=v$, $a=u$, and $p=2$, it is easily shown that $\mathbf{b}^v \geq \mathbf{b}^u$ if and only if $\mathbf{c}=\mathbf{0}$ in the addition of a to b, i.e., of u to $v-u$. The sufficiency is obvious. The necessity follows from the observation that there exists no carry into the least significant column. This will be indicated, by extension, as $\mathbf{c}_n=0$. It should be observed that if $\mathbf{b}^v \geq \mathbf{b}^u$, then $\nu(\mathbf{d}) = n$ and $\mathbf{d}_j$ is the sum digit in the same column as $\mathbf{a}_j$ and $\mathbf{b}_j$. If $\mathbf{c}_i=1$ for some column i, then there exists at least one column j, $i \leq j < n$, such that $\mathbf{c}_j=1$ and $\mathbf{c}_{j+1}=0$. It follows that $\mathbf{a}_j=\mathbf{b}_j=1$ and $\mathbf{d}_j=0$. But $\mathbf{d}_j=\mathbf{b}_j{}^v$ and $\mathbf{a}_j=\mathbf{b}_j{}^u$ and it follows from the fact that $\mathbf{b}_j{}^v \geq \mathbf{b}_j{}^u$ does not hold, that $\mathbf{b}^v \geq \mathbf{b}^u$ does not hold either, which is contrary to hypothesis. Hence $\mathbf{c}_i=0$ for all i, $\mathbf{c}=\mathbf{0}$, and $N=\sigma(\mathbf{c})=\sigma(\mathbf{0})=0$ if and only if $\mathbf{b}^v \geq \mathbf{b}^u$. Since 2^1 divides

$$\begin{bmatrix} v \\ u \end{bmatrix} \text{ if and only if } N>0$$

theorem 1 follows.

The Partial Difference Operation

Following Reed[4] and Akers,[5] the partial difference of the switching function $F(\mathbf{x})$ with respect to the argument $\mathbf{x}_k$ is the symmetric difference of the two function values $F(\bar{\mathbf{e}}^k \wedge \mathbf{x})$ and $F(\mathbf{e}^k \vee \mathbf{x})$ obtained by setting $\mathbf{x}_k=0$ and $\mathbf{x}_k=1$ respectively, in $F(\mathbf{x})$. The partial difference of $F(\mathbf{x})$ with respect to $m>1$ arguments is the extended symmetric difference (unique by the commutativity and associativity of Δ) of the 2^m function values obtained by assigning all configurations of values to those m arguments in $F(\mathbf{x})$.

The partial difference operation can be defined formally with the aid of the identity

$$\mathbf{x}=|\bar{\mathbf{u}}/\mathbf{x},\mathbf{u},\mathbf{u}/\mathbf{x}|$$

where $\mathbf{u}$ is any logical vector of the same dimension as $\mathbf{x}$. The vector resulting from the substitution in $\mathbf{x}$ of the coefficients of the m-digit base 2 representation of the integer k for the m arguments corresponding to components 1 of $\mathbf{u}$ is clearly

$$|\bar{\mathbf{u}}/\mathbf{x},\mathbf{u},\mathbf{b}^k|$$

where $\nu(\mathbf{b}^k)=\sigma(\mathbf{u})=m$.

The partial difference

$$\overset{\partial}{\mathbf{u}}F(\mathbf{x})$$

of $F(\mathbf{x})$ with respect to the arguments specified by $\mathbf{u}$ is defined as

$$\overset{\partial}{\mathbf{u}}F(\mathbf{x})=\underset{k=0}{\overset{2^{\sigma(\mathbf{u})}-1}{\Delta}} F(|\bar{\mathbf{u}}/\mathbf{x},\mathbf{u},\mathbf{b}^k|)$$

For example, let $n=4$ and $\mathbf{u}=(0,1,0,1)$. Then $\sigma(\mathbf{u})=2$ and

$$\begin{aligned}\overset{\partial}{\mathbf{u}}F(\mathbf{x})&=\underset{k=0}{\overset{3}{\Delta}} F(|(\mathbf{x}_0,\mathbf{x}_2),\mathbf{u},\mathbf{b}^k|)\\ &=F(\mathbf{x}_0,0,\mathbf{x}_2,0)\ \Delta\ F(\mathbf{x}_0,0,\mathbf{x}_2,1)\ \Delta\\ &\qquad F(\mathbf{x}_0,1,\mathbf{x}_2,0)\ \Delta\ F(\mathbf{x}_0,1,\mathbf{x}_2,1)\end{aligned}$$

The three special cases $\mathbf{u}=\mathbf{0}$, $\mathbf{u}=\mathbf{e}^k$, and $\mathbf{u}=\mathbf{e}$ yield

$$\overset{\partial}{\mathbf{0}}F(\mathbf{x})=F(\mathbf{x})$$

$$\overset{\partial}{\mathbf{e}^k}F(\mathbf{x})=F(\bar{\mathbf{e}}^k \wedge \mathbf{x})\ \Delta\ F(\mathbf{e}^k \vee \mathbf{x})$$

$$\overset{\partial}{\mathbf{e}}F(\mathbf{x})=\underset{j=0}{\overset{2^n-1}{\Delta}} F(\mathbf{b}^j)=\underset{j=0}{\overset{2^n-1}{\Delta}} \mathbf{f}_j$$

The partial difference operation can be used to expand an arbitrary switching function about its arguments, in a form with Δ as the primary connective. The expansion about $\mathbf{x}_k$ is derived as follows:

$$\begin{aligned}F(\mathbf{x})&=\bar{\mathbf{x}}_k F(\bar{\mathbf{e}}^k \wedge \mathbf{x}) \vee \mathbf{x}_k F(\mathbf{e}^k \vee \mathbf{x})\\ &=\bar{\mathbf{x}}_k F(\bar{\mathbf{e}}^k \wedge \mathbf{x})\ \Delta\ \mathbf{x}_k F(\mathbf{e}^k \vee \mathbf{x})\\ &=(1\ \Delta\ \mathbf{x}_k)F(\bar{\mathbf{e}}^k \wedge \mathbf{x})\ \Delta\ \mathbf{x}_k F(\mathbf{e}^k \vee \mathbf{x})\\ &=F(\bar{\mathbf{e}}^k \wedge \mathbf{x})\ \Delta\ \mathbf{x}_k[F(\bar{\mathbf{e}}^k \wedge \mathbf{x})\ \Delta\ F(\mathbf{e}^k \vee \mathbf{x})]\\ &=F(\bar{\mathbf{e}}^k \wedge \mathbf{x})\ \Delta\ \mathbf{x}_k \overset{\partial}{\mathbf{e}^k}F(\mathbf{x})\end{aligned}$$

If this expansion is performed about each argument in succession, an expression is obtained for $F(\mathbf{x})$ in terms of the products $\mathbf{r}$, defined earlier, and of the partial differences of $F(\mathbf{x})$ with respect to the variables of these products. In particular, it can be shown[5] that

$$F(\mathbf{x})=\underset{j=0}{\overset{2^n-1}{\Delta}}\left[\mathbf{r}_j \wedge \overset{\partial}{\mathbf{b}^j}F(\mathbf{b}^j \wedge \mathbf{x})\right] \tag{13}$$

In each partial difference of equation 13, all arguments have been set equal to zero except those with respect to which the partial difference is taken. For $n=2$, for example:

$$\begin{aligned}F(\mathbf{x}_0,\mathbf{x}_1)&=\overset{\partial}{\mathbf{b}^0}F(\mathbf{b}^0 \wedge \mathbf{x})\ \Delta\ \mathbf{x}_1 \overset{\partial}{\mathbf{b}^1}F(\mathbf{b}^1 \wedge \mathbf{x})\ \Delta\\ &\qquad \mathbf{x}_0 \overset{\partial}{\mathbf{b}^2}F(\mathbf{b}^2 \wedge \mathbf{x})\ \Delta\ \mathbf{x}_0\mathbf{x}_1 \overset{\partial}{\mathbf{b}^3}F(\mathbf{b}^3 \wedge \mathbf{x})\\ &=\overset{\partial}{\mathbf{0}}F(0,0)\ \Delta\ \mathbf{x}_1 \overset{\partial}{\mathbf{b}^1}F(0,\mathbf{x}_1)\ \Delta\\ &\qquad \mathbf{x}_0 \overset{\partial}{\mathbf{b}^2}F(\mathbf{x}_0,0)\ \Delta\ \mathbf{x}_0\mathbf{x}_1 \overset{\partial}{\mathbf{e}}F(\mathbf{x}_0,\mathbf{x}_1)\\ &=F(0,0)\ \Delta\ \mathbf{x}_1[F(0,0)\ \Delta\ F(0,1)]\ \Delta\\ &\qquad \mathbf{x}_0[F(0,0)\ \Delta\ F(1,0)]\ \Delta\ \mathbf{x}_0\mathbf{x}_1\\ &\qquad [F(0,0)\ \Delta\ F(0,1)\ \Delta\ F(1,0)\ \Delta\\ &\qquad F(1,1)]\end{aligned}$$

Transformations Among the Canonical Forms

CALCULATION OF **h** FROM **f**

Comparison of equation 13 with equation 7 provides the identification of the coefficient $\mathbf{h}_j$ as

$$\mathbf{h}_j=\overset{\partial}{\mathbf{b}^j}F(\mathbf{b}^j \wedge \mathbf{x})$$

$$\mathbf{h}_j=\overset{\partial}{\mathbf{b}^j}F(|\mathbf{0},\mathbf{b}^j,\mathbf{b}^j/\mathbf{x}|)$$

$$\mathbf{h}_j=\underset{k=0}{\overset{2^{\sigma(\mathbf{b}^j)}-1}{\Delta}} F(|\mathbf{0},\mathbf{b}^j,\mathbf{b}^k|) \tag{14}$$

where $\nu(\mathbf{b}^k)=\sigma(\mathbf{b}^j)$ and $\nu(\mathbf{b}^j)=n$. The term for $k=2^{\sigma(\mathbf{b}^j)}-1=2^{\nu(\mathbf{b}^k)}-1$ is $F(|\mathbf{0},\mathbf{b}^j,\mathbf{e}|)=F(\mathbf{b}^j)$. This term is obtained from $F(\mathbf{x})$ by assigning the value 1 to all arguments specified by $\mathbf{b}^j$ and the value zero to all others. The term for any other value of k is that resulting from the assignment of some other configuration to the arguments specified by $\mathbf{b}^j$. Each such assignment will yield a vector included by $\mathbf{b}^j$. Equation 14 may therefore be rewritten as

$$\mathbf{h}_j=\underset{k \in S_j}{\Delta} F(\mathbf{b}^k)$$

where $\nu(\mathbf{b}^k)$ is now n and where $S_j=\{k|\mathbf{b}^j \geq \mathbf{b}^k\}$ is the set of integers whose vector representations are included by the vector $\mathbf{b}^j$. The dimension of the set S_j is clearly $2^{\sigma(\mathbf{b}^j)}$.

But, by theorem 1

$$\mathbf{b}^j \geq \mathbf{b}^k \longleftrightarrow \begin{bmatrix} j \\ k \end{bmatrix}_2=1$$

where

$$\begin{bmatrix} j \\ k \end{bmatrix}_2$$ is the residue modulo 2 of the binomial coefficient $$\begin{bmatrix} j \\ k \end{bmatrix}$$

It follows that

$$\mathbf{h}_j=\underset{k=0}{\overset{j}{\Delta}} \mathbf{f}_k \begin{bmatrix} j \\ k \end{bmatrix}_2$$

and, since

$$\begin{bmatrix} j \\ k \end{bmatrix}=0 \text{ for } k>j$$

it follows further that

$$\mathbf{h}_j=\underset{k=0}{\overset{2^n-1}{\Delta}} \mathbf{f}_k \begin{bmatrix} j \\ k \end{bmatrix}_2$$

The transformation of the coefficients $\mathbf{f}$ into the coefficients $\mathbf{h}$ can therefore be expressed as

$$\mathbf{h}=\mathbf{A}\mathbf{f} \tag{15}$$

where matrix multiplication is defined with the operations Δ and $\wedge$, and $\mathbf{A}$ is the square matrix of dimension $r=2^n$ whose general element is

$$\mathbf{A}^{j}_{k}=\begin{bmatrix} j \\ k \end{bmatrix}_2$$

where $j=0, \ldots, r-1$ and $k=0, \ldots, r-1$ are the row and column indexes respectively. The matrices **A** for $n=1, 2, 3$ are

$$\left\|\begin{array}{c|c} 1 & 0 \\ \hline 1 & 1 \end{array}\right\| \quad \left\|\begin{array}{cc|cc} 1 & 0 & 0 & 0 \\ 1 & 1 & 0 & 0 \\ \hline 1 & 0 & 1 & 0 \\ 1 & 1 & 1 & 1 \end{array}\right\| \quad \left\|\begin{array}{cccc|cccc} 1 & 0 & 0 & 0 & 0 & 0 & 0 & 0 \\ 1 & 1 & 0 & 0 & 0 & 0 & 0 & 0 \\ 1 & 0 & 1 & 0 & 0 & 0 & 0 & 0 \\ 1 & 1 & 1 & 1 & 0 & 0 & 0 & 0 \\ \hline 1 & 0 & 0 & 0 & 1 & 0 & 0 & 0 \\ 1 & 1 & 0 & 0 & 1 & 1 & 0 & 0 \\ 1 & 0 & 1 & 0 & 1 & 0 & 1 & 0 \\ 1 & 1 & 1 & 1 & 1 & 1 & 1 & 1 \end{array}\right\|$$

The matrices have been partitioned to emphasize their recursive construction.

CALCULATION OF f FROM h

Muller[6] has stated that for $r=2^n$ the transformation $\mathbf{h}=\mathbf{Af}$ is its own inverse. This can be proved in general, and the restriction that the dimension of **A** be a power of 2 is not necessary. The expression $\mathbf{h}=\mathbf{Af}$ represents a system of 2^n linear equations in 2^n unknowns in the field J_2 of integers modulo 2. The system possesses a unique solution if and only if the determinant δ of **A** is not zero. Since the matrix **A** is triangular

$$\delta=\prod_{j=0}^{r-1}\mathbf{A}^{j}_{j}=\prod_{j=0}^{r-1}1=1$$

The system of equation 15 therefore possesses a unique inverse for vectors of any nonzero dimension. It is readily shown that the inverse of **A** is **A** itself. This can be demonstrated by induction for $r=2^n$, using the recursiveness noted above. Since it is true for all $r>0$, a more general proof is of interest.

Theorem 2

If **A** is a square matrix of dimension r with general element

$$\mathbf{A}^{j}_{k}=\begin{bmatrix} j \\ k \end{bmatrix}_2$$

in the field J_2, the product $\mathbf{B}=\mathbf{AA}$ is the identity matrix.

Proof:

$$\mathbf{B}^{j}_{k}=\mathop{\Delta}_{l=0}^{r-1}\mathbf{A}^{j}_{l}\mathbf{A}^{l}_{k}=\mathop{\Delta}_{l=0}^{r-1}\begin{bmatrix} j \\ l \end{bmatrix}_2\begin{bmatrix} l \\ k \end{bmatrix}_2$$

Case 1: $j=k$

$$\mathbf{B}^{j}_{k}=\mathop{\Delta}_{l=0}^{r-1}\begin{bmatrix} j \\ l \end{bmatrix}_2\begin{bmatrix} l \\ j \end{bmatrix}_2$$

But

$$\begin{bmatrix} j \\ l \end{bmatrix}_2\begin{bmatrix} l \\ j \end{bmatrix}_2=1$$

if and only if $l=j$. Hence

$$\mathbf{B}^{j}_{k}=1$$

Case 2: $j<k$

Either $l>j$ or $l<k$ (or both). If $l>j$, the first factor of the lth product is zero; if $l<k$, the second factor of the lth product is zero. Since each product is zero, so is their sum. Hence

$$\mathbf{B}^{j}_{k}=0$$

Case 3: $j>k$

If $l>j$, the first factor of the lth product is zero; if $l<k$, the second factor of the lth product is zero. The only nonzero contribution to

$$\mathbf{B}^{j}_{k}$$

is from products for which $k\leq l\leq j$, and

$$\mathbf{B}^{j}_{k}=\mathop{\Delta}_{l=k}^{j}\begin{bmatrix} j \\ l \end{bmatrix}_2\begin{bmatrix} l \\ k \end{bmatrix}_2$$

But

$$\begin{bmatrix} j \\ l \end{bmatrix}_2\begin{bmatrix} l \\ k \end{bmatrix}_2=1\longleftrightarrow\begin{bmatrix} j \\ l \end{bmatrix}_2=\begin{bmatrix} l \\ k \end{bmatrix}_2=1$$

Therefore by theorem 1

$$\begin{bmatrix} j \\ l \end{bmatrix}_2\begin{bmatrix} l \\ k \end{bmatrix}_2=1\longleftrightarrow\mathbf{b}^j\geq\mathbf{b}^l \text{ and } \mathbf{b}^l\geq\mathbf{b}^k$$

Then either all products are zero or there exists an integer l such that $\mathbf{b}^j\geq\mathbf{b}^l\geq\mathbf{b}^k$. In the latter event $\mathbf{b}^j$ and $\mathbf{b}^k$ differ in $q>0$ components, because $j\neq k$. Each of the 2^q assignments of values to those components yields a unique vector $\mathbf{b}^l$ such that $k\leq l\leq j$ and

$$\begin{bmatrix} j \\ l \end{bmatrix}_2\begin{bmatrix} l \\ k \end{bmatrix}_2=1$$

Then exactly 2^q products equal 1 and their modulo 2 sum

$$\mathbf{B}^{j}_{k}=0$$

Hence the theorem is proved.

Since **A** is self-inverse, it follows immediately from $\mathbf{h}=\mathbf{Af}$ that $\mathbf{f}=\mathbf{Ah}$.

THE REMAINING TRANSFORMATIONS

The transformation relating **f** and **g** can be determined by algebraic manipulation of equation 5 into a form similar to that of equation 6.

$$F(\mathbf{x})=\bigvee_{j=0}^{2^n-1}(\mathbf{f}_j\wedge\mathbf{p}_j) \qquad (5)$$

$$\bar{F}(\mathbf{x})=\bigvee_{j=0}^{2^n-1}(\bar{\mathbf{f}}_j\wedge\mathbf{p}_j)$$

by definition.

$$F(\mathbf{x})=\bigwedge_{j=0}^{2^n-1}(\mathbf{f}_j\vee\bar{\mathbf{p}}_j) \qquad (16)$$

by De Morgan's law extended.

$$F(\mathbf{x})=\bigwedge_{j=0}^{2^n-1}(\mathbf{g}_j\vee\mathbf{q}_j) \qquad (6)$$

But

$$\mathbf{q}_j=\bigvee_{k=0}^{n-1}\left(\mathbf{x}_k\,\Delta\,\mathbf{b}^{j}_{k}\right)=\bigvee_{k=0}^{n-1}\overline{\left(\mathbf{x}_k\,\nabla\,\mathbf{b}^{j}_{k}\right)}$$

and

$$\mathbf{p}_j=\bigwedge_{k=0}^{n-1}\left(\mathbf{x}_k\,\nabla\,\mathbf{b}^{j}_{k}\right)$$

Since $\mathbf{q}_j=\bar{\mathbf{p}}_j$, by De Morgan's law extended, a comparison of equations 16 and 6 yields the result $\mathbf{g}_j=\mathbf{f}_j$, for all j. The transformation relating the canonical forms of equations 5 and 6 is therefore the identity transformation $\mathbf{f}=\mathbf{g}$.

The transformation relating **h** and **i** is found similarly, with the use of the relation

$$\mathop{\nabla}_{j=0}^{r-1}z_j=1\,\Delta\left[\mathop{\Delta}_{j=0}^{r-1}\bar{z}_j\right] \qquad (17)$$

which follows immediately from the definitions of Δ and ∇. Equation 8 can be manipulated algebraically into a form similar to that of equation 7.

$$F(\mathbf{x})=\mathop{\nabla}_{j=0}^{2^n-1}(\mathbf{i}_j\vee\mathbf{s}_j) \qquad (8)$$

$$F(\mathbf{x})=1\,\Delta\left[\mathop{\Delta}_{j=0}^{2^n-1}\overline{(\mathbf{i}_j\vee\mathbf{s}_j)}\right]$$

by equation 17.

$$F(\mathbf{x})=1\,\Delta\left[\mathop{\Delta}_{j=0}^{2^n-1}(\bar{\mathbf{i}}_j\wedge\bar{\mathbf{s}}_j)\right]$$

by De Morgan's law.

$$F(\mathbf{x})=(1\,\Delta\,\bar{\mathbf{i}}_0)\,\Delta\left[\mathop{\Delta}_{j=1}^{2^n-1}(\bar{\mathbf{i}}_j\wedge\bar{\mathbf{s}}_j\right]$$

since $\bar{\mathbf{s}}_0=1$.

$$F(\mathbf{x})=\mathbf{i}_0\,\Delta\left[\mathop{\Delta}_{j=1}^{2^n-1}(\bar{\mathbf{i}}_j\wedge\bar{\mathbf{s}}_j)\right]$$

$$F(\mathbf{x})=\mathop{\Delta}_{j=0}^{2^n-1}\left[\left(\bar{\mathbf{i}}_j\,\Delta\,\mathbf{e}^{0}_{j}\right)\wedge\bar{\mathbf{s}}_j\right] \qquad (18)$$

But

$$F(\mathbf{x})=\mathop{\Delta}_{j=0}^{2^n-1}(\mathbf{h}_j\wedge\mathbf{r}_j) \qquad (7)$$

Since $\bar{\mathbf{s}}_j=\mathbf{r}_j$, by De Morgan's law extended, a comparison of equations 18 and 7 yields the result

$$\mathbf{h}_j=\mathbf{i}_j \, \Delta \, \mathbf{e}^{0}_{j}$$

which may be written more conveniently as

$$\mathbf{h}_j=\mathbf{i}_j \, \nabla \, \mathbf{e}^{0}_{j}$$

The transformations relating the canonical forms of equations 7 and 8 are therefore $\mathbf{h}=\mathbf{i} \nabla \mathbf{e}^0$ and its unique inverse $\mathbf{i}=\mathbf{h} \nabla \mathbf{e}^0$.

The various transformations are summarized below, showing the coefficient vectors of each of the four canonical forms presented, each as a function of each of the others, as follows:

$$\mathbf{f}=\mathbf{g}=\mathbf{Ah}=\mathbf{A}(\mathbf{i} \nabla \mathbf{e}^0)$$

$$\mathbf{h}=\mathbf{Af}=\mathbf{Ag}=\mathbf{i} \nabla \mathbf{e}^0$$

$$\mathbf{i}=\mathbf{h} \nabla \mathbf{e}^0=(\mathbf{Af}) \nabla \mathbf{e}^0=(\mathbf{Ag}) \nabla \mathbf{e}^0$$

Sector-Focused Cyclotrons

H. G. BLOSSER
MEMBER AIEE

THIS PAPER will discuss the principles of operation of the sector-focused cyclotron as well as the major design problems which have evolved and the progress which has been made as shown in recent studies of this device. The cyclotron[1] produces energetic beams of charged particles, which are used principally as a research tool to probe the atomic nucleus in an attempt to understand in detail the nature of the forces which hold the nucleus together. An important subsidiary use of the cyclotron beams is for isotope production work. Generally, only neutron-rich radioisotopes can be produced in a nuclear reactor. Neutron-deficient isotopes, of which there are many of practical importance, require the use of charged-particle beams such as are obtained from the cyclotron.

Cyclotron Fundamentals

As the cyclotron is not a conventional piece of electrical engineering equipment, a review of its basic principles of operation will be useful. Consider a charged particle moving at right angles to a uniform magnetic field. The particle moves in a circular orbit with the magnetic force balanced by the centripetal force as indicated in equation 1:

$$F_m=evB=F_{\text{cent}}=mv^2/r$$

$$\omega=v/r=eB/m \tag{1}$$

If this equation is solved for the angular velocity omega, it is seen that the angular velocity is determined entirely by the charge and mass of the particle and the strength of the magnetic field, and is independent of the linear velocity of the particle. In particular, if a pair of radio-frequency (r-f) electrodes is so placed in the region of the particle orbit that the orbit lies in a shielded region during unfavorable parts of the cycle and in a region of strong field during favorable portions of the cycle, and if the radio frequency matches the rotation frequency of the particle, then the particle will remain in phase with the radio frequency and will be accelerated at each passage through the region of strong field. Its linear velocity will therefore steadily increase until it reaches some limiting value which is the maximum the particular instrument is capable of containing. Since the process is fixed frequency, particles of low velocity such as those from a conventional ion source will be accepted on every r-f cycle, and a continuous output beam obtained.

On the basis of the simple picture, the cyclotron is then essentially a perfect accelerator; particles are accelerated continuously (and hence in copious quantities) to arbitrarily high energies. A closer look at details of the process reveals, unfortunately, several severe difficulties which drastically limit the effectiveness of the conventional cyclotron. First, from the theory of relativity, it is known that the mass of a particle is not really constant but depends on the energy of motion in the manner shown in equation 2,

$$m=E/c^2$$

$$\omega=eBc^2/E$$

$$E=(p^2c^2+m_0{}^2c^4)^{1/2}$$

$$p=erB \tag{2}$$

where E is the total energy consisting of the energy of motion plus the rest energy of the particle. Thus, as the particle gains velocity, E increases and hence the mass increases so that there is now a shift in the rotation frequency omega to lower values. This shift can be avoided as shown in equation 3

$$\omega=eBc^2/(e^2r^2B^2c^2+m_0{}^2c^4)^{1/2}$$

$$B(r)=m_0\omega/e\ (1-r^2\omega^2/c^2)^{1/2} \tag{3}$$

in which it is stipulated that the angular velocity shall be a constant, but the magnetic field B is allowed to vary with

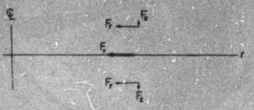

Fig. 3. Force vectors resulting from field of form illustrated in Fig. 2

radius in the cyclotron. With this condition, the first part of equation 3 can be solved for B as a function of r, yielding the result shown. In Fig. 1 the function B of r is plotted versus r, and as the figure shows, is a monatonic increasing function with an infinite singularity at the point where the quantity $r\omega/c$ is equal to 1. This singularity corresponds to rotation of the particle with velocity equal to that of the velocity of light which, on the basis of the theory of relativity, is an unattainable situation. The singularity also corresponds to particles of infinite energy so that for any practical device, the region of interest is the one prior to the singularity, in which the magnetic field rises smoothly from its central value to some maximum specified by the design energy of the particular accelerator. A magnetic field increasing with radius in this fashion (where the rotational frequency is constant) leads, however, to severe difficulties of another character.

To see the nature of these difficulties it is necessary to consider the restrictions which Maxwell's equations impose on the possible shapes of magnetic fields. In the gap of the magnet, the curl of the magnetic field is zero so that a set of equations can be set up relating the various partial derivatives of the magnetic field, as is seen in equation 4.

$$\text{curl } \mathbf{B}=0$$

$$\partial B_r/\partial z=\partial B_z/\partial r \tag{4}$$

If the magnetic field is expanded about the plane $z=0$, equation 5 is obtained. Because of the summetry of the magnetic field with respect to this plane, the z independent term is zero yielding the result

$$B_r(r,\theta,z)=B_r(r,\theta,o)+\partial B_r(r,\theta,z)/\partial z|_{z=0} +\ldots\ldots=z\partial B_z/\partial r \tag{5}$$

If the partial derivative of B_z with respect to r is positive then it is seen at once that the sign of B_r is the same as the sign of z or that the lines of magnetic force have the shape shown on Fig. 2, bending outward away from the center line.

If components of force are computed for particles lying off of the plane of symmetry, or median plane as it is called, the results shown in Fig. 3 are obtained and it is seen that the z component of force is in every case in such a direction as to pull further away from the plane particles which are already out of the plane. Particles exactly on the median plane feel no z force but are in a state of unstable equilibrium. This is a very serious situation. In being accelerated particles must move through a long path from the center of the cyclotron to the extraction region, of the order of miles in a typical cyclotron, and throughout the process must be within 1 inch of the median plane in order to avoid physical obstacles. Since the number of particles lying exactly in the median plane is essentially zero, almost no particles will survive the complete acceleration process if the force situation is as shown in Fig. 3. A field with such properties is referred to by analogy from optics as a defocusing field. Correspondingly, if the off-median plane forces tend to restore the particles to that plane, then the field would be described as focusing. There is, then, a fundamental contradiction between the requirements for focusing and for constant frequency acceleration in the case of magnetic fields with axial symmetry.

In the conventional fixed-frequency cyclotron,[2] this difficulty is resolved in a somewhat unsatisfactory manner by using a magnetic field which decreases with radius to provide the necessary focusing and a high-voltage r-f system which accelerates the particles to their maximum energy before they make a sufficient number of turns to slip out of phase. The maximum energy is then limited by the voltage which can be obtained on the r-f system. The maximum thus far achieved is 400 kv dee to dee in Oak Ridge National Laboratory's (ORNL) 86-inch cyclotron which then yields protons of energy 23 mev (million electron volts).[3]

Sector-Focused Cyclotron Development

PRINCIPLES

In 1938 L. H. Thomas[4] proposed an alternate solution to this dilemma of the fixed-frequency cyclotron. Thomas' solution utilized a magnetic field which varied with azimuth in such a manner that additional focusing forces were derived from the azimuthal variations. These forces could be of sufficient strength to overcompensate the defocusing forces arising from the base magnetic field so that the latter could be set to increase with radius in the manner necessary to provide constant-frequency acceleration. As proposed by Thomas, the variation of the magnetic field with azimuth was of sinusoidal form. It can be shown[5] that the sinusoidal magnetic waveform is not an essential feature of the design; the basic concepts are easier to envisage if one considers a cyclotron utilizing separate uniform-field magnets, as in Fig. 4 which depicts a cyclotron magnet composed of three separate wedge-shaped magnets, each with uniform magnetic field over the region of the wedge and zero field between the wedges. In such a situation, an orbit has the form shown in Fig. 4, being a straight line in the regions between the three wedge magnets and bending through 120 degrees in the regions of magnetic field. A close examination of the region near the edge of a wedge, as shown in section AA of Fig. 4, shows that because of the curvature of the magnetic lines at the edge of the magnet, a particle with trajectory not in the plane of symmetry will encounter an azimuthal component of magnetic field which is opposite in direction, depending upon the side of the median plane in which the particle is moving. Since the particle's trajectory is a straight line in the field-free region between magnets, the velocity v of the particle, if resolved at the point where the particle is entering a magnet, is seen to have both an azimuthal and a radial component. Using the usual cross-product rule, it is found that the cross product of the radial component of velocity and

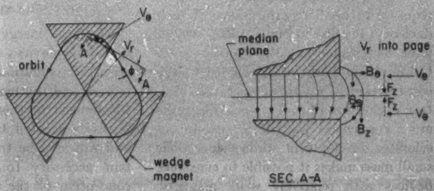

Fig. 4. Origin of sector focusing forces

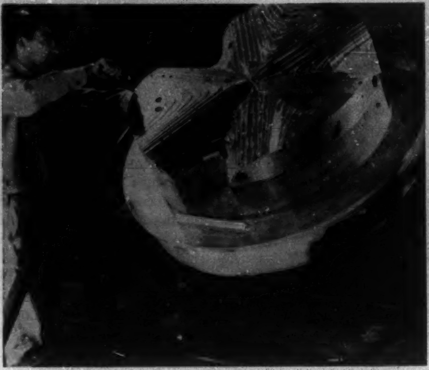

Fig. 5 (left). Assembled pole of University of California Lawrence Radiation Laboratory (UCLRL) 3-sector electron cyclotron

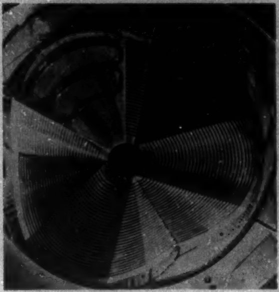

Fig. 6 (right). Orbit coils and three typical "hill" coils used in UCLRL cyclotron

the azimuthal component of the magnetic field is in a direction such as to give a restoring or focusing z force. Likewise, by similar analysis it will be found that a restoring force is also exerted in the region where the particle leaves the magnet; both the radial component of velocity and the azimuthal component of the magnetic field have changed signs, thereby yielding the same sign for the z component of the cross product. These forces at the edge of the magnet then constitute a separate source of restoring forces which can be used to focus the beams of accelerated particles so that they will remain in the desired region and eventually arrive at the extraction radius of the cyclotron. Detailed analysis and numerical calculations show that the strength of this additional focusing force is largely independent of the waveform of the azimuthal variation and, in fact, to good accuracy the focusing strength is found to be specified simply by the mean-square deviation of the field from its mean which can be made as large as necessary.

University of California Model Studies

Although proposed by Thomas in 1938, active development of the sector-focused cyclotron did not begin till much later, principally because of the complexity of the magnetic fields and of the analysis required to predict performance of such devices. Finally, around 1950, studies were undertaken[6] at the University of California in Berkeley which led to the construction of a pair of operating electron cyclotrons[7] of this type. (Electrons are a convenient particle for use in accelerator development studies since their small mass makes it possible to construct devices with relatively weak magnetic fields and small size, but in which the orbit properties are a simple photographic reduction from the orbit properties of devices to accelerate particles of heavier mass.) In these model explorations, three "sectors" were employed in the magnetic field, i.e., the profile of the magnetic field versus azimuth had a threefold symmetry. The azimuthal waveform of the magnetic field was of sinusoidal form in both of the models, the magnet face being intricately machined to a shape which would produce the desired field variation. Fig. 5 shows one of the poles of the magnet. In addition, an extensive arrangement of coils was employed to make empirical fine adjustments to the field, based on observations of beam phenomena. A portion of the coil array is seen in Fig. 6. The models operated successfully, accelerating particles through a large number of turns (of the order of 1,500) which established that uniformity of rotation frequency had been quite accurately achieved. Electrons were accelerated to a final velocity slightly larger than one half of the velocity of light. Fig. 7 shows the beam pattern as seen on a probe being slowly withdrawn from the cyclotron. The extraction of particles at the maximum design energy was also studied in some detail, and considerable success achieved.

Focusing Oscillation Resonances

The final energy of the University of California devices was determined by a resonance condition between the particle motion and the magnet field periodicity. Phenomena of this type have been extensively treated by several authors,[8,11] and will here be treated only to the extent necessary to obtain a qualitative conception of the phenomena involved. If the equations of motion are expanded and solved to yield an equation for the oscillation of a displaced particle about its stable or equilibrium orbit, an equation of the following form is obtained

$$x''+\nu^{2}{}_{x}=\sum a_n\cos n\theta+x\sum b_n\cos n\theta\ldots\ldots \qquad (6)$$

where the a_n, b_n, etc., are related to various harmonic components in the azimuthal variation of the magnetic field, and the quantity ν relates to the frequency of oscillation of the particle about its stable or equilibrium trajectory. From the character of this equation it is seen at once that if ν is equal to any of the integers n, then a resonance condition obtains in which the amplitude of the oscillation will build up in an unbounded manner. Due to the physical limitations on the cyclotron beam space, such a build-up usually leads to loss of the beam. It can be shown that, similarly, terms with coefficient proportional to x cause loss of beam when ν takes on certain half-integral values, and terms with coefficient proportional to x^2 cause loss when ν is equal to certain one-third integral values, etc. This can be understood qualitatively if one considers equation 6, focusing attention on terms of the form x cos$n\theta$, and solves by a successive approximation procedure. In the first approximation the right-hand side of equation 6 is neglected thus yielding the standard solution, $x\sim$ cos$\nu\theta$. Substituting this approximate solution for x in the right-hand side of equa-

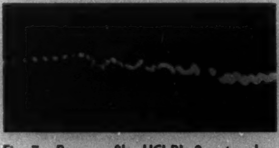

Fig. 7. Beam profile, UCLRL 3-sector electron cyclotron

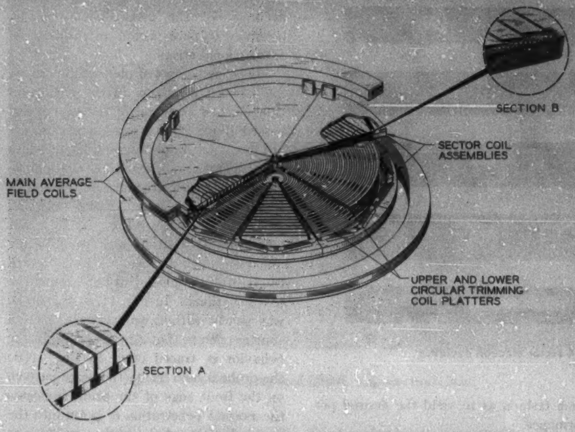

Fig. 8. Schematic drawing of coil structure of ORNL 4-sector electron cyclotron

tion 6 yields terms of the form $\cos\nu\theta\cos n\theta$ which, by standard trigonometric identities, are equivalent to $\cos(n+\nu)\theta+\cos(n-\nu)\theta$. If ν takes on the value $n/2$, then $n-\nu$ is also $n/2$, giving a driving term in resonance with the oscillation and yielding the characteristic rapid buildup of the oscillation amplitude.

For the axial motion of particles in the cyclotron, it is possible by proper manipulation of the amplitude of the sector-focusing fields so to control the oscillation frequency that no resonant value is approached. For the radial motion, this type of control is unfortunately not possible due to the requirement of uniform orbital period for the circulating particles which constrains the radial focusing frequency to a specific pattern of behavior. Thus, in all cases the radial focusing frequency is equal to the orbital frequency at the center of the cyclotron and thereafter rises in approximate direct proportion to the total energy. Hence, if the energy of the cyclotron is sufficiently high, resonant values are eventually encountered.

In the University of California model studies the principal component of the magnetic field was $\cos 3\theta$ so that terms with n equal to 3 were the dominant terms in equation 6. If the radial focusing frequency is measured in units of the orbital frequency, then at the center of the cyclotron it has the value one and thereafter rises, the first integral submultiple of n which is encountered being the value three halves. It was at this point that the acceleration was terminated in the Berkeley models.

More detailed analysis of orbit behavior in the neighborhood of resonances shows that for integral and half-integral resonances an actual stop band exists, by which is meant a band of energies for which there are no stable orbits; 3-sector cyclotrons must then, of necessity, terminate at or before the three-halves point. As the order of the resonance increases, its severity decreases and it is found[8] that for fifth and higher submultiples a region of stability exists even when the frequency of oscillation is exactly equal to the resonant value while for the intermediate third and fourth submultiple resonances, the region of stability vanishes when the frequency takes on exactly the resonant value, but there is no band of unstable frequencies as is the case for the integral and half-integral resonances.

OAK RIDGE NATIONAL LABORATORY MODEL STUDIES

The theoretical analysis leading to the foregoing predictions regarding the behavior of the various types of resonance are of an approximate nature and so in the period 1954–56 studies were undertaken at ORNL to test experimentally several of these predictions. A 4-sector electron cyclotron was constructed[13] which allowed the study of two important resonances. First, it should be noted that the four-halves resonance, which gives the first stop band, now occurred at a radial focusing frequency of 2 so that at intermediate energies the beam would pass through the next higher order essential resonance which occurred at a frequency

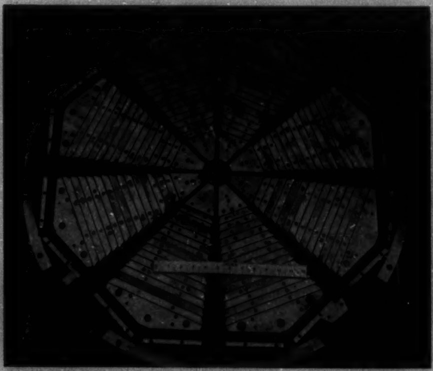

Fig. 9. Set of azimuthal coils for ORNL 4-sector electron cyclotron

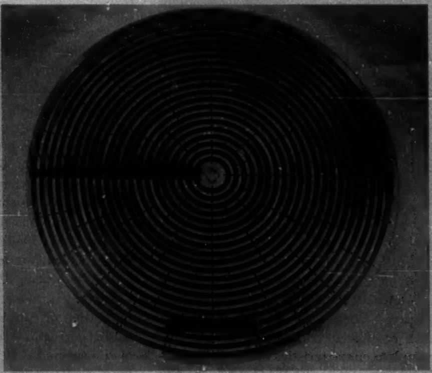

Fig. 10. Set of circular coils for ORNL 4-sector electron cyclotron

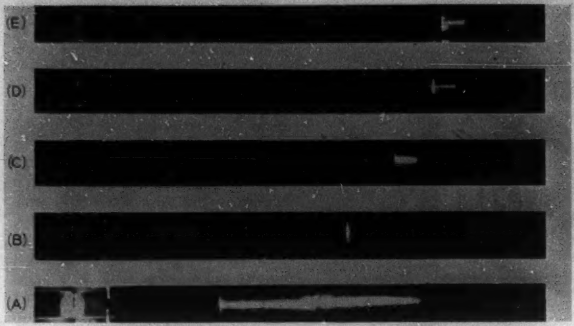

Fig. 11. Beam patterns for ORNL 4-sector electron cyclotron

of 4/3. In addition, although the magnetic field was designed to have purely fourth and higher harmonics, it was of interest to test the effect of the small amounts of third harmonic which would occur in the magnetic field as imperfection components. These imperfection components would manifest themselves as a three-halves resonance, which is therefore termed an "imperfection resonance."

The Oak Ridge electron cyclotron was of air-cored construction, i.e., no ferromagnetic materials were employed. Fig. 8 is a schematic diagram of the coil structure used in the device. Sets of circular coils provided a base field which increased with radius in the manner necessary to compensate the increase in mass of the particles as they were accelerated. Superimposed on this base field were azimuthal variations formed from the wedge-shaped sector windings seen in the figure. Fig. 9 is an actual photograph of a set of the wedge-shaped windings assembled and ready to be installed in the cyclotron. It will be noticed that there are eight coils, one coil of each pair of wedge sections being used to produce a hill or strong region of field, the adjacent coil being used to produce a valley or weak region of the field. Fig. 10 shows the layer of circular trimming coils which were used in conjunction with a large main field coil to produce the proper increase of field with radius. In the design process, the magnetic field produced by each of the coils was numerically computed and utilized for prior study of the orbit properties by means of numerical integration of the equations of motion. With a digital computer it was then possible to compute in advance the complete characteristics of the beam performance in the cyclotron and to modify the design in advance of construction in such fashion as to yield the desired performance.

Utilization of the digital computer for studies of this type has, in fact, become characteristic of recent development studies on the sector-focused cyclotrons, and is probably more responsible than any other factor for recent rapid progress in the development of such machines. Computer routines capable of tracking the trajectory of a particle through complex magnetic and electric field configurations have been developed by a number of persons,[13,14] and for several different types of computers. Such routines make it possible to study the behavior of orbits in close detail; with such information, the type of alteration necessary to effect improvements in performance is usually self-evident or becomes so after study of a few trial alterations.

The ORNL electron cyclotron was the first sector-focused accelerator to be completely designed on the basis of precomputed magnetic fields and orbit properties. Construction of the device consisted of fabrication of coils in careful conformity with computed specifications. Construction was completed and the cyclotron put into operation without recourse to mapping of the magnetic field, which is always a laborious process.

As a check on the reliability of such procedures, the performance of the device was experimentally studied in some detail after construction. Electrons in the machine made as many as 2,000 revolutions before reaching the extraction radius, indicating that a precision of the order of 1 in 5,000 had been achieved in realization of constant orbital frequency. Radial and axial focusing frequencies were also measured. In each case the measured performance duplicated the computed predictions to within either the accuracy of the measurement or the accuracy to be expected on the basis of fabricational errors.

Fig. 11 is a series of photographs showing beam phenomena in the cyclotron; they illustrate several of the effects discussed above. Each band across the figure is a separate photograph looking into the cyclotron. In each of the photographs, particles originate at the source which is on the far left of the band and are accelerated until they strike a flat metal probe coated with scintillating material which is seen to shine toward the right of the photograph in each of the five situations. In Fig. 11(A) the probe was slowly withdrawn with the camera shutter open so that a radial profile of the behavior is traced out. In Fig. 11(B) the probe is held fixed; the beam pattern on the front edge of the probe indicates the normal penetration of beam into the probe due to radial focusing oscillations and to acceleration. In Fig. 11(C) the penetration of the beam into the probe has greatly increased due to effects of the four thirds resonance which has excited large focusing oscillations in part of the beam, causing this portion to penetrate deeply into the probe. In Fig. 11(D) an additional view of the beam somewhat further out is shown in which the separation of the beam into two components is quite clearly evidenced. The "normal" or undisturbed component of the beam gives a bright vertical line on the front edge of the probe similar to that in Fig. 11(B), while the horizontal line extending across the probe is produced by particles of very-large-amplitude radial oscillation, the oscillation having been excited in passing through the resonance. In Fig. 11(E) a careful look will show that the "normal" component of the beam has now also begun to stream across the probe which indicates that the particles have reached the maximum energy and are moving into the band of instability at radial focusing frequency 2. Effects of the three-halves imperfection resonance are too small to be discerned. The studies of resonant phenomena which were made on this electron model showed agreement with the theoretically predicted behavior; this was a very important result and indicated at once that one of the most serious problems in cyclotrons of this type was of a tractable character.

HIGH-ENERGY SECTOR-FOCUSED-CYCLOTRON PROPOSAL

As a result of this work, the Oak Ridge group has made a study of a very large cyclotron of the sector-focused type utilizing an 8-sector magnetic field to accelerate

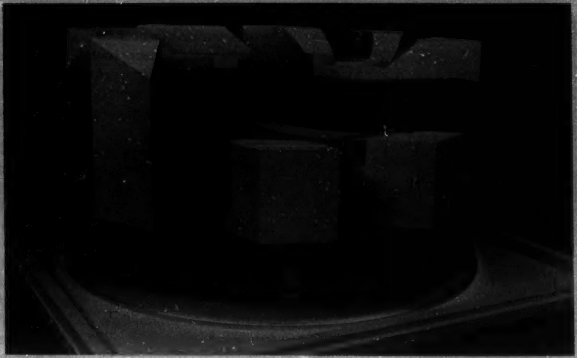

Fig. 12. Model of proposed ORNL 850-mev cyclotron

protons to a final energy of 850 mev.[15] Fig. 12 shows a model of this proposed cyclotron. The over-all diameter is approximately 50 feet, and about 2,500 tons of iron are required for construction of the magnet. Acceleration would be provided by two S-shaped r-f cavities which thread through the machine, the cavities being excited in the transverse electric mode, with the particles passing in and out of the cavity through thin slots cut along nodes of the cavity current distribution. Both the r-f cavities and the magnet would be enclosed in a large cylindrical chamber to obtain the necessary vacuum. It will be noted in the illustration that the magnet sectors are spiraled, an important effect not mentioned up to this point.

The influence of spiral sectors in strengthening the net axial focusing was first pointed out by D. W. Kerst of the Midwestern Universities Research Association.[16] Introduction of spiral clearly greatly strengthens the focusing at one edge of a sector and correspondingly weakens the force at the opposite edge with the result that one edge is strongly focusing and the other rather strongly defocusing. This is just the situation which is necessary to obtain the so-called "strong" or "alternating gradient" focusing which is being employed in several large synchrotrons now in construction. Details of the effect have been extensively discussed elsewhere[17] and so will not be considered further here. (For the reader who desires a qualitative understanding of the effect a review of the corresponding optical situation is suggested. It will be found that a positive and negative lens of equal focal length when separated by some distance L give rise to a net positive focusing force of considerable strength because a given ray passes through the positive lens further from the axis than when passing through the negative lens and so receives a larger positive bend.)

The feasibility of this very large spiral-ridge cyclotron is presently being further explored at Oak Ridge. A second electron model is in design which will realistically incorporate essential features of the large 8-sector machine.

MEDIUM-ENERGY SECTOR-FOCUSED CYCLOTRONS

Subsequent to the University of California and Oak Ridge model studies of high-energy sector-focused cyclotrons, considerable interest has arisen in the application of the principle in the medium-energy region (the region extending from approximately 30 to 100 mev). This region is just above the boundary of the region accessible to conventional fixed-frequency cyclotrons (as mentioned above, the highest particle velocity which has been achieved in a cyclotron of this type is in the Oak Ridge 86-inch cyclotron which yields 23-mev protons). Coupled with the use of sector focusing to extend the energy range has been a movement toward greater flexibility and variability of the beam characteristics of the cyclotron, which results in research tools of unusually versatile character.

The first major step along these lines was made at the Los Alamos Scientific Laboratory in a major redesign and rebuilding of the Los Alamos 42-inch cyclotron[18] which was completed about 2 years ago. Small sector-focusing shims were incorporated in the cyclotron, adding somewhat to the focusing strength which was then derived from a combination of conventional cyclotron focusing plus sector focusing. The base field in the cyclotron still decreases with radius so only a limited number of turns can be accomplished before the particles slip out of phase, the situation being analogous to that which would obtain in a strictly conventional cyclotron. In addition to the sector shims, the cyclotron was provided with an oscillator of adjustable frequency and with devices to permit variation of the magnetic field over a considerable range of field strength, so that it became possible to vary the energies of the output particles and also to accelerate different particles. Prior to the Los Alamos work a small conventional cyclotron with adjustable magnetic field and radio frequency had been constructed at the University of Rochester and a second larger instrument at the University of California's Livermore Laboratory.[19]

Recently a group of Russian scientists reported the completion of a sector-focused spiral-ridged cyclotron at the government laboratory in Dubna.[20] In this cyclotron, the main field increases with radius as is required to provide for constant-frequency acceleration and the machine thus is one of the first operating cyclotrons depending entirely on sector focusing to contain the particles.

Similar devices are in design or construction at a number of laboratories in the United States. In particular, the

Fig. 13. Magnet yoke for 75-mev Oak Ridge relativistic isochronus cyclotron

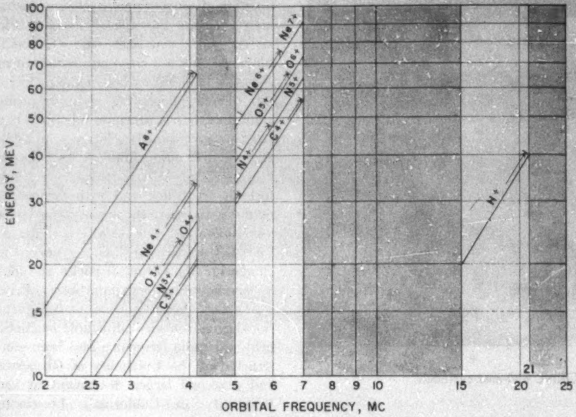

Fig. 14. Particle energy versus orbital frequency for the various particles and energies to be obtained from proposed MSU 64-inch cyclotron

laboratories engaged in actual construction of new cyclotrons of this type are the Oak Ridge National Laboratory, The University of California's Lawrence Radiation Laboratory, University of California at Los Angeles, and the University of Colorado. It seems probable that one or more of these machines will be in operation late in the year 1961. Fig. 13 shows the magnet which will be used in the Oak Ridge cyclotron and gives some idea of the size of equipment involved.

DESIGN FEATURES OF PROPOSED MICHIGAN STATE UNIVERSITY CYCLOTRON

In addition to the above listed machines which are in construction, a number of groups are engaged in the active design of machines of this type, including a group at Michigan State University (MSU) of which the author is a member. In order to provide some idea of the properties of machines of this type, the major features of the proposed MSU cyclotron will be reviewed. This machine is, in most respects, similar to machines being designed or constructed at other institutions and so will be a reasonably typical example of the type of instrument. It also, of course, is the one with which the author is most familiar.

Fig. 14 is a plot of the particles and energies which it is expected to obtain from the MSU cyclotron. The r-f system will operate over the range from 15 to 21 mc which will, in turn, by virtue of the properties of the cyclotron, accelerate particles on any odd submultiple of the radio frequency so that particles or orbital frequency from 5 to 7 mc are accelerated on the third submultiple and similarily for lower orbital frequencies. On the fundamental frequency, protons of energy adjustable in the range 20 to 40 mev are obtained. On the lower frequency a variety of so-called "heavy ions" are accelerated to a broad range of energies; where the term "heavy ions" refers to partially ionized nucleii of atoms in the carbon, nitrogen, oxygen, neon range of the periodic table.

Fig. 15 is a diagram of the pole-tip profile which will be used in the magnet to provide the sector-focusing forces. Of particular interest is the relatively simple geometric configuration of the pole tip; the simple geometry results from taking full advantage of the arbitrary character of the azimuthal waveform of the magnetic field. This pole is in marked contrast to the complex pole structure required to achieve an explicit sinusoidal dependence for the azimuthal variation. The simplification of the pole structure from that thought necessary in the early work is one of the major factors in the evolution of the sector-focused cyclotron to a state of proved feasibility.

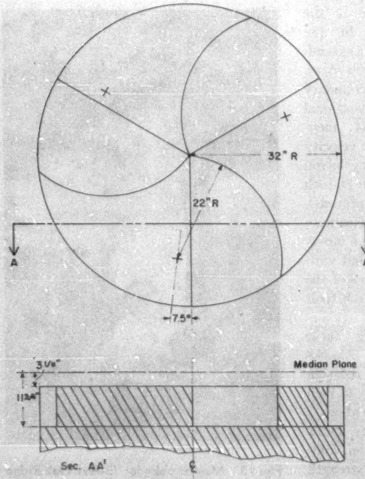

Fig. 15 (left). Pole-tip geometry of proposed MSU 64-inch cyclotron

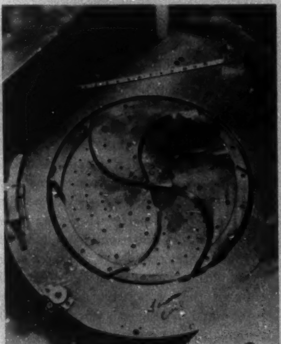

Fig. 16 (right). Model magnet used in design studies of UCLRL 88-inch cyclotron

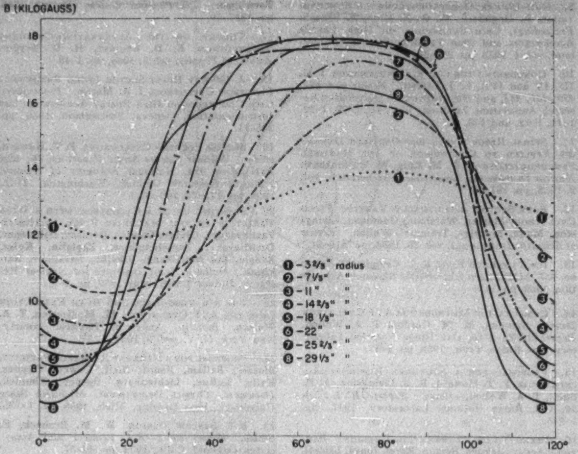

Fig. 17. Magnetic field obtained from pole tip of the type shown in Fig. 15

Fig. 16 shows one of the pole geometries being considered for use in the UCLRL 88-inch cyclotron now in construction. The illustration shows the 1/5-scale model which is being used in the studies. It will be noted that considerably greater spiral is employed than in the geometry shown in Fig. 15.

The actual variation of magnetic field with azimuth produced by the pole-tip shape of Fig. 15 is shown in Fig. 17. It is seen that the field varies from roughly 8 to 18 kilogauss in going from valley to hill at radii near the maximum. This is sufficient to provide adequate focusing for all the proposed particles. Fig. 18 shows the computed axial focusing frequency for protons and a typical heavy ion. Such studies of the properties of cyclotrons of this type are carried out by constructing accurately scaled models of the proposed magnet and measuring the field produced by the model. The measured field information is used to make digital computations of the properties of orbits. In this way it can be established whether the focusing is adequate and the rotational frequency sufficiently constant to provide the desired acceleration of particles to the maximum energy.

Considerable study has been made of the possibility of using one of the resonances in such a device as a means for extraction of the beam of particles. Conceptually, such an extraction is accomplished by so perturbing the field that a resonance is reached at the maximum energy. Particles reaching this energy then undergo the typical resonant increase in the amplitude of their focusing oscillation so that a very large gain in amplitude occurs, the gain being large enough in some situations to carry the particles completely out of the machine, thus accomplishing the extraction with a minimum of additional physical components. Extensive studies of processes of this sort have been carried out at Michigan State and other institutions and further studies are in progress.[21,22] At the present state of progress, it is well established that systems of this type are feasible, although complete details have not yet been worked out.

Fig. 19 shows in schematic form the r-f system[23] for the MSU cyclotron. The D-shaped accelerating electrodes are seen at the lower part of the figure. These electrodes constitute a capacitive load which is coupled through an inductive line to yield a system resonant at the required frequency. Adjustment of the resonant frequency is accomplished by variation of the characteristic impedance of the inductive line, the variation of impedance being achieved by an actual mechanical shift in the shape of the external conductor of the line using a system of flexible panels. In this way a system resonant over the range from 15 to 21 mc can be achieved with high Q such that the dee's can be excited to 140 kv by an r-f power source of approximately 200 kw. Other features are of less importance and will not be discussed further in this paper.

Conclusions

It is expected that in the United States during the next 5 to 10 years approximately a dozen cyclotrons will be built of the medium-energy sector-focused type such as the one described above. In addition, there is a distinct possibility that one or more of the high-energy cyclotrons discussed earlier in the paper will also be built. These devices will constitute powerful new tools for use in

Some Basic Concepts for Magnet Coil Design

W. F. GAUSTER
MEMBER AIEE

IN THE United States and abroad there is intensive activity in thermonuclear research.[1] A major part of this effort is directed toward containment, in strong magnetic fields, of plasma of the necessary high-particle energies, corresponding to temperatures of hundreds of millions of degrees Kelvin. Magnetic field design in thermonuclear research has already been developed to a relatively broad field of electrical engineering.[2] The purpose of this paper is to discuss some theorems which are of special interest for the design of large d-c magnet coils as used, for instance, in the DCX (d-c experiment) thermonuclear research program of the Oak Ridge National Laboratory.[3]

1. Cylindrical Magnet Coils With Square Ends and Uniform Current Density

The design of high-power magnet coils is based on fundamental work by Fabry,[4,5] Cockcroft,[6] and Bitter.[7] It is advisable to summarize a few well-known points contained in this theory. The simplest type of magnet coil is cylindrical with square ends and is designed for operation with uniform current density; see Fig. 1. Fabry showed that the magnetic field strength at the coil center H_0 can be expressed by

$$H_0 = G\sqrt{\frac{P\lambda}{\rho a_1}} \tag{1}$$

where

P = ohmic loss power, watts

λ = space factor $= \dfrac{\text{conducting cross section}}{\text{total cross section including insulation}}$

ρ = resistivity of the coil conductor, ohm-cm (ohm-centimeters)

a_1 = inside radius of the coil, cm

H_0 is measured in oersteds, and B_0 has the same numerical value in gausses (no ferromagnetic material is supposed to be in the magnetic field). G is a dimensionless factor, the so-called Fabry factor, which does not depend on the size but only on the shape of the coil.

By introducing the ratios

$$\alpha = \frac{a_2}{a_1};\quad \beta = \frac{b}{a_1} \tag{2}$$

(see Fig. 1), G can be expressed as a function of α and β in an elementary way.[4] It is convenient to represent G by a family of curves; see Fig. 2.[8] A "flat"

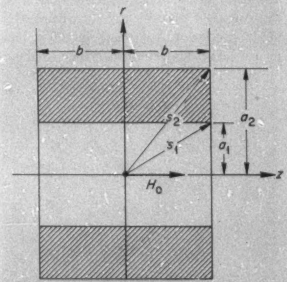

Fig. 1. Coil with rectangular cross section and uniform current density

Paper 60-1409, recommended by the AIEE Nucleonics Committee and approved by the AIEE Technical Operations Department for publication. Manuscript submitted November 25, 1959; made available for printing September 29, 1960.

W. F. Gauster is with the Oak Ridge National Laboratory, Oak Ridge, Tenn.

The author wishes to express his gratitude to Dr. J. P. Neal and to T. F. Connolly for their helpful co-operation in editing this paper. After completing the manuscript the author became aware of the excellent work of Dr. F. Gaume,[13] a complete presentation which includes, besides coil optimization, heat transfer and mechanical force problems.

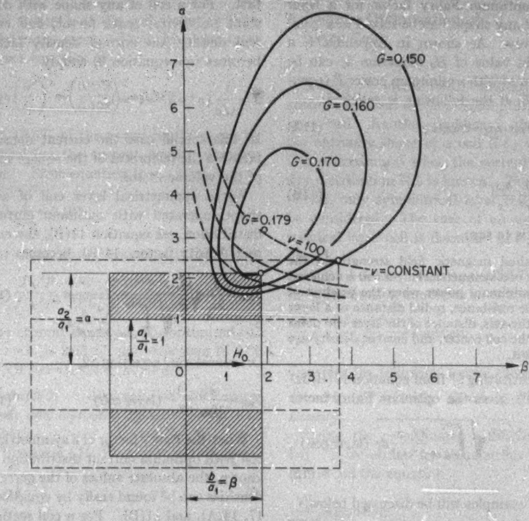

Fig. 2. Fabry and volume factor diagrams of cylindrical magnet coils with square ends and uniform current density

maximum of $G = 0.179$ occurs for $\alpha = 3.09$, $\beta = 1.88$.

Fabry also used a volume factor v, defined by

$$v=\frac{\text{total coil volume}}{a_1^3} \tag{3}$$

For instance, in the case of a cylindrical coil with square ends, $v = 2\pi(\alpha^2-1)\beta$. In Fig. 2, v = constant curves are shown by dashed lines. $G_{\max}$ corresponds to $v=101$. A somewhat smaller G can be achieved with a much smaller volume factor. For instance, the DCX coils are designed with the following data:[9]

$\alpha=1.53$
$\beta=0.618$
$v=5.21$
$G=0.128$

Fabry gave a table showing, for volume factors between 1 and 10^5, values of α and β for which G assumes maximal values.[10] The DCX coil is such a minimum-volume coil. It should be pointed out, however, that for many applications a minimum volume factor is not of special importance, since the whole field configuration produced by the magnet coil must be considered.

2. Fabry Factor of a Layer Coil

A coil shall be called a "layer coil" if it is wound in straight homogeneous layers; i.e., if current density i, measured in amp/cm² (amperes per cm²), resistivity ρ, and space factor λ are functions only of the distance from the axis of r. If these quantities are functions of r and z, the coil will be called a "loop coil." Fig. 3 shows a layer coil which is symmetrical to a plane through 0 perpendicular to the z-axis. In the following, a general expression for the Fabry factor G will be derived for a symmetric layer coil where the magnetic field strength H_0 is referred to the coil center. A similar expression can be found for an asymmetric layer coil, and H_0 referred to any point at the axis; see Appendix II.

A cylindrical current sheet with a radius r, the length $2z$, and a thickness dr produces in the center the field strength (compare, for instance, reference 11).

$$dH_0=\frac{4\pi}{10}\lambda i\cos\phi\, dr=\frac{4\pi}{10}\lambda i\frac{z}{s}\,dr$$

Therefore

$$H_0=\frac{4\pi}{10}\int_{r=a_1}^{a_2}\lambda i\frac{z}{s}\,dr \tag{4}$$

The power dissipated in the infinitesimal current sheet is

$$dP=\rho i^2 dV_{Cu}=\rho\lambda i^2 dV=4\pi\rho\lambda i^2 rz\,dr$$

Therefore

$$P=4\pi\int_{r=a_1}^{a_2}\rho\lambda i^2 rz\,dr \tag{5}$$

Normalized (dimensionless) quantities, which are in general functions of r, are introduced as follows:

$$i^+=\frac{i}{i_1};\ \rho^+=\frac{\rho}{\rho_1};\ \lambda^+=\frac{\lambda}{\lambda_1} \tag{6}$$

The subscript 1 refers to the innermost layer where $r=a_1$.

Equations 4 and 5 become

$$H_0=\frac{4\pi}{10}\lambda_1 i_1\int_{r=a_1}^{a_2}\lambda^+ i^+\frac{z}{s}\,dr \tag{4A}$$

and

$$P=4\pi\rho_1\lambda_1 i_1^2\int_{r=a_1}^{a_2}\rho^+\lambda^+(i^+)^2 rz\,dr \tag{5A}$$

Eliminating i_1 from these equations (compare Bitter's computation of G for several special cases[7]) yields

$$H_0=G\sqrt{\frac{P\lambda_1}{\rho_1 a_1}} \tag{7A}$$

$$G=\sqrt{\frac{\pi a_1}{5}}\,\frac{\int_{r=a_1}^{a_2}\lambda^+ i^+\frac{z}{s}\,dr}{\sqrt{\int_{r=a_1}^{a_2}\rho^+\lambda^+(i^+)^2 rz\,dr}}$$

(layer coil) **(7B)**

Equation 7(B) contains a_1; however, G is dimensionless and therefore independent of the magnitude of a_1.

3. Fabry Factors of Cylindrical Coils with Tapered Ends

As an example of the application of equations 7(A) and 7(B), a cylindrical coil with tapered ends (see Fig. 4), constant space factor ($\lambda^+=1$), and constant specific resistance ($\rho^+=1$) will be considered. The current density is also assumed to be constant, inversely proportional to the radius r, or inversely proportional to r^2.

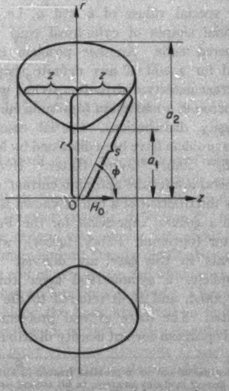

Fig. 3. Symmetrical layer coil

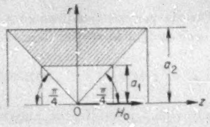

Fig. 4. Cylindrical coil with tapered ends

Case 1: $i^+=1$

$$G=\frac{\sqrt{3\pi}}{5}\sqrt{\frac{k}{1+k^2}}\frac{\alpha-1}{\sqrt{\alpha^2-1}} \tag{8}$$

The maximum value for G is 0.172, for an angle $\phi=45$ degrees ($k=1$), and $\alpha=2.7$. This is case 4 of Bitter's paper.[7]

Case 2: $i^+=a_1/r$

$$G=\frac{\sqrt{\pi}}{5}\sqrt{\frac{k}{1+k^2}}\frac{\ln\alpha}{\sqrt{\alpha-1}} \tag{9}$$

The maximum value for G is 0.201, again for an angle $\phi=45$ degrees, but for $\alpha=4.5$. This is Bitter's case 5.

Case 3: $i^+=(a_1/r)^2$

$$G=\frac{\sqrt{\pi}}{5}\sqrt{\frac{k}{1+k^2}}\sqrt{\frac{\alpha-1}{\alpha}} \tag{10}$$

The maximum value for G is 0.250, for an angle $\phi=45$ degrees, and α approaching infinity. This case has been previously discussed by Gaume.[12] It deserves interest because this current distribution yields the maximum G for a cylindrical layer coil with tapered ends.

4. Optimum Current Density Distribution of a Layer Coil

In the previous paragraph maximum values of G were considered which occur for special values of k and α, i.e., for special shapes of cylindrical coils with tapered ends. Another problem is to find for a coil of any definite shape a current density distribution $i(r)$ at which G becomes a maximum (optimum current density distribution). Special cases of this problem have been discussed by Maxwell,[13] Fabry,[*] and Bitter.[7] Here a general law for the optimum current density distribution of a coil of known shape and a general expression for the Fabry factor (optimum Fabry factor), which results in this case, are derived. For simplicity a symmetrical layer coil is supposed, and H_0 is referred to the coil center. The more general problem, to find optimum current density distribution and optimum Fabry factor for a layer coil of any shape, can be solved in a similar way. As shown in Appendix I, a certain value of H_0 (equation 4) can be produced with a minimum power P (equation 5) if the following is satisfied:

$$\rho r s i=\rho_1 a_1 s_1 i_1=\text{constant} \tag{11A}$$

Thus

$$i^+=\frac{1}{\rho^+}\frac{a_1 s_1}{s} \tag{11B}$$

That is to say:

A desired magnetic field strength in the center of a symmetrical layer coil is achieved with minimum power when the product of specific resistance, radial distance of a layer from the axis, distance of the layer end point from the coil center, and current density are constant.

Substituting i^+ from equation 11(B) into 7(B), gives the optimum Fabry factor

$$G_{\text{opt}}=\frac{\sqrt{\pi a_1}}{5}\sqrt{\int_{r=a_1}^{a_2}\frac{\lambda^+}{\rho^+}\frac{z}{rs^2}\,dr}\ \text{(layer coil)} \tag{12}$$

Some examples will be discussed below.

5. Current Density Factor J of a Layer Coil

As shown, the Fabry factor G is dimensionless and characteristic of a certain coil shape and the distribution of relative current density, space factor, and resistivity. The absolute value of H_0 is found by multiplying G by a scaling factor:

$$\sqrt{\frac{P\lambda_1}{\rho_1 a_1}}$$

See equation 7(A).

A similar procedure may now be used to find the absolute value of the current density i_1. From equation 5(A)

$$i_1=\sqrt{\frac{P}{4\pi\rho_1\lambda_1\int_{r=a_1}^{a_2}\rho^+\lambda^+(i^+)^2 rz\,dr}} \tag{13}$$

This equation can be written as

$$i_1=J\sqrt{\frac{P}{\rho_1\lambda_1 a_1^3}} \tag{14A}$$

$$J=\frac{1}{2}\sqrt{\frac{a_1^3}{\pi}}\sqrt{\frac{1}{\int_{r=a_1}^{a_2}\rho^+\lambda^+(i^+)^2 rz\,dr}} \tag{14B}$$

The dimensionless factor J shall be called the "current density factor." The absolute value of i_1 is found by multiplying J by a scaling factor:

$$\sqrt{\frac{P}{\rho_1\lambda_1 a_1^3}}$$

The analogy to the Fabry factor is obvious.

Two special cases might be considered first. For a coil of any shape with constant resistivity, space factor, and current density, the current density factor becomes (see equation 3) simply

$$J=\frac{1}{\sqrt{v}}\ (\rho^+=\lambda^+=i^+=1) \tag{15}$$

In this special case the current density factor is the reciprocal of the square root of the volume factor.

For a symmetrical layer coil of any shape, operated with optimum current distribution, see equation 11(B), the current density factor, 14(B), becomes

$$J_{\text{opt}}=\frac{1}{2s_1}\sqrt{\frac{a_1}{\pi}}\frac{1}{\sqrt{\int_{r=a_1}^{a_2}\frac{\lambda^+}{\rho^+}\frac{z}{rs^2}\,dr}} \tag{16}$$

Or, considering equation 12,

$$J_{\text{opt}}=\frac{a_1}{10s_1}\frac{1}{G_{\text{opt}}}\ \text{(layer coil)} \tag{17}$$

When the Fabry factor of a symmetrical coil with optimum current distribution is known, the absolute values of the current densities can be found easily by equations 17, 14(A), and 11(B). For a coil section similar to that shown in Fig. 3, $a_1=s_1$, and therefore

$$J_{\text{opt}}=\frac{1}{10}\frac{1}{G_{\text{opt}}}\ \text{(layer coil)},\ a_1=s_1 \tag{17A}$$

6. Examples of Layer Coils with Optimum Current Density Distribution

Example 1. Cylindrical Coil with Square Ends and Optimum Radial Current Distribution, $\rho^+=\lambda^+=1$; *see Fig 1*[5,7]

In this case equation 11(B) becomes

$$i^+=\frac{a_1\sqrt{a_1^2+b^2}}{r\sqrt{b^2+r^2}} \tag{18}$$

and equation 12 yields

$$G_{\text{opt}}=\frac{1}{10}\sqrt{\frac{2\pi}{\beta}\ln\frac{\alpha^2(1+\beta^2)}{\alpha^2+\beta^2}} \tag{19}$$

For a coil with $\alpha=3$, $\beta=2$, the Fabry factor is $G_{\text{opt}}=0.197$. From equation 17 the current density factor is

$$J_{\text{opt}}=\frac{1}{10\sqrt{5}}\times\frac{1}{0.197}=0.226$$

Equation 11(B) yields for the current density at $r=a_2=3a_1$

$$i_2=\frac{a_1 s_1 i_1}{a_2 s_2}=\frac{\sqrt{5}}{3\sqrt{13}}i_1=0.206i_1$$

It is interesting to compare these data with those for a cylindrical coil with square ends and constant current density and with the same a_1, α, β, ρ, and λ. The

---

[*] One special optimum problem treated in Fabry's first paper[4] contains an error; in his second paper,[5] however, all optimum values indicated are correct.

Vol
Pt.
196

field strength at the coil center in both cases is the same. Then the power ratio is (see equation 1)

$$\frac{P}{P'}=\left(\frac{G'}{G}\right)^2=\left(\frac{0.179}{0.197}\right)^2=0.825$$

i.e., 17.5% of the power can be saved by optimizing the current density distribution. From equation 15

$$J'=\frac{1}{\sqrt{v}}=0.100$$

Therefore, noting equation 14(A),

$$\frac{i_1}{i_1'}=\frac{J\sqrt{P}}{J'\sqrt{P'}}=\frac{JG'}{J'G}=\frac{0.226\times0.179}{0.100\times0.197}=2.05$$

The current density in the optimized coil at $r=a_1$ is 2.05 i_1', and decreases to 2.05 $i_1'\times0.206=0.424\ i_1'$ at $r=a_2$.

Example 2. Cylindrical Coil with Tapered Ends and Optimum Radial Current Distribution, $\rho^+=\lambda^+=1$; *see Fig. 4*

Equation 11(B) becomes in this case

$$i^+=\left(\frac{a_1}{r}\right)^2 \tag{20}$$

A cylindrical coil with tapered ends (resistivity and space factor constant) has a maximum Fabry factor when the current density is inversely proportional to the square of the distance from the axis. This is exactly the previously considered third example of section 3. For $k=1$ and $\alpha=3$, equation 10 yields $G_{\text{opt}}=0.204$. From equation 17, $J_{\text{opt}}=0.346$.

From equation 8 it follows that for a cylindrical coil with tapered ends, with $k=1$ and $\alpha=3$ but with constant current density, $G'=0.170$. With H_0 the same in each coil

$$\frac{P}{P'}=\left(\frac{0.170}{0.204}\right)^2=0.695$$

i.e., 30.5% power can be saved by optimizing the current distribution. From equation 15

$$J'=\frac{1}{\sqrt{\frac{4\pi}{3}(\alpha^3-1)}}=\frac{1}{\sqrt{108.9}}=0.0958$$

Therefore

$$\frac{i_1}{i_1'}=\frac{0.346\times0.170}{0.0458\times0.204}=3.01$$

The current density in the optimized coil at $r=a_1$ is 3.05 i_1' and decreases to $^1/_9$ of this value, i.e., to 0.334 i_1' at $r=a_2$. Whether or not the absolute value of the maximum current density is acceptable depends on the numerical value of the scaling factor

$$\sqrt{\frac{P}{\rho_1\lambda_1 a_1^3}}$$

7. Shape Optimization of Layer Coils

Section 4 dealt with finding the optimum current density distribution of a layer coil. Another problem is that of the optimum shape of a coil (i.e., where G is a maximum) when the current density distribution $i(r)$ is known. For simplicity, only symmetrical layer coils will be considered. The case of an unsymmetrical layer coil is discussed in Appendix II.

It can be shown (see Appendix I) that the optimization condition in this case is

$$\frac{\rho s^3 i}{r}=\frac{\rho(r^2+z^2)^{3/2} i}{r}=\text{constant} \tag{21}$$

Consider the following special cases:

Case 1: $\rho^+=i^+=1$, *Constant Current Density*

Using the co-ordinates s and ϕ (see Fig. 3), we obtain for the contour curve of the coil the equation

$$\frac{s^2}{\sin\phi}=\text{constant} \tag{22}$$

This case was considered by Fabry,[5] who found $G_{\max}=0.18$.

Case 2: $\rho^+=1$, $i^+=a_1/r$, *Current Density Inversely Proportional to the Distance from the Axis*

The equation of the contour curve is

$$\frac{s}{\sin^2\phi}=\text{constant} \tag{23}$$

The Fabry factor is again near 0.18.

Case 3: $\rho^+=1$, $i^+=(a_1/r)^2$, *Current Density Inversely Proportional to the Square of the Distance from the Axis*

In this case

$$\phi=\text{constant}=\frac{\pi}{4} \tag{24}$$

This layer coil is a coil with tapered ends, as considered in section 3, case 3, and section 6, example 2. It can be shown that this type of a layer coil represents the solution of the problem of finding the optimum Fabry factor when both shape and current density distribution are optimized simultaneously. However, in this case the maximum current density is relatively very high, and this combined with the difficulties of building such coils seems to limit their practical application.

8. Loop Coils

As mentioned previously, a loop coil, in contrast to a layer coil, is one in which the quantities i, r, ρ, and λ are functions of both co-ordinates r and z. Loop coils have little practical importance (although a slightly higher G is attainable) since their design is difficult. However, some basic theorems concerning loop coils and some numerical examples may be of interest.

Assume that a loop has an infinitesimally small cross-sectional area dA, in the z-r plane, and that its location is determined by the co-ordinates a and r (distance from the origin $s=\sqrt{z^2+r^2}$); then the magnetic field strength produced at the origin is (compare Bitter's computation of G for several special cases[7]):

$$H_0=\frac{2\pi}{10}\int_A \lambda\frac{r^2}{s^3}\,i\,dA \tag{25}$$

When normalized with respect to an appropriately selected reference loop (indicated by the subscript 1), this equation becomes

$$H_0=\frac{2\pi}{10}\lambda_1 i_1\int_A \lambda^+\frac{r^2}{s^3}i^+dA \tag{25A}$$

The power dissipated is

$$P=2\pi\int_A \rho\lambda r i^2 dA \tag{26}$$

or, normalized,

$$P=2\pi\rho_1\lambda_1 i_1^2\int_A \rho^+\lambda^+ r(i^+)^2\,dA \tag{26A}$$

Corresponding to equations 7(A) and 7(B) we obtain now for a loop coil

$$H_0=G\sqrt{\frac{P\lambda_1}{\rho_1 a_1}} \tag{27A}$$

$$G=\frac{\sqrt{2\pi a_1}}{10}\,\frac{\int_A \lambda^+\frac{r^2}{s^3}i^+\,dA}{\sqrt{\int_A \rho^+\lambda^+ r(i^+)^2\,dA}}\quad\text{(loop coil)} \tag{27B}$$

For the current density factor we obtain (compare equations 14(A) and 14(B)):

$$i_1=J\sqrt{\frac{P}{\rho_1\lambda_1 a_1^3}} \tag{28A}$$

$$J=\sqrt{\frac{a_1^3}{2\pi}}\,\frac{1}{\sqrt{\int_A \rho^+\lambda^+ r(i^+)^2 dA}}\quad\text{(loop coil)} \tag{28B}$$

Maxwell solved the problem of designing a galvanometer in which a given small electromotive force would produce the greatest possible deflection.[13] In a more general way we can ask about the optimum current density distribution of a loop coil of any shape, for which ρ and λ are known functions of z and r. Reasoning along the lines which led to finding the optimum current density distribution of a layer coil (see Appendix I) leads to the following optimization condition of a loop coil; compare with equations 11(A) and 11(B):

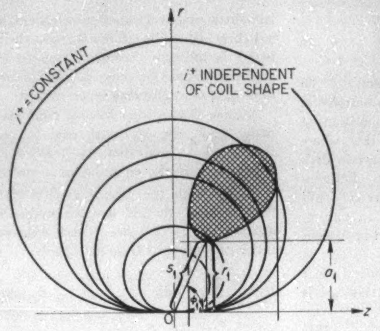

Fig. 5 (left). Optimum current density distribution of a loop coil

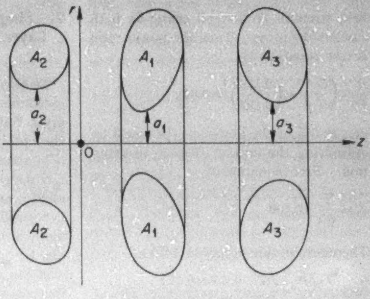

Fig. 7 (right). Set of optimized loop coils

$$\frac{\rho s^3 i}{r}=\frac{\rho_1 s_1^3 i_1}{r_1}=\text{constant} \tag{29A}$$

$$i^+=\frac{1}{\rho^+}\frac{s_1^3 r}{r_1 s^3}=\frac{1}{\rho^+}\frac{s_1^2}{\sin\phi_1}\frac{\sin\phi}{s^2} \tag{29B}$$

Substituting this value in equations 27(B) and 28(B) yields

$$G_{\text{opt}}=\frac{\sqrt{2\pi a_1}}{10}\sqrt{\int_A \frac{\lambda^+}{\rho^+}\left(\frac{\sin\phi}{s}\right)^2 dA} \tag{30}$$

$$J=_{\text{opt}}\frac{\sin^3\phi_1}{10G_{\text{opt}}} \quad \text{(loop coil)} \tag{31}$$

Equation 29(B) shows that the current density distribution does not depend on the shape of the cross-sectional area A of the coil, since the co-ordinates of the contour of the coil cross section do not appear in this equation. A family of curves can be drawn to represent the $i=$ constant lines which yield a maximum G for any shape of coil cross section; see Fig. 5. From equation 30 it follows that G_{opt} assumes the highest values if the coil cross section A extends from points as close as possible to its axis of symmetry. This is illustrated by the following examples of loop coils with optimized current density distribution.

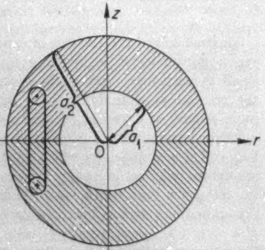

Fig. 6. Spherical coil

Example 1: Spherical Coil; Inside Radius a_1, Outside Radius a_2; see Fig. 6

A spherical coil is difficult to construct, since it must be built in two halves in order to provide access to the inner empty sphere. In this case

$$G_{\text{opt}}=\frac{1}{5}\sqrt{\frac{2\pi}{3}}\sqrt{\frac{\alpha-1}{\alpha}} \tag{32}$$

For very large α the Fabry factor approaches the value 0.289.[5]

Example 2: Long Cylindrical Solenoid; Inside Radius a_1, Outside Radius a_2

$$G_{\text{opt}}=\frac{\pi\sqrt{3}}{20}\sqrt{\frac{\alpha-1}{\alpha}} \tag{33}$$

For very large α the Fabry factor approaches the value 0.272.[6,7]

Example 3: Cylindrical Coil With Tapered Ends (Fig. 4)

$$G_{\text{opt}}=\frac{\sqrt{2\pi}}{10}\sqrt{\frac{3}{4}\left(\frac{\pi}{2}-\phi\right)+\frac{1}{2}\sin 2\phi-\frac{1}{16}\sin 4\phi}\;\sqrt{\frac{\alpha-1}{\alpha}} \tag{34}$$

For $\phi=\pi/4$

$$G_{\text{opt}}=0.262\sqrt{\frac{\alpha-1}{\alpha}} \tag{34A}$$

This yields $G_{\text{opt}}=0.213$ for $\alpha=3$.

As shown in example 2 of section 6, cylindrical layer coil of the same shape optimized in respect to current density distribution has a Fabry factor $G_{\text{opt}}=0.204$, which is only slightly smaller. The current density factor J_{opt}, however, increases noticeably from 0.346 for the layer coil to 0.470 for the optimized loop coil. This shows clearly the merely academic interest of this case.

Finally, the following theorem might be derived. Consider a set of n loop coils of any cross sections; see Fig. 7. The optimized Fabry factor of the coil k is, from equation 30,

$$G_{k\,\text{opt}}=\frac{\sqrt{2\pi a_k}}{10}\sqrt{\int_{A_k}\frac{\lambda^+}{\rho^+}\left(\frac{\sin\phi}{s}\right)^2 dA} \tag{35}$$

The optimized Fabry factor of the whole loop arrangement is

$$G_{\text{opt}}=\frac{\sqrt{2\pi a_1}}{10}\sqrt{\int_A\frac{\lambda^+}{\rho^+}\left(\frac{\sin\phi}{s}\right)^2 dA} \tag{36A}$$

The integration has to be performed over the total cross-sectional area A, i.e., over all the incremental areas A_k. Expressed in somewhat different notation,

$$G_{\text{opt}}=\frac{\sqrt{2\pi a_1}}{10}\sqrt{\sum_{k=1}^{n}\int_{A_k}\frac{\lambda^+}{\rho^+}\left(\frac{\sin\phi}{s}\right)^2 dA_k} \tag{36B}$$

Therefore

$$\frac{G_{\text{opt}}^2}{a_1}=\sum_{k=1}^{n}\frac{G_{k\,\text{opt}}^2}{a_k} \tag{37}$$

The Fabry factor is increased by the addition of more coils to the set. Its highest value is achieved when the whole available space is filled with windings. This is in contrast to layer coils. For these the Fabry factor decreases when a certain optimum winding space is exceeded.

Conclusions

1. General expressions for the Fabry factor of a layer coil (for which coil variables depend on the distance r from the axis only), and for a loop coil (coil variables depend on r and on axial coordinate z) have been derived; see equations 7(B) and 27(B). These general forms are convenient for the computation of the Fabry factor of a coil of any shape and any distribution of current density, resistivity, and space factor.

2. To produce a desired field strength

H_0 at any point on the axis, with the minimum power P, the following kinds of optimization are possible:

The coil shape and the distribution of ρ and λ are known; the problem is to find the optimum current density distribution. For symmetrical loop coils and layer coils with variable ρ and λ, general solutions have been found; see equations 11(B) and 29(B). The following result is of particular interest: A desired magnetic field strength in the center of a symmetrical layer coil is achieved with the minimum power when the product of resistivity ρ, radial distance r of a layer from the axis, distance of the layer end point from the coil center s, and current density i is constant.

The current density distribution of a layer coil is any known function $i=i(r)$, likewise the distributions of ρ and λ are known; find the shape of the optimum coil. A general solution has been found; see equation 21. Of particular interest is the current density distribution

$$i=\left(\frac{a_1}{r}\right)^2 i_1$$

In this case the optimum coil is cylindrical with tapered ends.

Simultaneously optimizing current density distribution and coil shape likewise leads to the cylindrical coil with tapered ends and current density inversely proportional to the square of the distance from the axis.

3. For any magnet coil, the current density i_1 in the innermost layer (or in the loop with smallest radius) can be represented by the product of a dimensionless factor, the current density factor J, and a scaling factor

$$i_1=J\sqrt{\frac{P}{\rho_1\lambda_1 a_1^3}} \qquad (14A)$$

The analogy to the Fabry factor is obvious. General expressions for the current density factors of layer and loop coils have been derived [equations 14(B) and 28(B)]. For a coil of any shape with constant resistivity, space factor, and current density, the current density factor J is the reciprocal value of the square root of the volume factor; see equation 15.

4. For coils with optimum current density distribution, simple general expressions for the Fabry factor G_{opt} have been derived; see equations 12 and 30. In this case the current density factor of a layer coil becomes

$$J_{\text{opt}}=\frac{a_1}{10 s_1}\frac{1}{G_{\text{opt}}}\text{(layer coil)} \qquad (17)$$

and that of a loop coil

$$J_{\text{opt}}=\frac{\sin^2\phi_1}{10}\frac{1}{G_{\text{opt}}}\text{(loop coil)} \qquad (31)$$

5. The Fabry factor, optimized with respect to current density, of n loop coils, each having the optimized Fabry factors $G_{k\,\text{opt}}$, is

$$\frac{G_{\text{opt}}^2}{a_1}=\sum_{k=1}^{n}\frac{G_{k\,\text{opt}}^2}{a_k} \qquad (37)$$

Numerical examples illustrate the basic concepts and theorems mentioned above.

Appendix I

Bitter[7] showed how to find the optimum current density distribution and the corresponding values of the Fabry factor of coils of known shape. He did this by the method of indeterminate multipliers, and the same mathematical method shall be applied here to the optimization of the current density $i(r)$ of a layer coil of any symmetrical shape and with any $\rho(r)$ and $\lambda(r)$ distribution.

From equations 4 and 5

$$F[i(r)]=H_0+\mu P=\frac{4\pi}{10}\int_{r=a_1}^{a_2}\lambda i\frac{z}{s}dr+\mu 4\pi\int_{r=a_1}^{a_2}\rho\lambda i^2 rz\,dr \qquad (38)$$

μ being an arbitrary constant.

$$\delta F[i(r)]=0 \qquad (39)$$

is satisfied if

$$\frac{4\pi}{10}\lambda\frac{z}{s}+\mu 8\pi\rho\lambda irz=0 \qquad (40)$$

Therefore

$$\rho rsi=-\frac{1}{20\mu}=\text{constant}=\rho_1 a_1 s_1 i_1 \qquad (41)$$

This is equation 11(A). Note that $\lambda(r)$ does not occur in this optimization condition for $i(r)$. The space factor $\lambda(r)$, of course, influences the Fabry factor, as shown in equation 12. A similar calculation can be used to prove equation 21.

Appendix II

Equations for Asymmetrical Layer Coils

Fig. 8 shows a layer coil with the z-axis as the axis of rotational symmetry. The coil, however, is not symmetrical to any plane perpendicular to the z-axis (asymmetrical layer coil). Referring to Fig. 8, the abbreviation

$$\cos\phi_{II}-\cos\phi_I=\psi \qquad (42)$$

is used. The magnetic field strength at the point 0 assumes the form

$$H_0=\frac{\pi}{5}\int_{r=a_1}^{a_2}\lambda\psi i\,dr \qquad (43)$$

This can be written in normalized form:

$$H_0=\frac{\pi}{5}\lambda_1 i_1\int_{r=a_1}^{a_2}\lambda^+\psi i^+dr \qquad (44)$$

The ohmic power loss becomes

$$P=2\pi\int_{r=a_1}^{a_2}\rho\lambda r(z_{II}-z_I)i^2dr$$
$$=2\pi\rho_1\lambda_1 i_1^2\int_{r=a_1}^{a_2}\rho^+\lambda^+r(z_{II}-z_I)(i^+)^2dr \qquad (45)$$

From these equations it follows that the Fabry factor

$$G=\frac{1}{5}\sqrt{\frac{\pi a_1}{2}}\frac{\int_{r=a_1}^{a_2}\lambda^+\psi i^+dr}{\sqrt{\int_{r=a_1}^{a_2}\rho^+\lambda^+r(z_{II}-z_I)(i^+)^2dr}} \qquad (46)$$

and the current density factor

$$J=\sqrt{\frac{a_1^3}{2\pi}}\frac{1}{\sqrt{\int_{r=a_1}^{a_2}\rho^+\lambda^+r(z_{II}-z_I)(i^+)^2dr}} \qquad (47)$$

The current density distribution for which G is a maximum can be found by the method discussed in Appendix I. The result is

$$\frac{\rho(z_{II}-z_I)r}{\psi}i=\text{constant} \qquad (48)$$

If we consider a coil cross section similar to that shown in Fig. 7, equation 48 applied to the point $r=a_1$ assumes the form 0/0, which evaluates to

$$\frac{\rho(z_{II}-r_I)r}{\psi}i=\frac{\rho_1 a_1^2}{\sin^2\phi_1}i_1 \qquad (49)$$

or

$$i^+=\frac{\psi}{\sin^2\phi_1}\frac{a_1^2}{(z_{II}-z_I)r\rho^+} \qquad (50)$$

This value substituted in equations 46 and 47 leads to

$$G_{\text{opt}}=\frac{1}{5}\sqrt{\frac{\pi a_1}{2}}\sqrt{\int_{a_1}^{a_2}\frac{\lambda^+\psi^2}{\rho^+}\frac{dr}{(z_{II}-z_I)r}} \qquad (51)$$

$$J_{\text{opt}}=\frac{\sin^2\phi_1}{10}\frac{1}{G_{\text{opt}}} \qquad (52)$$

IN RECENT YEARS, power klystrons, traveling-wave amplifiers (TWA), and various forms of crossed-field amplifiers and oscillators have been produced in relatively large numbers with essentially reproducible characteristics. Gradually these devices have found their way into more and more sophisticated systems applications with the logical result that they are competing with one another with regard to the most desirable set of characteristics. This competition deals with weight, efficiency, bandwidth, average power capability, and modulation characteristics, to name just a few items. In general it is not feasible to optimize or maximize all of these parameters in one tube and hence there seems to be room for all the above-mentioned device types, depending upon the particular application and which of the characteristics is most critical. The day of the high-gain high-power high-efficiency broad-bandwidth short-length lightweight low-noise amplifier to be powered by a solar cell is not yet here. The Crestatron amplifier to be described in this paper affords a means of optimizing several of these characteristics in one device.

The conventional growing-wave TWA utilizing a helical line as an r-f (radio-frequency) structure has a broad bandwidth capability due to the nonresonant nature of the helix. The helix is incapable of dissipating much r-f power because it in general can be radiation cooled only when supported inside a glass vacuum envelope. For example, an S-band TWA cannot handle more than approximately 250 watts of r-f power if only radiation cooling is used. Some increase has been obtained by using conduction cooling of the helix through ceramic rods to an outside metallic vacuum envelope. R-f structures that can handle more power are usually resonant periodic waveguides and these have a more limited bandwidth than the helix. Both types of TWA require an r-f attenuator capable of dissipating the output power in order to prevent oscillations due to reflections when the gain is high.

Unfortunately this attenuator limits the efficiency and power output and, of course, reduces the gain; hence it makes the tube longer for any given gain as compared with an attenuatorless tube.

In transmitter output tubes where power supply requirements are severe and high efficiency is very desirable, it would seem that a power tube with high efficiency, broad bandwidth, short length, and no attenuator would be most desirable in almost any systems application. It is feasible to build high gain in the low-power stages where high efficiency is not of paramount importance and to require only moderate gain of the final output tube.

Increasing the r-f power-handling capability of any tube is largely a problem of providing adequate conduction cooling of the structure and it is common to all types, i.e., klystron, TWA, and crossed-field devices. (This topic will not be further discussed here.) The question of broad-band versus narrow-band structures is one of nonresonant versus resonant structures. Helical waveguides can operate over an octave or more of frequencies, whereas most loaded-waveguide circuits operate only over a bandwidth of 5% to 15% of the center frequency.

In recent years, two devices operating at moderate gains without attenuators and at high efficiencies have been developed. One is a crossed-field device called the Amplitron and the other is an O-type device called the Crestatron.[1,2] The Amplitron may be described as an injection-locked oscillator having a nominal gain of 10 db (decibels), a bandwidth of 10%, and an operating efficiency of some 60%; it will not be further discussed here. The object of this paper is to present experimental results obtained on a series of S-band Crestatron amplifiers.

Crestatron Principle

The Crestatron amplifier is a form of traveling-wave device which operates on a beating-wave principle in that three constant-amplitude r-f waves traveling at different phase velocities along an r-f circuit beat with one another to produce a power gain. Two of the waves are out of phase at the input and the device length is chosen so that at its output the waves add in phase. It will be shown later in this paper that this is a broad-band

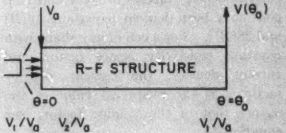

Fig. 1. Illustration of beating-wave amplification

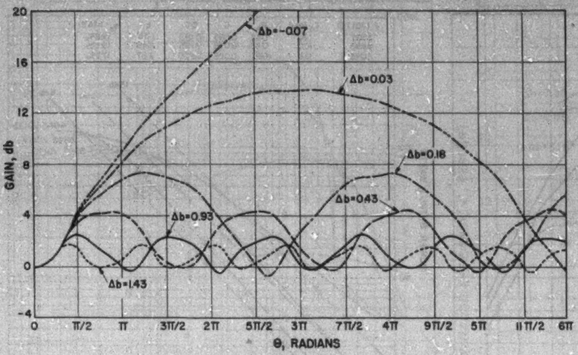

Fig. 2. Gain versus length; $C=0.1$, $QC=0.25$, $d=0$, $b_{x_1=0}=2.57$

phenomenon. A solution of the secular equation describing the effect of the beam on the circuit and the effect of the circuit on the stream gives a third-order equation in the propagation constants. The three waves result when an r-f voltage is applied to the input of the amplifier where the electron stream enters the interaction region, and this splits into three waves when the continuity of electron stream velocity and convection current are satisfied across the input boundary. This beating-wave phenomenon is illustrated in Fig. 1.

The Crestatron is operated with the electron stream velocity sufficiently larger than the circuit phase velocity so that the wave propagation constants are purely imaginary and only constant-amplitude waves traveling at different phase velocities exist on the structure. This stream voltage (velocity) is considerably higher than that used in the conventional growing-wave amplifier. It leads to an increased efficiency and power output over the growing-wave device. The gain of the Crestatron is proportional to the excess velocity over that at which the conventional growing-wave gain goes to zero. This is the point on the propagation constant diagram where the propagation constants change from complex values to purely imaginary ones. The detailed theory behind the Crestatron is given in reference 2.

Let us define the value of the velocity parameter b for which the growing-wave constant x_1 goes to zero as $b_{x_1}=0$ and then define Δb as the excess over this value.

$$b \triangleq \frac{1}{C}\left(\frac{u_0-v_0}{v_0}\right) \tag{1}$$

and

$$\Delta b \triangleq b-b_{x_1=0} \tag{2}$$

where

C = gain parameter
$u_0=(2\eta V_0)^{1/2}$, electron stream velocity
v_0 = circuit phase velocity

The gain of the Crestatron for a typical set of circuit and stream parameters is shown in Fig. 2. The parameters used in the figure are:

QC = space-charge parameter
$\theta=2\pi CN_s$, radian tube length
N_s = length of tube, stream wavelengths

The gain is calculated from the following voltage ratio, which involves the initial wave amplitudes and the propagation constants:

$$\frac{V(\theta)}{V_c(0)}=e^{-j\frac{\theta}{C}}\sum_{i=1}^{3}\left(\frac{V_{ci}}{V_c(0)}\right)e^{\delta_i\theta} \tag{3}$$

These gain calculations were made with a linear theory and it is seen that as Δb increases, the gain decreases and the device becomes shorter. The optimum length is seen to be approximately six slow wavelengths for the case shown.

For shortest device length it is always desirable to operate at the first maximum of the gain curve. This optimum length is given below as a function of Δb.

$$CN_s=\frac{\theta}{2\pi}=\frac{0.25}{(\Delta b)^{1/2}} \tag{4}$$

As the gain parameter C is increased through an increase in either the stream perveance or the circuit impedance, the optimum length decreases and the gain increases. The highest value of C achievable depends upon the frequency and the type of circuit used. Either a helical waveguide or any form of periodically loaded waveguide may be utilized. If C is considered constant the abscissa of Fig. 2 is proportional to frequency and it can be seen that the 3-db bandwidth is approximately 3 to 1. Clearly, then, this is a broad-band phenomenon.

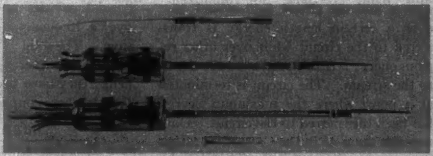

Fig. 3. S-band 100-watt Crestatron (approximately 1/5 size); $G=10$–12 db, $\eta>20\%$

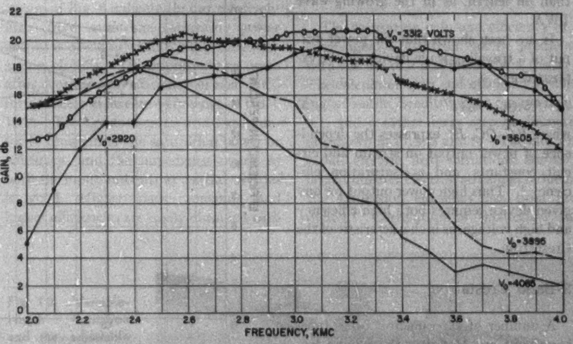

Fig. 4. Small-signal gain versus frequency for S-8-3 Crestatron. Drive level≅100 milliwatts; at 3.0 kmc, $C=0.095$, $QC=0.185$, $P\mu\cong0.60$

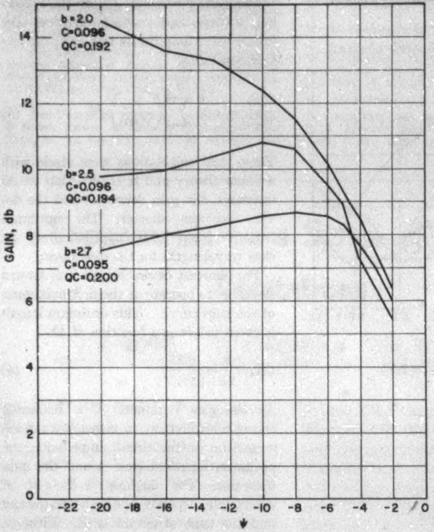

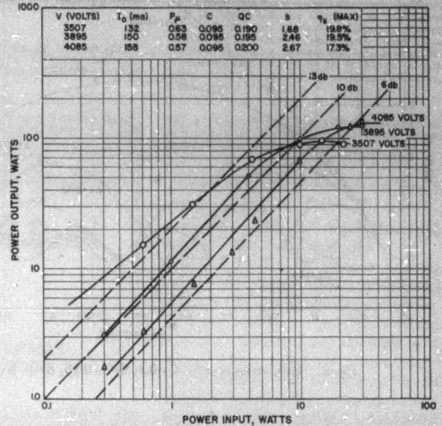

Fig. 5 (left). Saturation gain versus ψ (input signal level in db relative to $CI_0 V_0$) with b as parameter for S-8-3 Crestatron at 3.0 kmc; d = 0.0279

Fig. 6 (above). Power output versus power input for the S-8-3 Crestatron at 3 kmc

There is power gain in the device, and the added energy at the output comes from the electron stream. The three waves set up on the structure travel along at different phase velocities and the phase relationship between the r-f current in the stream and the circuit field is such that over a certain length energy is transferred to the circuit while over other regions energy is transferred from the circuit to the stream. The circuit is terminated at a point where the maximum energy has been transferred to the circuit. Gain depends upon Δb in the Crestatron rather than on length, as in the growing-wave TWA.

It has been shown that the power output of a traveling-wave device can be expressed as

$$P_0 = f(C,QC,B)\eta_s V_0^{5/2} \tag{5}$$

where $f(C, QC, B)$ expresses the dependence of power output on stream and circuit constants, and η_s = saturation efficiency.[3] Thus high power output for any given device requires both high efficiency and high voltage, as is characteristic of the Crestatron.

S-Band Crestatron

A number of experimental tubes have been built and tested in the S-band frequency range. The power level, efficiency, and gain are generally functions of the electron stream perveance. A typical S-band model giving over 120 watts is shown in Fig. 3. The active circuit (helix) is 2.5 inches and 3.75 inches long in the two tubes shown. The input and output transducers used were coaxial cavities and the tube operated over a frequency range of nearly an octave. The solid cylinders at the ends of the helix are necessary to terminate the helix; they have been eliminated on later models where coupled-helix couplers were used. This, of course, results in a further reduction in the tube length. The helix in this tube was not specifically designed for Crestatron operation but was taken from a growing-wave tube and simply made shorter in accordance with small-signal calculations. The electron gun was of modest perveance and the tube uses electromagnet focusing.

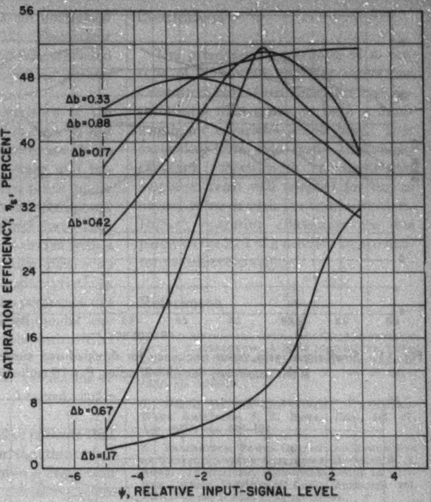

Fig. 9 (right). Efficiency versus drive power for constant b, C=0.1, QC=0.125, d=0, B=1

voltage (electron velocity). The high gain is associated with the fact that the drive level is small: 100 milliwatts. It is seen that the 3-db bandwidth is nearly an octave. The two reasons for the bandwidth limitation are: 1. The transducers have a high voltage standing-wave ratio (VSWR) at the band edges. 2. The helix is dispersive, giving rise to a higher impedance at the low frequencies, which results in a slower drop-off of the gain at high voltages for low frequencies. The coupler VSWR is less than 1.4 to 1 over most of the band. The total insertion loss including helix and both couplers is approximately 2 db.

The gain-versus-frequency characteristic at high voltages can easily be flattened by placing a metallic shield over the helix at a radius of 1.5 to 2 times the mean helix radius. This has the effect of lowering the low-frequency impedance of the helix more than the high-frequency impedance since the fields extend further from the circuit at low frequencies than at high frequencies. The shield tends to divert a fraction of the helix field to the region between the helix and the shield where it is not seen by the electrons. At low frequencies the gain is due to a growing-wave interaction, since x_1 is not zero here. This indicates that an extremely broad-band operation can be obtained by designing the tube to operate as a Crestatron in the high-frequency ranges and operate as a growing-wave amplifier at low frequencies. It is possible to effect a design of this type and obtain a flat gain curve versus frequency over a wide range.

The gain as a function of the drive level to the amplifier is shown in Fig. 5 for a range of some 20 db of drive relative to the product of the gain parameter times the d-c beam power CI_0V_0. For high voltages and moderate gains the saturation gain is relatively independent of the drive level, which is sometimes a desirable limiting characteristic. At high values of the amplifier drive power, even though the saturation output increases, the gain decreases to some 3 to 6 db.

The power output versus power input curves of Fig. 6 indicate that at relatively high drive levels the saturation power output is near 130 watts for this tube with a gain of 6 db. This represents an operating (conversion) efficiency of near 20% for an electron stream perveance of 0.6×10^{-6}. The Crestatron has no r-f attenuator to limit either the saturation power or efficiency, and the impedance match of both the input and output coaxial cavities is good. Higher power outputs and higher efficiencies are easily obtained with higher electron stream perveances. A stream perveance of 1×10^{-6} will give saturation efficiencies of well over 30%. It is seen that saturation gains of 10 db with a power output of 100 watts can be obtained simultaneously.

In the beating-wave regime of operation the saturation efficiency generally increases with the drive level, reaching a maximum for relatively high input powers, as shown in Fig. 7. Generally low values of the space-charge parameter, $QC \approx 0.1-0.2$, are desirable in order to achieve highest conversion efficiencies and power outputs. Circuit loss tends to reduce both the gain and the efficiency.

Theoretical Predictions

The saturation gain and efficiency of a large-signal Crestatron can be predicted with the use of a nonlinear TWA theory.[4] The calculated gain and efficiency assuming a lossless circuit, a gain parameter of 0.1, and a rather large stream diameter are shown in Figs. 8 and 9. The effect of radial electric field variations across a large-diameter electron stream in reducing the saturation efficiency has been predicted.[4] Correlation of theoretical and

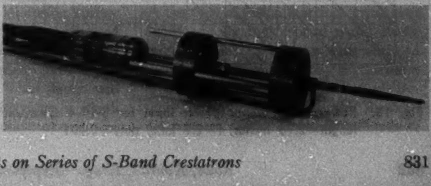

Fig. 10. Variable-length Crestatron and the adjustable coupled-helix assembly

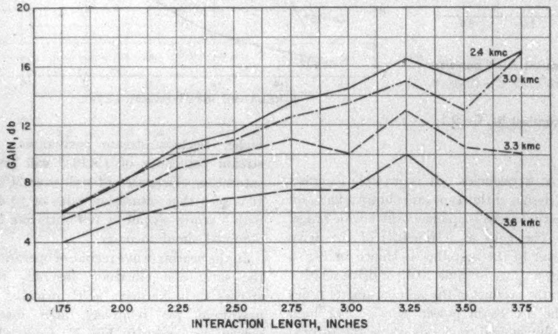

Fig. 12. Small-signal gain versus interaction length for S-10-4 Crestatron; V_0 = 3,700, $b/a = \infty$

experimental data is complicated because of the difficulty encountered in determining C and QC accurately. This uncertainty is also reflected in the calculation of the operating Δb.

Variable-Length Crestatron

For complete study of the effect of length on Crestatron performance, a Crestatron was constructed with a 7-inch helix, and a set of coupled-helix couplers were designed and mounted in a movable carriage so that any desired length could be selected. The couplers were terminated outside to eliminate reflected power. The tube mounted in the couplers and carriage is shown in Fig. 10. The couplers had a characteristic VSWR of less than 1.6 to 1 over the 2- to 4-kmc (kilomegacycle) frequency range. The total insertion loss was approximately 2 db for the two couplers and the interaction helix. The same helix design was used in this variable-length Crestatron as in the previously discussed tube, the *S-10-4*, which was operated without an attenuator as was the *S-8-3*, and like its predecessor utilized an electromagnet for focusing of the stream.

On this Crestatron, with the use of a relatively low-perveance electron gun, a vast amount of data has been taken, but only a small part will be presented here. It is planned in the future to carry out similar tests using higher-perveance guns. As mentioned earlier, the helix used was slightly dispersive at low frequencies and

hence a metallic shield was placed around the glass vacuum envelope at a radius of 1.6 times the inner helix radius. This shield has the effect of lowering the helix impedance at low frequencies more than it does at high frequencies. Experimental data were taken on this Crestatron both with the shield and without it.

The small-signal gain as the coupled-helix couplers were adjusted to give an interaction length of 3 inches, is shown in Fig. 11 as a function of frequency and voltage both for the shielded and unshielded cases. A comparison of the gain-versus-frequency results for particular voltages between the shielded and unshielded cases indicates that the gain at low frequencies is lowered and hence the constant-gain region is broadened in frequency. Octave bandwidths are evidently easily achieved in the Crestatron and this limitation is due only to the finite bandwidths of the couplers.

It is interesting to plot the gain versus the interaction length for this Crestatron at particular frequencies since it shows that the optimum length from both a wide bandwidth and a reasonable gain standpoint is approximately 3 to 3.25 inches. These results for the unshielded case are shown in Fig. 12. They agree quite well with the theoretically predicted gains for the various operating parameters.

The saturation characteristics of the *S-10-4* Crestatron appear in Figs. 13 and 14, where power output curves are shown as a function of both voltage and frequency. These data were taken under pulsed conditions and it is seen that power outputs of up to 190 watts have been obtained when the tube is driven with a large signal. The saturation efficiencies are not particularly high, primarily because the electron stream perveance was quite low. Work is presently under way to obtain data from this tube with stream perveances of 1×10^{-6} and 2×10^{-6}. It is expected that saturation efficiencies of well over 30% can be obtained under these conditions.

Recent theoretical studies indicate that a significant increase in the theoretical efficiency can be obtained in a Crestatron by prebunching of the electron stream. This also has the effect of increasing the gain and further reducing the device length.

Conclusions

The principles of operation of a new type of microwave amplifier called the Crestatron have been described and experimental data given on both a fixed-length and a variable-length tube. It is concluded from this study that high-efficiency short-length moderate-gain amplifiers seem well adapted for use as output tubes in high-power transmitters. Highest operating efficiencies are due partly to the lack of a need for an attenuator to achieve stability.

Fusion Power from Magnetically Confined Plasma

R. G. MILLS
MEMBER AIEE

ON THE BASIS of an assumed magnetically confined, stable, quiescent plasma, the relations for the fusion power liberated and the electric power consumed to generate an externally applied magnetic field are recalled. From these, appropriate scaling laws are developed which show the relative importance of various machine parameters, independently of the specific form of machine assumed. In the event that any of this class of machines should be proved physically possible, the directions of development needed to improve the economy of a resulting power-generating system are indicated. The advantages and disadvantages of various methods of increasing the yield of a fusion plant are compared.

Release of Energy by Thermonuclear Fusion

For the purposes of this paper, it is necessary to assume that a successful method will be found to confine a thermonuclear plasma in a quiescent, stable manner for periods long enough to allow usefully large amounts of fusion energy to be liberated. It is further assumed that the basic confinement tool is an externally applied magnetic field of an unspecified geometry. This paper will indicate some of the directions in which development could be undertaken to increase the economy of any fusion reactor resulting from this postulated successful magnetic confinement method.

The basic physics of fusion reactions has been reviewed in a paper by Post,[1] in which it is shown that the fusion power density of a high-temperature gas of two fusible isotopes is given by

$$p_F = n_1 n_2 (\overline{\sigma v}) E \tag{1}$$

where n_1 and n_2 are the particle densities of the two reacting isotopes, $(\overline{\sigma v})$ is the product of the reaction cross section and the relative velocity of two reacting particles averaged over the velocity distribution of the gas, and E is the energy liberated in a single fusion event. In the case of a reacting gas of a single species such as deuterium, the product $n_1 n_2$ is replaced by $n^2/2$.

In an operating reactor, whatever may be the fuel, a certain mixture will be established and a certain average energy E will be produced per fusion event. The exact value of the number E will depend on the type of fusion reactions being produced and by the disposal made of the energy carried by the resulting neutrons such as by thermalization, regenerative production of fuel, production of isotopes, or production of fission. We need not concern ourselves with the details of

the energy budget, but merely note that the fusion power density, when the constants are dropped, is given by the proportion

$$p_F \sim n^2(\overline{\sigma v}) \tag{2}$$

An important dimensionless parameter in plasma physics has been given the name β. This represents the ratio of gas pressure to external magnetic field energy density, or

$$\beta \equiv \frac{8\pi nkT}{B^2} \tag{3}$$

If a magnetic field is used to confine a plasma, this number must be less than 1, since $\beta = 1$ represents the situation where the gas pressure and the effective magnetic pressure are equal and any slight increase in material pressure will cause the gas to burst through the confinement. In practice, however, β is likely to be limited to values far less than 1 (perhaps 3% to 10%) because of stability considerations. The theory of hydromagnetic stability[2] indicates that for any given confinement geometry there exists a critical β above which the system will become unstable. Thus β is an important parameter, and it is convenient to use equation 3 to solve for the density n, in terms of the other variables, or

$$n = \frac{\beta B^2}{8\pi kT} \tag{4}$$

If this expression is inserted into equation 2, one finds that the fusion power density is given by

$$p_F \sim \left(\frac{\overline{\sigma v}}{T^2}\right) \beta^2 B^4 \tag{5}$$

Here we have three factors which can be manipulated to vary the fusion power density. We shall consider them in turn.

The first factor $(\overline{\sigma v}/T^2)$ represents a physical property of the fuel being used. Fig. 1 shows this quantity as a function of temperature for two fuels, a deuterium-tritium (D-T) mixture, and pure deuterium (D). Note that the quantity is some 100 times higher for the D-T than for the D-D reaction. Since this is a property of the material, we cannot change it; we can only choose our operating temperature. In the case of the D-T reaction, the maximum of the curve is well above the ignition point[1] (the temperature at which the release of fusion energy to charged particles is just sufficient to supply the radiative losses, and is therefore the minimum self-sustaining temperature), so that one would hope to operate at this optimum temperature: 150 million K (degrees Kelvin).

On the other hand, the ignition point for the D-D reaction is approximately 400 million K, so that one would have to operate at or above this higher temperature. It is interesting to note that, even though the reaction cross sections continue to climb with energy for a range well beyond the limits of Fig. 1, the presence of T² in the denominator depresses the maxima of these curves to a 15-kv level (1 electron-volt is equivalent to 11,600 K). In practice one would select an operating temperature as near as possible to the maxima of these curves. The fusion power density would then be proportional to the product $\beta^2 B^4$.

With regard to the second factor β^2, mentioned briefly above, a prime problem of theory and experiment will be to provide the highest possible stable confinement β achievable. In fact, it is this problem that is now receiving world-wide intensive study.

The maximization of the third factor B^4 is a very interesting problem in technology beyond the scope of this paper. The presence of the exponent 4 makes this a particularly attractive approach. Coil design involves two problems which ultimately limit progress in this direction. In qualitative terms, if the device is of small size, achievable cooling rates will limit the designer, while strength considerations will dominate in larger sizes. With present-day technology, field strengths up to the level of 100,000 gausses are feasible. Development to extend this limit by a factor of 3 does not seem out of the question.

Fusion Reactors

Let us now consider a complete machine. Since the fusion power density is proportional to $\beta^2 B^4$, the total power generated by the machine as a result of fusion reactions will be given by

$$P_F = k_1 \beta^2 B^4 r^3 \tag{6}$$

where r is some characteristic length of the machine such as the radius of the vacuum tube containing the plasma, and k_1 is a proportionality constant dependent on all the details of the machine. By far the largest amount of power consumed to operate the machine will almost certainly be that required to operate the magnet, and we assume here that, compared with this quantity, other power requirements of the plant may be neglected. In the absence of magnetic materials, the power required to operate any magnet may be represented by

$$P_M = k_2 \rho B^2 r \tag{7}$$

where ρ is the resistivity of the conductor material, B is the magnetic field strength at any particular point in the system, r is a characteristic length of the device (such as the radius of the internal opening), and k_2 is a proportionality constant depending only on the geometric shape of the electric conductor system used to generate the field.

196

It follows that the power for sale from a fusion power plant is given by

$$P_S = P_F - P_M = k_1\beta^2 B^4 r^3 - k_2 \rho B^2 r \qquad (8)$$

If nature were such that the second of these two terms tended to be very much smaller than the first, the future of fusion power plants would appear quite bright, once physical possibility were proven. Unfortunately this is not the case. Evaluations of k_1 and k_2, on the basis of various assumptions derived from technical considerations, show that these two terms are of the same order of magnitude.[3]

Increasing the Economy of a Fusion Plant

If we are to achieve a practical power plant, P_F must be considerably larger than P_M. If it were only slightly larger, the plant would be circulating a very large amount of power within itself in order to sell a small quantity, and the resulting investment cost per output kilowatt would be impossibly high. In other words, the ratio

$$\frac{P_F}{P_M} = k_3 \frac{\beta^2 B^2 r^2}{\rho} \qquad (9)$$

must be greater than 1 to have any power yield at all, and should be considerably higher (probably a minimum of 2) to be of practical interest.

From equation 9 there are four obvious ways to proceed to improve this ratio. The first is to select the best type of machine. This involves k_3 and β. No results are yet available on this question. Much laboratory experimentation must be done to determine the highest percentage β attainable and to determine which form of machine can deliver the highest k_3.

The second method is to increase the field strength but, as mentioned above, this has technical limitations.

The third method is simply to scale up the size of the reactor. The presence of r^2 in equation 9 implies that if fusion reactors are proved physically possible, they can certainly be made practical if built in large enough sizes. A serious difficulty with this approach is that the cost rapidly increases with increasing size and although the investment cost per kilowatt may be brought down within reason by a unit of large enough size, the output might be too large for any market in the foreseeable future.

The fourth method is to choose a material of lower resistivity than that provided by normal use of copper conductors. Silver is out of the question because of its very high cost for a relatively small improvement in ρ. It has been frequently suggested, however, that refrigeration of conductors be used, to take advantage of the decreasing resistivity with temperature.* Let us compare operating a magnet at ambient temperature T to operating it at a low temperature T_0 with an appropriate refrigerator to remove the heat from the load at T_0 and reject it at ambient temperature T. Let the resistance of the magnet R be

$$R = cT \qquad (10)$$

where T is the absolute temperature, and c a coefficient. Note that c is not a constant but is itself a function of the temperature. Then

$$P_M(T) = I^2 c_T T \qquad (11)$$

and

$$P_M(T_0) = I^2 c_{T_0} T_0 \qquad (12)$$

where I is the current required to generate the magnetic field. If we operate at T_0, we need a refrigerator which will require a power P_R, given by

$$P_R = I^2 c_{T_0} T_0 \left(\frac{T - T_0}{T_0}\right) \frac{1}{\eta} \qquad (13)$$

where η is the coefficient of performance of the refrigerator. The total power required to generate the magnetic field is obtained by adding equations 12 and 13. This is approximately

$$P_M + P_R \cong \frac{1}{\eta} [I^2 c_{T_0} T] \qquad (14)$$

This expression is exact for $\eta = 1$ and only about 3% in error at $\eta = 50\%$.

Compare equation 11 with equation 14. If the coefficient c were a constant and if Carnot refrigerators were available, the total power required would be independent of temperature. In practice, c is almost constant down to temperatures in the cryogenic region. Since practical refrigerators fall short of Carnot performance, it would always waste power to cool the magnet with chilled water or even liquid nitrogen.

On the other hand, in the neighborhood of 20 K and below, the coefficient c drops to very low values compared to its value at higher temperatures for many substances. Post has suggested sodium.[4] Laquer has operated cryogenic magnets of copper for several years.[5] Aluminum is another possibility. This approach may ultimately be of very great importance, particularly since it improves the relative yield P_F/P_M without simultaneously increasing the generated power P_F. Factors of improvement of the order of 10 may be achieved by this method. An unknown factor, however, is the cost required for the extremely large cryogenic refrigerators that would have to be developed for such an installation. In recent years, considerable progress has been made in this direction.

Another, less obvious, approach is cyclic field peaking. Division of the two terms in equation 8 to yield equation 9 implies time independence of all the variables. Suppose the confining field B is periodic in time. The mean value of B^4 over a cycle divided by the mean value of B^2 over the cycle will have different values depending on the waveshape. All other factors remaining constant, the former measures the fusion power liberated and the latter the magnet power consumed.

It is possible to select waveshapes which improve the ratio of P_F/P_M; Fig. 2 presents several examples. To illustrate the potential advantages, in the figure is a tabulation of the mean value of B^4 divided by the mean value of B^2 and normalized to constant magnet power by dividing by the mean value of B^2, i.e., $\overline{B^4}/(\overline{B^2})^2$. For d-c the value is, of course, 1, and the other curves should be compared with this. The waves shown are: simple sine wave, optimized biased sine wave, optimized first and third harmonic mixture, and an optimized biased first and third harmonic mixture. In principle the value of this ratio could be raised to arbitrarily high values by inclusion of higher and higher harmonics to give a more peaked wave. But skin-effect considerations limit the highest usable frequencies, and maximum allowable temperature excursions limit the lowest, so that improvement factors greater than three are unlikely. Since the problem is basically one of increasing a ratio (P_F/P_M) from some value between 1 and 2 to a value in excess of 2, such an improvement could be of great importance.

Combinations of Methods

Clearly the type of machine exhibiting the highest intrinsic economic potential should be chosen for a fusion plant, but high fields, large size, cryogenic cooling, and cyclic field peaking cannot all be combined to obtain an ultimate facility. In fact, almost all combinations of these approaches lead to technical difficulties which would require extensive development for full understanding. As examples, the following may be mentioned.

---

* We are discussing only normal conductivity here; the interesting idea of using superconductivity for technical apparatus is a different topic.

The combination of high fields with large sizes leads to the problem of structural strength, mentioned earlier. If high fields are combined with cryogenic cooling, a phenomenon known as the magnetoresistive effect causes trouble. The resistance of a conductor rises as the magnetic field through it is increased. At room temperatures, this is a very unimportant effect, but at cryogenic temperatures it can be the major component of the resistance. If peaking is to be combined with high fields and large volumes, one finds that thousands of volts per turn may be required in the magnet to cycle the large fluxes involved, and insulation becomes a serious problem. Finally, the combination of cryogenic cooling and cyclic field peaking seems out of the question because of the skin-effect problems. The skin depth decreases with the square root of the resistivity, and becomes so small at cryogenic temperatures (0.01 inch at 60 cycles) that one would have to wind large magnets with wire so fine that fabrication and insulation would be impossible. The two most promising methods seem to be cryogenic d-c magnets and ambient temperature peaked-field magnets.

This paper has considered only that class of machine in which an externally generated magnetic field is used. Thus all pinch machines are excluded, but included are the stellarator,[6] magnetic mirror,[7] astron,[8] miscellaneous cusped geometries,[9,10] the interesting form of stellarator suggested by Lehnert,[11] and others. It is too early to predict which of these, if any, will prove to be potentially an economic reactor, and far too early to make any good cost estimates of a resulting plant.

LATE DISCUSSION

Discussion of "Properties of Octafluorocyclobutane, a Dielectric Gas," by F. W. Blodgett, published in Communication and Electronics, March 1959, pages 63–66.

S. Yamakura (Kanagawa, Japan): I would like to comment on the interesting paper describing a new dielectric gas, octafluorocyclobutane (OFCB) by Dr. Blodgett. In the near future, I plan to carry out some fundamental experiments and applications.

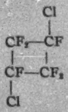
We expect dielectric gases to be chemically inert and nontoxic, and to have high dielectric strength. Most fluorogases are chemically stable, e.g., fluorocarbons and sulfur hexafluoride.

OFCB is highly stable, but we suppose that at high temperatures it produces some products of decomposition. The decomposition temperature, for long-term use, is higher than that for sulfur hexafluoride, but the gas is slowly decomposed in a corona discharge, and the chemical properties change.

Many engineers hope that the gas will have high dielectric strength in uniform and nonuniform fields. OFCB has a high dielectric strength compared with sulfur hexafluoride. Of course, these gases tend to be electronegative in the molecular state. During the past half-century the mechanism of dielectric breakdown of gases has been widely discussed, but no entirely satisfactory theory has been developed.

Fig. 2 shows that the corona-starting voltage of OFCB is about five times that of air. This is important data for design engineers. The breakdown voltage as a function of pressure is shown in Fig. 4(A) as a straight line for a uniform field, but random variations probably occur. I am now experimenting with sulfur hexafluoride imported from England. At low pressures, the random variation is 20%, so that I assume the author's data may have been averaged. In a nonuniform field, the maximum dielectric strength is shown at relatively low pressures; see Fig. 4(B). I don't know just how space charge might distort these values, but sulfur hexafluoride appears superior to OFCB.

Hopefully, two chlorine atoms could be introduced symmetrically into the molecule to give a higher dielectric strength than that of OFCB. The boiling point would be higher, but the dipole moment would still be zero.



The evaluation of physiological hazards is difficult for new chemical products which are still under development. When they are not completely pure, any observed physiological effects may be caused either by the impurities or by the pure material itself. Dr. Blodgett points out that the toxicity of OFCB is very low, but we hope that this will be investigated further.

F. W. Blodgett: Mr. Yamakura has raised several interesting points about the new dielectric gases. The extent of decomposition of OFCB at high temperatures, in a corona discharge, or in an arc, is difficult to evaluate. Some surfaces are more catalytically active than others. The intensity of the corona or the arc in relation to the amount of OFCB is usually unknown. New analytical tests are being developed to detect and identify the decomposition products. The chemical breakdown of the gas, and the final products isolated, may eventually contribute to our understanding of the electrical breakdown process.

Random variations of 10% to 20% in corona-starting voltage and breakdown voltage data do occur. It is important to control factors such as the finish and cleanliness of the electrodes used, the illumination of the electrode surfaces, and the static charges which tend to accumulate on the surfaces of solid insulation near the electrodes. The data shown in the figures are average values.

Fig. 4(B) shows the complexity of the breakdown voltage as a function of pressure in a particular nonuniform field. OFCB has a higher breakdown voltage than sulfur hexafluoride, but both maxima appear at low pressures. The maxima may be moved to higher pressures by diluting the electronegative gases with nitrogen, as shown. Some of the lower molecular-weight fluorocarbon gases show broader but lower maxima versus OFCB (see reference 1 of the paper).

The symmetrical trans-1,3-dichlorohexafluorocyclobutane suggested by Mr. Yamakura would indeed have a zero dipole moment, a higher boiling point (about 60 C), and a higher dielectric strength as compared to OFCB. Unfortunately, it would be less stable chemically, and probably anesthetic or slightly toxic. The presence of the chlorine atoms would lead to corrosion of metals and deterioration of cellulosic insulation if any corona or arcing should occur in a system containing traces of moisture.

OFCB is now made in very high purity, and the pure material was found to be essentially inert physiologically. Animals showed no anesthesia or other ill effects, and no tissue pathology at autopsy, after exposure to 80% OFCB and 20% oxygen (by volume) for 6 hours, or after 90 6-hour exposures to 10% OFCB in air containing 20% oxygen.

As indicated above, however, slight decomposition of OFCB, with the formation of some toxic products, does occur at high temperatures or after electrical breakdown. Although OFCB is nontoxic as supplied, it is necessary to avoid breathing gas after it has been exposed to fire, arc, or corona. We expect to develop suitable adsorbents that can be placed in the dielectric gas enclosure to remove any decomposition products formed.
